For men with oligospermia, human chorionic gonadotropin (hCG) (equivalent to LH) may be given at a dosage of 2000–3000 units intramuscularly three times weekly and testosterone replacement discontinued. The dose of hCG is adjusted to normalize serum testosterone levels. After 6–12 months of hCG treatment, if the sperm count remains low, hCG injections are continued along with injections of follitropin beta (synthetic recombinant FSH) or urofollitropins (urine-derived FSH). An alternative for patients with an intact pituitary is the use of leuprolide (GnRH analog) by intermittent subcutaneous infusion. With treatment, testicular volumes increase within 5–12 months, and some spermatogenesis occurs in most cases. With persistent treatment and the use of intracytoplasmic sperm injection for some cases, the pregnancy success rate is about 70%. Men often feel better during hCG therapy than during testosterone replacement. Therefore, some men may elect to continue hCG therapy long term.

Clomiphene, 25–50 mg/day orally, can sometimes stimulate men's own pituitary gonadotropins (when his pituitary is intact), thereby increasing testosterone and sperm production. For fertility induction in females, ovulation may be induced with clomiphene, 50–100 mg/day orally for 5 days every 2 months. Ovulation induction with FSH and hCG can induce multiple births and should be used only by those experienced with their administration.

D. Human Growth Hormone (hGH) Replacement

Symptomatic adults with GH deficiency may be treated with a subcutaneous recombinant human growth hormone (rhGH, somatropin) injections starting at a dosage of about 0.2 mg/day (0.6 international units/day), administered three times weekly. The dosage of rhGH is increased every 2–4 weeks by increments of 0.1 mg (0.3 international units) until side effects occur or a sufficient salutary response and a normal serum IGF-1 level are achieved. In adults, if the desired effects (eg, improved energy and mentation, reduction in visceral adiposity) are not seen within 3–6 months at maximum tolerated dosage, rhGH therapy is discontinued. Therapy with hGH can bring out central hypothyroidism, so serum FT_4 levels require monitoring when beginning hGH therapy.

During pregnancy, rhGH may be safely administered to women with hypopituitarism at their usual pregestational dose during the first trimester, tapering the dose during the second trimester, and discontinuing rhGH during the third trimester.

Oral estrogen replacement reduces hepatic IGF-1 production. Therefore, prior to commencing rhGH therapy, oral estrogen should be changed to transdermal or transvaginal estradiol.

Treatment of adult GH deficiency usually improves the patient's overall quality of life, with better emotional sense of well-being, increased muscle mass, and decreased visceral fat and waist circumference. Long-term treatment with rhGH does not appear to affect mortality.

Side effects of rhGH therapy may include peripheral edema, hand stiffness, arthralgias and myalgias, paresthesias, carpal tunnel syndrome, tarsal tunnel syndrome, headache, pseudotumor cerebri, gynecomastia, hypertension, and proliferative retinopathy. Treatment with rhGH can also cause sleep apnea, insomnia, dyspnea, sweating, and fatigue. Side effects usually remit promptly after a sufficient reduction in dosage. Therapy with rhGH does not increase the risk of any malignancy or the regrowth of pituitary or brain neoplasms; serum IGF-1 levels should be kept in the normal range.

GH should not be administered during critical illness, since administration of very high doses of rhGH increased mortality in patients receiving intensive care. There is currently no proven role for GH replacement for the physiologic GH deficiency that is seen with abdominal obesity or normal aging.

E. Other Treatment

Selective transsphenoidal surgery is usually performed to resect non-prolactinoma pituitary masses and Rathke cleft cysts that cause local symptoms or hypopituitarism. Such surgery reverses hypopituitarism in a minority of cases. Patients with lymphocytic hypophysitis have been treated with corticosteroid therapy and other immunosuppressants without much response and without reversing hypopituitarism.

Prognosis

Hypopituitarism resulting from a pituitary tumor may be reversible with dopamine agonists for prolactinomas (see Prolactinoma, below) or with careful selective resection of the tumor. Spontaneous recovery from hypopituitarism associated with pituitary stalk thickening has been reported. Patients can also recover from functional hypopituitarism. Spontaneous reversal of idiopathic isolated hypogonadotropic hypogonadism occurs in about 10% of patients after several years of hormone replacement therapy (HRT). However, hypopituitarism is usually permanent, and long-term HRT is ordinarily required.

Patients with hypopituitarism have an increased mortality risk, particularly women and those in whom diagnosis was made at a younger age, who have a craniopharyngioma, or who required transcranial surgery or radiation therapy. There is also an increased risk of death from infections with adrenal crisis in patients with untreated secondary insufficiency. Some pituitary tumors are locally invasive. In patients who have received pituitary radiation therapy, there is an increased risk of a second intracranial neoplasm and small-vessel stroke. Asymptomatic Rathke cleft cysts may not require surgery but do require endocrine, ophthalmic, and scan surveillance.

Functionally, most patients with hypopituitarism do very well with hormone replacement. Men with infertility who are treated with hCG/FSH or GnRH are likely to resume spermatogenesis if they have a history of sexual maturation, descended testicles, and a baseline serum inhibin B level over 60 pg/mL. Women under age 40 years, with infertility due to hypogonadotropic hypogonadism, can usually have successful ovulation induction.

CENTRAL DIABETES INSIPIDUS

ESSENTIALS OF DIAGNOSIS

- Antidiuretic hormone (ADH) deficiency with polyuria (2–20 L/day) and polydipsia.
- Hypernatremia occurs if fluid intake is inadequate.

General Considerations

Central diabetes insipidus is an uncommon disease caused by a deficiency in vasopressin (antidiuretic hormone [ADH]) from the posterior pituitary.

Primary central diabetes insipidus (without an identifiable lesion noted on MRI of the pituitary and hypothalamus) accounts for about one-third of all cases of diabetes insipidus. Familial diabetes insipidus occurs as a dominant genetic trait with symptoms developing at about 2 years of age. Diabetes insipidus also occurs in Wolfram syndrome, a rare autosomal recessive disorder that is also known by the acronym DIDMOAD (diabetes insipidus, type 1 diabetes mellitus, optic atrophy, and deafness). Central diabetes insipidus may also be idiopathic or due to autoimmunity against hypothalamic arginine vasopressin (AVP)-secreting cells. Reversible central diabetes insipidus can occur during chemotherapy with temozolomide and in the myelodysplastic preleukemic phase of acute myelogenous leukemia.

Secondary central diabetes insipidus is due to damage to the hypothalamus or pituitary stalk by tumor, hypophysitis, infarction, hemorrhage, anoxic encephalopathy, surgical or accidental trauma, infection (eg, encephalitis, tuberculosis, syphilis), or granulomas (sarcoidosis or Langerhans cell granulomatosis). Cancer immune therapy with the anti-PD-L1 monoclonal antibody avelumab has been reported to cause reversible central diabetes insipidus. Metastases to the pituitary are more likely to cause diabetes insipidus (33%) than are pituitary adenomas (1%).

Clinical Findings

A. Symptoms and Signs

The symptoms of the disease are intense thirst, especially with a craving for ice water, with the volume of ingested fluid varying from 2 L to 20 L daily, and polyuria, with large urine volumes and low urine specific gravity (usually less than 1.006 with ad libitum fluid intake). The urine is otherwise normal. Partial diabetes insipidus presents with less intense symptoms and should be suspected in patients with enuresis. Most patients with diabetes insipidus are able to maintain fluid balance by continuing to ingest large volumes of water. However, in patients without free access to water or with a damaged hypothalamic thirst center and altered thirst sensation, diabetes insipidus may present with hypernatremia and dehydration. Diabetes insipidus is aggravated by administration of high-dose corticosteroids, which increases renal free water clearance.

B. Laboratory Findings

Diagnosis of central diabetes insipidus is a clinical one; there is no single diagnostic laboratory test. Evaluation should include a 24-hour urine collection for volume and creatinine. A urine volume of less than 2 L/24 h (in the absence of hypernatremia) rules out diabetes insipidus. The patient can be tested during ad libitum fluid intake. A random urine is tested for osmolality. Blood testing includes plasma vasopressin and serum glucose, urea nitrogen, calcium, potassium, sodium, and uric acid.

With central diabetes insipidus and primary polydipsia, the plasma AVP level is usually low (below 1 pg/mL), while the urine osmolarity is also low (less than 300 mOsm/L). With nephrogenic diabetes insipidus, the plasma AVP level is normal or elevated (more than 2.5 pg/mL), while the urine osmolarity is low (less than 300 mOsm/L). Hyperuricemia occurs in many patients with central diabetes insipidus, since reduced vasopressin stimulation of the renal V1 receptor causes a reduction in the renal tubular clearance of urate.

A supervised “vasopressin challenge test” may be done: Desmopressin acetate 0.05–0.1 mL (5–10 mcg) intranasally (or 1 mcg subcutaneously or intravenously) is given, with measurement of urine volume for 12 hours before and 12 hours after administration. A serum sodium is obtained baseline, 12 hours after the desmopressin, and immediately if symptoms of hyponatremia develop. Patients with central diabetes insipidus notice a distinct reduction in thirst and polyuria; serum sodium usually remains normal. The dosage of desmopressin is doubled if the response is marginal. In patients with primary polydipsia, a desmopressin challenge causes no significant reduction in polydipsia, but does reduce polyuria that caused hyponatremia. Patients with nephrogenic diabetes insipidus show no response in polydipsia or urine volume.

Another test to distinguish central diabetes insipidus from primary polydipsia involves the carefully supervised hypertonic 3% saline-stimulated measurement of plasma copeptin, the C-terminal fragment of pre-pro-arginine vasopressin. Hypertonic 3% saline is administered intravenously as a 250 mL bolus, followed by a continuous infusion rate of 0.15 mL/kg/min. Plasma sodium is measured stat every 30 minutes; when the plasma sodium level reaches 150 mmol/L, blood is drawn for plasma copeptin. A level 4.9 pmol/L or less helps confirm the diagnosis of central diabetes insipidus.

C. Imaging

Distinguishing central diabetes insipidus from primary polydipsia usually requires an MRI of the pituitary and hypothalamus. The normal posterior “bright spot” seen on the MRI T1-weighted imaging is undetectable or small with central diabetes insipidus. MRI can also detect pathology responsible for central diabetes insipidus.

Differential Diagnosis

Central diabetes insipidus must be distinguished from polyuria caused by psychogenic polydipsia, diabetes mellitus, Cushing syndrome, hypercalcemia, hypokalemia, and nocturnal polyuria of Parkinson disease.

Vasopressinase-induced diabetes insipidus may be seen in the last trimester of pregnancy, associated with oligohydramnios, preeclampsia, or liver dysfunction, and in the puerperium. Maternal circulating vasopressin is destroyed by placental vasopressinase; however, synthetic desmopressin is unaffected.

Nephrogenic diabetes insipidus is caused by unresponsiveness of the kidney tubules to the normal secretion of vasopressin. A congenital form is familial and transmitted as an X-linked trait; it is caused by defective expression of renal vasopressin V2 receptors or vasopressin-sensitive water channels. Adults often also have hyperuricemia. Acquired forms are usually less severe and occur in pyelonephritis, renal amyloidosis, myeloma, potassium depletion, Sjögren syndrome, sickle cell anemia, chronic hypercalcemia, or recovery from acute tubular necrosis. Certain drugs (eg, corticosteroids, diuretics, demeclocycline, lithium, foscarnet, or methicillin) may induce nephrogenic diabetes insipidus.

Complications

If water is not readily available, the excessive output of urine will lead to severe dehydration. Patients with an impaired thirst mechanism are very prone to hypernatremia, as are those with impaired mentation who forget to take their desmopressin. Excessive desmopressin acetate can induce water intoxication and hyponatremia.

Treatment

Mild cases of diabetes insipidus require no treatment other than adequate fluid intake. Reduction of aggravating factors (eg, corticosteroids) will improve polyuria.

Desmopressin acetate is the treatment of choice for central diabetes insipidus and for vasopressinase-induced diabetes insipidus associated with pregnancy or the puerperium. Desmopressin acetate (100 mcg/mL solution) is given intranasally every 12–24 hours as needed for thirst and polyuria. It may be administered via metered-dose nasal inhaler containing 0.1 mL (10 mcg/spray) or via a calibrated rhinal tube. The starting dose is one metered-dose spray or 0.05–0.1 mL every 12–24 hours, and the dose is then individualized according to response. Desmopressin nasal may cause rhinitis or conjunctivitis. If the generic preparation is ineffective, switching to the desmopressin brand may provide relief.

Oral desmopressin, 0.1- and 0.2-mg tablets, is given in a starting dose of 0.05 mg twice daily and increased to a maximum of 0.4 mg every 8 hours, if required. Sublingual desmopressin, 60, 120, or 250 mcg, is not available in the United States; hyponatremia has been reported with this formulation. Oral desmopressin is particularly useful for patients in whom rhinitis or conjunctivitis develops from the nasal preparation.

Gastrointestinal symptoms, asthenia, and mild increases in hepatic enzymes can occur with the oral preparation.

Desmopressin can also be given intravenously, intramuscularly, or subcutaneously in doses of 1–4 mcg every 12–24 hours as needed.

Desmopressin may cause hyponatremia, but this is uncommon if minimum effective doses are used and the patient allows thirst to occur every 1–2 days. Desmopressin can sometimes cause agitation, emotional changes, and depression with an increased risk of suicide. Patients should be monitored by family, friends, and medical staff when desmopressin therapy is started.

Prognosis

Central diabetes insipidus after pituitary surgery or head trauma usually remits after days to weeks but may be permanent if the hypothalamus or upper pituitary stalk is damaged.

Chronic central diabetes insipidus is ordinarily more an inconvenience than a dire medical condition. Treatment with desmopressin allows normal sleep and activity. Hypernatremia can occur, especially when the hypothalamic thirst center is damaged, but diabetes insipidus does not otherwise reduce life expectancy, and the prognosis is that of the underlying disorder.

ACROMEGALY & GIGANTISM

ESSENTIALS OF DIAGNOSIS

- Pituitary tumor.
- **Gigantism** before closure of epiphyses.

- **Acromegaly:** excessive growth of hands, feet, jaw, internal organs.
- Amenorrhea, hypertension, headaches, visual field loss, weakness.
- Soft, doughy, sweaty handshake.
- Elevated serum IGF-1.

General Considerations

GH exerts much of its growth-promoting effects by stimulating the release of IGF-1 from the liver and other tissues.

Acromegaly is nearly always caused by a pituitary adenoma. Most are macroadenomas (over 1 cm in diameter). These tumors may be locally invasive, particularly into the cavernous sinus. Less than 1% are malignant. Acromegaly is usually sporadic but may rarely be familial, with less than 3% being due to multiple endocrine neoplasia (MEN) types 1 or 4. Acromegaly may also be seen rarely in McCune-Albright syndrome and Carney complex. Acromegaly is very occasionally caused by ectopic secretion of GHRH or GH secreted by a lymphoma, hypothalamic tumor, bronchial carcinoid, or pancreatic tumor.

Clinical Findings

A. Symptoms and Signs

Excessive GH causes tall stature and gigantism if it occurs in youth, before closure of epiphyses. Afterward, acromegaly develops. The hands enlarge and a doughy, moist handshake is characteristic. The fingers widen, causing patients to enlarge their rings. Carpal tunnel syndrome is common. The feet also grow, particularly in shoe width. Facial features coarsen since the bones and sinuses of the skull enlarge; hat size increases. The mandible becomes more prominent, causing prognathism and malocclusion. Tooth spacing widens. Older photographs of the patient can be a useful comparison.

Macroglossia occurs, as does hypertrophy of pharyngeal and laryngeal tissue; this causes a deep, coarse voice and sometimes makes intubation difficult. Obstructive sleep apnea may occur. A goiter may be noted. Hypertension (50%) and cardiomegaly are common. At diagnosis, about 10% of acromegalic patients have a dilated left ventricle and heart failure with reduced ejection fraction. Weight gain is typical, particularly of muscle and bone. Insulin resistance is usually present and frequently causes diabetes mellitus (30%). Arthralgias and degenerative arthritis occur. Overgrowth of vertebral bone can cause spinal stenosis. Colon polyps are common, especially in patients with skin papillomas. The skin may also manifest hyperhidrosis, thickening, cystic acne, skin tags, and acanthosis nigricans.

GH-secreting pituitary tumors usually cause some degree of hypogonadism, either by cosecretion of PRL or by direct pressure upon normal pituitary tissue. Decreased libido and erectile dysfunction are common in men and irregular menses or amenorrhea in women. Women who become pregnant have an increased risk of gestational diabetes and hypertension. Secondary hypothyroidism sometimes occurs; hypoadrenalism is unusual. Headaches are frequent. Temporal hemianopia may occur as a result of the optic chiasm being impinged by a suprasellar growth of the tumor.

B. Laboratory Findings

For screening purposes, a random serum IGF-1 can be obtained. If it is normal for age, acromegaly is ruled out.

For further evaluation, the patient should be fasting for at least 8 hours (except for water), not be acutely ill, and not have exercised on the day of testing. Assay for the following: serum GH, IGF-1 (increased and usually over five times normal in acromegalic patients), PRL (cosecreted by many GH-secreting tumors), glucose (diabetes mellitus is common in acromegaly), liver enzymes and serum creatinine or urea nitrogen (liver failure or kidney disease can misleadingly elevate GH), serum calcium (to exclude hyperparathyroidism), serum inorganic phosphorus (frequently elevated), serum free T_4, and TSH (secondary hypothyroidism is common in acromegaly; primary hypothyroidism may increase PRL). Acromegaly is excluded if any serum GH is less than 1 mcg/L; however, many normal individuals can have a serum GH above this level. Therefore, the glucose suppression test is usually performed. Glucose syrup (100 g) is administered orally, and serum GH is measured 60 minutes afterward; acromegaly is excluded if the serum GH is suppressed to below 0.4 mcg/L with an ultrasensitive GH assay. The serum IGF-1 and glucose-suppressed GH are usually complementary tests; however, disparities between the two occur in up to 30% of patients.

C. Imaging

MRI shows a pituitary tumor in over 90% of acromegalic patients. MRI is generally superior to CT scanning, especially in the postoperative setting. Radiographs of the skull may show an enlarged sella and thickened skull. Radiographs may also show tufting of the terminal phalanges of the fingers and toes. A lateral view of the foot shows increased thickness of the heel pad.

Differential Diagnosis

Active acromegaly must be distinguished from familial coarse features, large hands and feet, and isolated prognathism and from inactive ("burned-out") acromegaly in which there has been a spontaneous remission due to infarction of the pituitary adenoma. GH-induced gigantism must be differentiated from familial tall stature and from aromatase deficiency.

Misleadingly high serum GH levels can be caused by exercise or eating just prior to the test; acute illness or agitation; liver failure or kidney disease; malnourishment; diabetes mellitus; or concurrent treatment with oral estrogens, beta-blockers, or clonidine. Acromegaly can be difficult to diagnose during pregnancy, since the placenta produces GH and commercial GH assays may not be able to distinguish between pituitary and placental GH. During normal adolescence, serum IGF-1 is usually elevated and GH may fail to be suppressed.

Complications

Complications include hypopituitarism, hypertension, glucose intolerance or frank diabetes mellitus, cardiac enlargement, heart failure, and colon polyps. Arthritis of hips, knees, and spine can be troublesome as can carpal tunnel syndrome. Cord compression may occur. Visual field defects may be severe and progressive. Acute loss of vision or cranial nerve palsy may occur if the tumor undergoes spontaneous hemorrhage and necrosis (pituitary apoplexy).

Treatment

A. Pituitary Microsurgery

Transsphenoidal pituitary microsurgery removes the adenoma while preserving anterior pituitary function in most patients. Transsphenoidal surgery is usually well tolerated, but complications occur in about 12% of patients, including infection, cerebrospinal fluid (CSF) leak, and hypopituitarism.

Postoperatively, GH levels fall immediately. Fluid and electrolyte disturbances occur in most patients; diabetes insipidus can occur within 2 days postoperatively but is usually mild and self-correcting. Hyponatremia can occur abruptly 4–13 days postoperatively in 21% of patients; symptoms may include nausea, vomiting, headache, malaise, or seizure. It is treated with free water and hypotonic fluid restriction. It is prudent to monitor serum sodium levels postoperatively. Diaphoresis and carpal tunnel syndrome often improve within a day after surgery.

Corticosteroids are administered perioperatively and tapered to replacement doses over 1 week; hydrocortisone is discontinued and a cosyntropin stimulation test is performed about 6 weeks after surgery. At that time, the patient is screened for secondary hypothyroidism (by a serum FT_4) and secondary hypogonadism.

B. Medications

Acromegalic patients with an incomplete biochemical remission after pituitary surgery may benefit from medical therapy with dopamine agonists, somatostatin analogs, tamoxifen, or pegvisomant.

Cabergoline is the oral dopamine agonist of choice. It is most successful for tumors that secrete both PRL and GH but can also be effective for patients with normal serum PRL levels. Cabergoline will shrink one-third of acromegaly-associated pituitary tumors by more than 50%. It appears to be safe during pregnancy. The initial dose is 0.25 mg orally twice weekly, which is gradually increased to a maximum dosage of 1 mg twice weekly (based on serum GH and IGF-1 levels). Side effects of cabergoline include nausea, fatigue, constipation, abdominal pain, and dizziness.

Octreotide and **lanreotide** are long-acting somatostatin analogs that are given by monthly subcutaneous injection. They can achieve serum GH levels under 2 ng/mL in 79% of patients and normal serum IGF-1 levels in 53% of patients.

Tamoxifen is a selective estrogen receptor modulator (SERM) that may be particularly useful for persistent acromegaly in men and in women who are postmenopausal or who have had breast cancer. Tamoxifen (20–40 mg orally daily) does not reduce serum GH levels but reduces serum IGF-1 levels in 82% of patients and normalizes serum IGF-1 levels in 47%. Serum testosterone levels increase in men.

Pegvisomant, a GH receptor antagonist, is given by daily subcutaneous injection. It blocks hepatic IGF-1 production but does not shrink GH-secreting tumors. Pegvisomant therapy produces symptomatic relief and normalizes serum IGF-1 levels in over 90% of patients. Patients need to be monitored carefully for growth of the pituitary tumor with visual field examinations, GH levels, and MRI scanning of the pituitary.

C. Stereotactic Radiosurgery

Acromegalic patients who do not achieve a complete remission with transsphenoidal surgery or medical therapy may be treated with one or a combination of three types of stereotactic radiosurgery: linear accelerator (eg, Cyberknife), gamma knife radiosurgery, and proton beam radiosurgery. Following any pituitary radiation therapy, patients are advised to take lifelong daily low-dose aspirin because of the increased risk of small-vessel stroke. Stereotactic radiosurgery to pituitary tumors causes anterior hypopituitarism in 35–60% of patients within 5 years, so patients must have regular monitoring of their pituitary function.

Prognosis

Acromegaly is usually chronic and progressive unless treated. Spontaneous remissions are rare but have been reported following clinical or subclinical apoplexy (hemorrhage) within the tumor. Patients with acromegaly have increased morbidity and mortality from cardiovascular disorders and progressive acromegalic symptoms. Those who are treated and have a random serum GH under 1.0 ng/mL or a glucose-suppressed serum GH under 0.4 ng/mL with a normal age-adjusted serum IGF-1 level have reduced morbidity and mortality.

Transsphenoidal pituitary surgery achieves a remission in about 70% of patients followed over 3 years. In patients with tumors smaller than 2 cm in diameter and GH levels below 50 ng/mL, transsphenoidal pituitary surgery is successful in 80%. Extrasellar extension of the pituitary tumor, particularly cavernous sinus invasion, reduces the likelihood of surgical cure.

Adjuvant medical therapy is successful in treating patients who are not cured by pituitary surgery. Postoperatively, normal pituitary function is usually preserved. Soft tissue swelling regresses but bone enlargement is permanent. Hypertension frequently persists despite successful surgery. Conventional radiation therapy (alone) produces a remission in about 40% of patients by 2 years and 75% of patients by 5 years after treatment. Gamma knife or cyberknife radiosurgery reduces GH levels an average of 77%, with 20% of patients having a full remission after 12 months. Proton beam radiosurgery produces a remission in about 70% of patients by 2 years and 80% of patients by 5 years. Radiation therapy eventually produces some degree of hypopituitarism in most patients. Conventional radiation therapy may cause some degree of organic brain syndrome and predisposes to small strokes. Patients must receive lifelong follow-up, with regular monitoring of serum GH and IGF-1 levels. Serum GH levels over 5 ng/mL and rising IGF-1 levels usually indicate a recurrent tumor. Most pregnant women with acromegaly do not have an increase in the size of the pituitary tumor and neonatal outcome is unaffected.

HYPERPROLACTINEMIA

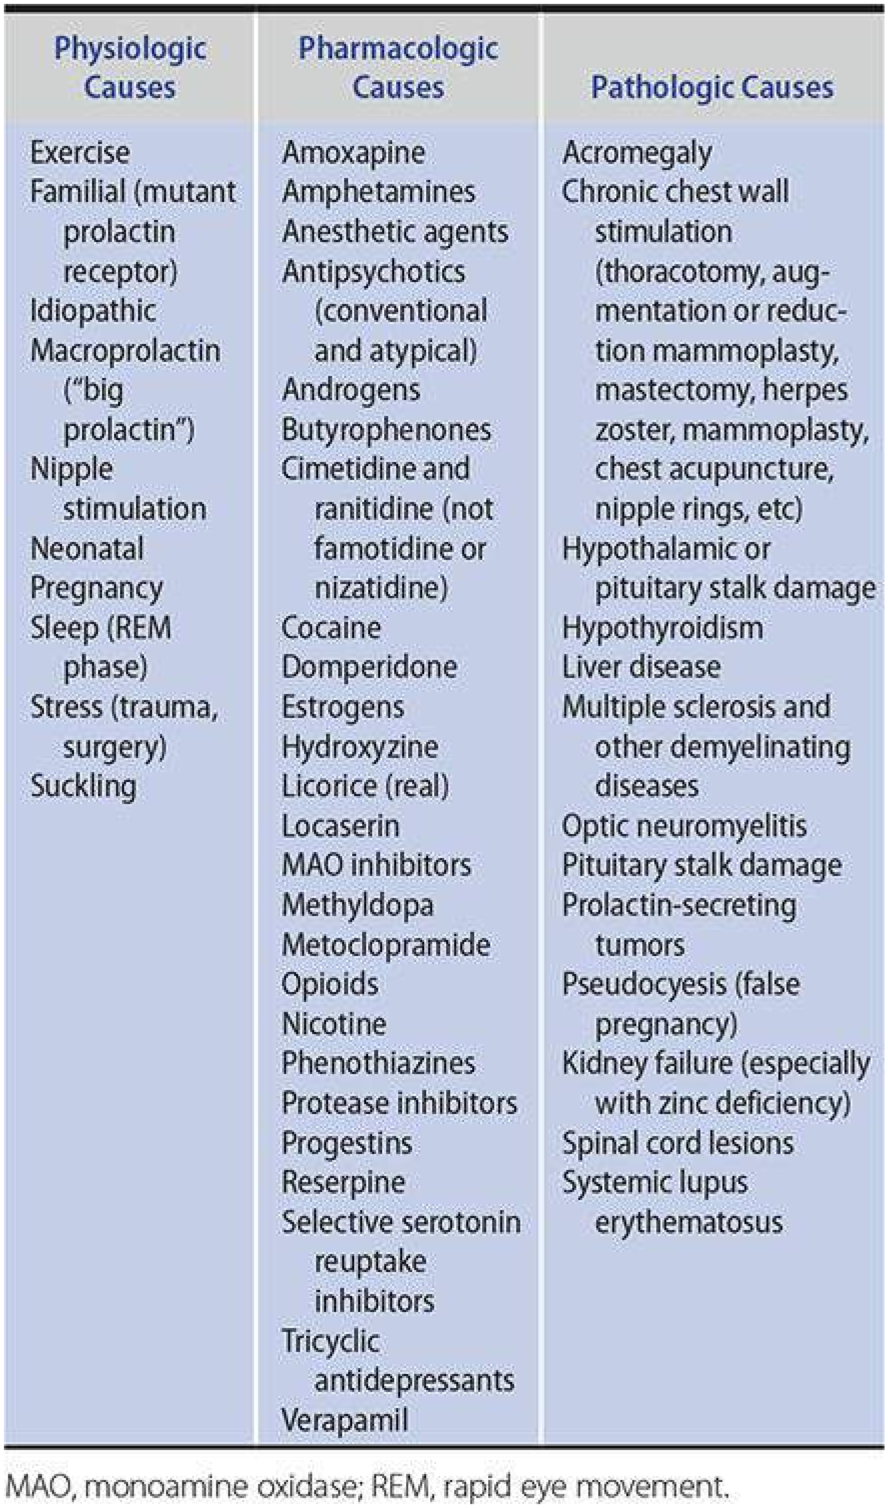
ESSENTIALS OF DIAGNOSIS

- **Women:** Oligomenorrhea, amenorrhea; galactorrhea; infertility.
- **Men:** Hypogonadism; decreased libido and erectile dysfunction; infertility.
- Elevated serum PRL; PRL is normally elevated during pregnancy.
- CT or MRI may show a pituitary adenoma.

General Considerations

The causes of hyperprolactinemia are shown in Table 26–1. In acromegaly, there may be cosecretion of GH and PRL. Hyperprolactinemia (without a pituitary adenoma) may also be familial. PRL-secreting pituitary tumors are more common in women than in men and are usually sporadic but may rarely be familial as part of MEN type 1 or 4. Most are microadenomas (smaller than 1 cm in diameter) that do not grow even with pregnancy or oral contraceptives. However, some giant prolactinomas (over 3 cm in diameter) can spread into the cavernous sinuses and suprasellar areas; rarely, they may erode the floor of the sella to invade the paranasal sinuses.

Table 26–1. Causes of hyperprolactinemia.



Physiologic Causes	Pharmacologic Causes	Pathologic Causes
Exercise Familial (mutant prolactin receptor) Idiopathic Macroprolactin (“big prolactin”) Nipple stimulation Neonatal Pregnancy Sleep (REM phase) Stress (trauma, surgery) Suckling	Amoxapine Amphetamines Anesthetic agents Antipsychotics (conventional and atypical) Androgens Butyrophenones Cimetidine and ranitidine (not famotidine or nizatidine) Cocaine Domperidone Estrogens Hydroxyzine Licorice (real) Locaserin MAO inhibitors Methyldopa Metoclopramide Opioids Nicotine Phenothiazines Protease inhibitors Progestins Reserpine Selective serotonin reuptake inhibitors Tricyclic antidepressants Verapamil	Acromegaly Chronic chest wall stimulation (thoracotomy, augmentation or reduction mammoplasty, mastectomy, herpes zoster, mammoplasty, chest acupuncture, nipple rings, etc) Hypothalamic or pituitary stalk damage Hypothyroidism Liver disease Multiple sclerosis and other demyelinating diseases Optic neuromyelitis Pituitary stalk damage Prolactin-secreting tumors Pseudocyesis (false pregnancy) Kidney failure (especially with zinc deficiency) Spinal cord lesions Systemic lupus erythematosus

MAO, monoamine oxidase; REM, rapid eye movement.

Clinical Findings

A. Symptoms and Signs

Hyperprolactinemia may cause hypogonadotropic hypogonadism and reduced fertility. Men usually have diminished libido and erectile dysfunction that may not respond to testosterone replacement; gynecomastia sometimes occurs. The diagnosis of a prolactinoma is often delayed in men, such that pituitary adenomas may grow and present with late manifestations of a pituitary macroprolactinoma (diameter 10 mm or larger).

About 90% of premenopausal women with prolactinomas experience amenorrhea, oligomenorrhea, or infertility. Estrogen deficiency can cause decreased vaginal lubrication, irritability, anxiety, and depression. Galactorrhea (lactation in the absence of nursing) is common. During pregnancy, clinically significant enlargement of a microprolactinoma (diameter smaller than 10 mm) occurs in less than 3%; clinically significant enlargement of a macroprolactinoma occurs in about 30%.

Pituitary prolactinomas may cosecrete GH and cause acromegaly. Large tumors may cause headaches, visual symptoms, and pituitary insufficiency.

Aside from pituitary tumors, some women secrete an abnormal form of PRL that appears to cause peripartum cardiomyopathy. Suppression of PRL secretion with dopamine agonists can reverse the cardiomyopathy.

B. Laboratory Findings

Evaluate for conditions known to cause hyperprolactinemia, particularly pregnancy (serum hCG), hypothyroidism (serum FT_4 and TSH), kidney disease (blood urea nitrogen [BUN] and serum creatinine), cirrhosis (liver tests), and hyperparathyroidism (serum calcium). Men are evaluated for hypogonadism with serum total and free testosterone, LH, and FSH. Women who have amenorrhea are assessed for hypogonadism with serum estradiol, LH, and FSH. Patients with pituitary macroadenomas larger than 3 cm in diameter should have PRL measured on serial dilutions of serum, since certain immunoradiometric assay assays may otherwise report falsely low titers, the “high-dose hook effect.” Patients with macroprolactinomas or manifestations of possible hypopituitarism should be evaluated for hypopituitarism. Patients with hyperprolactinemia who are relatively asymptomatic and have no apparent cause for hyperprolactinemia should have an assay for macroprolactinemia, which is an increased circulating level of a high molecular weight PRL that is biologically inactive but is detected on assays.

C. Imaging

Patients with hyperprolactinemia not induced by drugs, hypothyroidism, or pregnancy should be examined by pituitary MRI. Small prolactinomas may be demonstrated, but clear differentiation from normal variants is not always possible. In the event that a woman with a macroprolactinoma becomes pregnant and elects not to take dopamine agonists during her pregnancy, MRI is usually not performed since the normal pituitary grows during pregnancy. However, if visual-field defects or other neurologic symptoms develop in a pregnant woman, a limited MRI study should be done, focusing on the pituitary without gadolinium contrast.

Differential Diagnosis

The differential diagnosis for galactorrhea includes the small amount of breast milk that can normally be expressed from the nipple in many parous women. Nipple stimulation from nipple rings, chest surgery, or acupuncture can cause galactorrhea; serum PRL levels may be normal or minimally elevated. Some women can have idiopathic galactorrhea with normal serum PRL levels. Normal breast milk may be various colors besides white. However, bloody galactorrhea requires evaluation for breast cancer.

Other pituitary lesions can produce hyperprolactinemia by damaging the hypothalamus or pituitary stalk, thereby reducing the amount of dopamine reaching pituitary lactotrophes that produce PRL unless inhibited by dopamine. About 40% of nonfunctional pituitary macroadenomas produce some degree of hyperprolactinemia. These and other lesions and malignancies can be misdiagnosed as prolactinomas. One distinguishing characteristic is that the serum PRL is usually only marginally elevated in the latter tumors, whereas with pituitary macroprolactinomas the serum PRL typically exceeds 100 mcg/L.

Pregnant women have high serum PRL levels, with physiological hyperplastic enlargement of the pituitary on MRI. Increased pituitary size is a normal variant in young women. Primary hypothyroidism can cause hyperprolactinemia and hyperplasia of the pituitary that can be mistaken for a pituitary adenoma. Macroprolactinemia occurs in 3.7% of the general population and accounts for 10–25% of all cases of hyperprolactinemia; pituitary MRI shows a nonpathological abnormality in 22% of such patients.

Treatment

Medications known to increase PRL should be stopped if possible (Table 26–1). Hyperprolactinemia due to hypothyroidism is corrected by levothyroxine.

Women with microprolactinomas who have amenorrhea or are desirous of contraception may safely take estrogen replacement or oral contraceptives—there is minimal risk of stimulating enlargement of the microadenoma. Patients with infertility and hyperprolactinemia may be treated with a dopamine agonist in an effort to improve fertility. Women with amenorrhea who elect to receive no treatment have an increased risk of developing osteoporosis; such women require periodic bone densitometry.

Pituitary macroprolactinomas have a higher risk of progressive growth, particularly during estrogen or testosterone HRT or during pregnancy. Therefore, patients with macroprolactinomas should not be treated with HRT unless they are in remission with dopamine agonist medication or surgery.

Pregnant women with macroprolactinomas should continue to receive treatment with dopamine agonists throughout the pregnancy to prevent tumor growth. If dopamine agonists are not used during pregnancy in a woman with a macroprolactinoma, visual field testing is required in each trimester. Measurement of PRL is not useful surveillance for tumor growth due to the fact that PRL increases greatly during normal pregnancy.

A. Dopamine Agonists

Dopamine agonists (cabergoline, bromocriptine, or quinagolide) are the initial treatment of choice for patients with giant prolactinomas and those with hyperprolactinemia desiring restoration of normal sexual function and fertility. Even cystic prolactinomas respond to dopamine agonists; in one report, median cyst volume was reduced by 83% and chiasmal compression resolved in four of five cases. Cabergoline is the most effective and usually the best-tolerated ergot-derived dopamine agonist. The beginning dosage is 0.25 mg orally once weekly for 1 week, then 0.25 mg twice weekly for the next week, then 0.5 mg twice weekly. Further dosage increases may be required monthly, based on serum PRL levels, up to a maximum of 1.5 mg twice weekly. Bromocriptine (1.25–20 mg/day orally) is an alternative. Women who experience nausea with oral preparations may find relief with deep vaginal insertion of cabergoline or bromocriptine tablets; vaginal irritation sometimes occurs. Quinagolide (Norprolac; not available in the United States) is a non–ergot-derived dopamine agonist for patients intolerant or resistant to ergot-derived medications; the starting dosage is 0.075 mg/day orally, increasing as needed and tolerated to a maximum of 0.6 mg/day. Patients whose tumor is resistant to one dopamine agonist may be switched to another in an effort to induce a remission.

Dopamine agonists are given at bedtime to minimize side effects of fatigue, nausea, dizziness, and orthostatic hypotension. These symptoms usually improve with dosage reduction and continued use. Erythromelalgia is rare. In doses used for prolactinomas, dopamine agonists have not caused valvulopathy. Dopamine agonists can cause a variety of psychiatric side effects that are not dose related and may take weeks to resolve once the drug is discontinued.

Because dopamine agonists usually restore fertility promptly, many pregnancies have resulted; no increased risk of miscarriage or teratogenicity has been noted. However, women with microadenomas may have treatment withdrawn during pregnancy and may safely breastfeed postpartum without dopamine agonist therapy. Macroadenomas may enlarge significantly during pregnancy; if therapy is withdrawn, patients must be monitored with serum PRL determinations and computer-assisted visual fields. Women with macroprolactinomas who have responded to dopamine agonists may safely receive oral contraceptives as long as they continue receiving dopamine agonist therapy.

B. Surgical Treatment

Transsphenoidal pituitary surgery may be urgently required for large tumors undergoing apoplexy or those severely compromising visual fields. It is also used electively for patients who do not tolerate or respond to dopamine agonists. Transsphenoidal pituitary surgery is generally well tolerated, with a mortality rate of less than 0.5%. For pituitary microprolactinomas, skilled neurosurgeons are successful in normalizing PRL in 87% of patients and some patients prefer surgery to lifetime therapy with dopamine agonists.

Complications, such as CSF leakage, meningitis, stroke, or visual loss, occur in about 3% of cases; sinusitis, nasal septal perforation, or infection complicates about 6.5% of transsphenoidal surgeries. Diabetes insipidus can occur within 2 days postoperatively but is usually mild and self-correcting. Hyponatremia can occur abruptly 4–13 days postoperatively in 21% of patients; symptoms may include nausea, vomiting, headache, malaise, or seizure. It is treated with free water and hypotonic fluid restriction.

C. Stereotactic Radiosurgery

Stereotactic radiosurgery is seldom required for prolactinomas, since they usually respond to cabergoline or surgery. It is reserved for patients with macroadenomas that are growing despite treatment with dopamine agonists.

D. Chemotherapy

Some patients with aggressive pituitary macroadenomas or carcinomas are not surgical candidates and do not respond to dopamine agonists or radiation therapy. A small percentage of patients with aggressive tumors respond to temozolomide (150–200 mg/m^2 orally daily for 5 days of each 28-day cycle); after three cycles, treatment efficacy is determined by PRL measurement and MRI scanning.

Prognosis

Pituitary prolactinomas generally respond well to dopamine agonist therapy. Ninety percent of patients with prolactinomas experience a fall in serum PRL to 10% or less of pretreatment levels and about 80% of treated patients achieve a normal serum PRL level. Shrinkage of a pituitary adenoma occurs early, but the maximum effect may take up to 1 year. Nearly half of prolactinomas—even massive tumors—shrink more than 50%. During pregnancy, growth of a pituitary prolactinoma occurs in 2.7% of women with a microprolactinoma and in 22.9% of those with a macroprolactinoma. If cabergoline is stopped after 2 years of therapy, hyperprolactinemia recurs in 68% of patients with idiopathic hyperprolactinemia, 79% with microprolactinomas, and 84% with macroprolactinomas.

The 10-year recurrence rate is 13% for pituitary microadenomas after transsphenoidal surgery; pituitary function can be preserved in over 95% of cases. However, the surgical success rate for macroprolactinomas is much lower, and the complication rates are higher.

DISEASES OF THE THYROID GLAND

THYROIDITIS

ESSENTIALS OF DIAGNOSIS

Autoimmune thyroiditis (Hashimoto)

- Most common thyroiditis.
- Antithyroperoxidase or antithyroglobulin antibodies usually high.

- Often progresses to hypothyroidism.

Painful subacute thyroiditis

- Hallmark is tender thyroid gland with painful dysphagia.
- Elevated erythrocyte sedimentation rate (ESR).
- Low antithyroid antibodies distinguish it from autoimmune thyroiditis.

Infectious thyroiditis

- Severe, painful thyroid gland.
- Febrile with leukocytosis and elevated ESR.

Riedel thyroiditis

- Most often in middle age or older women.
- Usually part of a systemic fibrosing syndrome.

General Considerations

Autoimmune thyroiditis is the most common thyroid disorder in the United States. Cell-mediated autoimmunity is present with T-lymphocytes invading the thyroid gland, giving the microscopic appearance of "lymphocytic thyroiditis." Humoral autoimmunity, with detectable serum antithyroid antibodies, is present in most but not all affected patients. This condition is also known as "Hashimoto thyroiditis." Elevated serum levels of antithyroid antibodies (antithyroperoxidase or antithyroglobulin antibodies, or both) are detectable in the general population in 3% of men and 13% of women. Women over the age of 60 years have a 25% incidence of elevated serum levels of antithyroid antibodies, yet thyroid dysfunction develops in only a small subset of such individuals. However, 1% of the population has serum antithyroid antibody titers greater than 1:640, and they are at particular risk for thyroid dysfunction. The incidence of autoimmune thyroiditis varies by kindred, race, and sex. It is commonly familial. In the United States, elevated levels of antithyroid antibodies are found in 14.3% of whites, 10.9% of Mexican Americans, and 5.3% of blacks.

Childhood or occupational exposure to head-neck external beam radiation increases the lifetime risk of autoimmune thyroiditis. Women with gonadal dysgenesis (Turner syndrome) have a 15% incidence of thyroiditis by age 40 years. Thyroiditis is also commonly seen in patients with hepatitis C. Subclinical thyroiditis is extremely common; autopsy series have found focal thyroiditis in about 40% of women and 20% of men.

Dietary iodine supplementation (especially when excessive) increases the risk of autoimmune thyroiditis. Certain drugs can trigger autoimmune thyroiditis, including tyrosine kinase inhibitors, denileukin diftitox, alemtuzumab, interferon-alpha, interleukin-2, thalidomide, lenalidomide, lithium, amiodarone, and immune checkpoint inhibitors.

Autoimmune thyroiditis often progresses to hypothyroidism, which may be linked to thyrotropin receptor–blocking antibodies, detected in 10% of patients with Hashimoto thyroiditis. Hypothyroidism is more likely to develop in smokers than in nonsmokers, possibly due to the thiocyanates in cigarette smoke. High serum levels of thyroid peroxidase antibody also predict progression from subclinical to symptomatic hypothyroidism. Although the hypothyroidism is usually permanent, up to 11% of patients experience a remission after several years. Autoimmune thyroiditis is the most common cause for hyperthyroidism (Graves disease) and most patients with Graves disease have concomitant antithyroid antibodies.

Autoimmune thyroiditis is sometimes associated with other endocrine deficiencies as part of autoimmune polyendocrine syndrome type 2 (APS-II). Adults with APS-II are prone to autoimmune thyroiditis, type 1 diabetes mellitus, autoimmune gonadal failure, hypoparathyroidism, and adrenal insufficiency. Thyroiditis is frequently associated with other autoimmune conditions: pernicious anemia, Sjögren syndrome, vitiligo, inflammatory bowel disease, celiac disease, and gluten sensitivity. It is less commonly associated with alopecia areata, hypophysitis, encephalitis, myocarditis, primary pulmonary hypertension, and membranous nephropathy.

Painless postpartum thyroiditis is an acute autoimmune thyroiditis that occurs soon after delivery in 7.2% of women. The affected thyroid releases stored thyroid hormone, resulting in transient hyperthyroidism (that may be mild and undiagnosed), followed by hypothyroidism. Most women recover normal thyroid function. Women in whom postpartum thyroiditis develops have a 70% chance of recurrence after subsequent pregnancies. It occurs most commonly in women who have high levels of antithyroperoxidase antibody in the first trimester of pregnancy or immediately after delivery. It is also more common in women with preexistent type 1 diabetes mellitus, other autoimmunity, or a family history of Hashimoto thyroiditis.

Painless sporadic subacute thyroiditis is a form of autoimmune thyroiditis that is similar to painless postpartum thyroiditis, except that it is not related to pregnancy. It is caused by a release of stored thyroid hormone and accounts for about 1% of cases of thyrotoxicosis. It is followed by hypothyroidism that may or may not resolve spontaneously.

Painful subacute thyroiditis—also called de Quervain thyroiditis, granulomatous thyroiditis, and giant cell thyroiditis—is relatively common. Its hallmark is a tender thyroid gland associated with painful dysphagia. Low-grade fever is common. The ESR is often elevated. Multinucleated giant cells are found on histology. Some patients also have antithyroid antibodies. Like painless subacute thyroiditis, most affected patients have transient hyperthyroidism, followed by hypothyroidism. Painful subacute thyroiditis is likely caused by a viral infection and often follows an upper respiratory tract infection. Its incidence peaks in the summer. It affects both sexes, but young and middle-aged women are most commonly affected.

Infectious (suppurative) thyroiditis, a nonviral infection of the thyroid gland, is quite rare among immunocompetent patients, since the thyroid is resistant to infection due to its vasculature, encapsulation, and high iodine content. Congenital pyriform sinus fistulas are a cause for recurrent infectious thyroiditis. While infectious thyroiditis is usually bacterial, mycobacterial, fungal, and parasitic infections can occur, particularly in immunosuppressed individuals. In affected patients who are appropriately treated, when immunosuppression is reduced, the patient may experience an immune reconstitution inflammatory syndrome (IRIS) from residual antigens triggering the normal immune response.

Riedel thyroiditis, also called invasive fibrous thyroiditis, Riedel struma, woody thyroiditis, ligneous thyroiditis, and invasive thyroiditis, is the rarest form of thyroiditis. It is found most frequently in middle-aged or elderly women and is usually part of a multifocal systemic fibrosis syndrome. It may occur as a thyroid manifestation of IgG_4-related systemic disease.

Clinical Findings

A. Symptoms and Signs

In **autoimmune thyroiditis**, the thyroid gland may be diffusely enlarged, firm, and finely nodular. One thyroid lobe may be asymmetrically enlarged, raising concerns about neoplasm. Although patients may complain of neck tightness, pain and tenderness are not usually present. Other patients have no palpable goiter and no neck symptoms. About 10% of cases are atrophic, the gland being fibrotic, particularly in elderly women.

Symptoms and signs are mostly related to ambient levels of thyroid hormone. There may be hyperthyroidism caused by destructive release of thyroid hormones (followed by hypothyroidism), or hyperthyroidism caused by increased synthesis of thyroid hormones (Graves disease). Affected patients may have combinations of these presentations. For example, a patient with hypothyroidism might later develop hyperthyroidism that can wax and wane.

Depression and chronic fatigue are more common in such patients, even after correction of hypothyroidism. About one-third of patients have mild dry mouth (xerostomia) or dry eyes (keratoconjunctivitis sicca) related to Sjögren syndrome. Associated myasthenia gravis is usually of mild severity, mainly affecting the extraocular muscles and having a relatively low incidence of detectable AChR Ab or thymic disease. Associated celiac disease or gluten intolerance can produce fatigue or depression, sometimes in the absence of gastrointestinal symptoms.

Postpartum thyroiditis is typically manifested by hyperthyroidism that begins 1–6 months after delivery and persists for only 1–2 months. Then, hypothyroidism tends to develop beginning 4–8 months after delivery.

In painless sporadic thyroiditis, thyrotoxic symptoms are usually mild; a small, nontender goiter may be palpated in about 50% of such patients. The course is similar to postpartum thyroiditis.

Subacute thyroiditis presents with an acute, usually painful enlargement of the thyroid gland, often with dysphagia. The pain may radiate to the ears. Patients usually have a low-grade fever and fatigue. The manifestations may persist for weeks or months and may be associated with malaise. If there is no pain, it is called silent thyroiditis. Thyrotoxicosis develops in 50% of affected patients and tends to last for several weeks. Subsequently, hypothyroidism develops that lasts 4–6 months. Normal thyroid function typically returns within 12 months, but persistent hypothyroidism develops in 5% of patients.

Patients with **infectious thyroiditis** usually are febrile and have severe pain, tenderness, redness, and fluctuation in the region of the thyroid gland. In **Riedel thyroiditis**, thyroid enlargement is often asymmetric; the gland is stony hard and adherent to the neck structures, causing signs of compression and invasion, including dysphagia, dyspnea, pain, and hoarseness. Related conditions include retroperitoneal fibrosis, fibrosing mediastinitis, sclerosing cervicitis, subretinal fibrosis, and sclerosing cholangitis.

B. Laboratory Findings

In **Hashimoto thyroiditis** with clinically evident disease, there are usually increased circulating levels of antithyroperoxidase (90%) or antithyroglobulin (40%) antibodies. However, some patients with autoimmune thyroiditis have no detectable antithyroid antibodies. In patients with thyroiditis caused by immune checkpoint inhibitors, most have no detectable antithyroid antibodies. Antithyroid antibodies decline during pregnancy and are often undetectable in the third trimester. Once Hashimoto thyroiditis has been diagnosed, monitoring of these antibody levels is not helpful. The serum TSH level is elevated if thyroid hormone is not released in adequate amounts by the thyroid gland. High serum antithyroperoxidase antibody concentrations are found in only 50% of patients with painless sporadic thyroiditis.

Patients with Hashimoto thyroiditis have a 15% incidence of having serum antibodies (IgA tissue transglutaminase [tTG] antibody) associated with celiac disease, and at least 5% have clinically significant celiac disease. Seronegative gluten sensitivity is even more common.

In **subacute thyroiditis,** the ESR is markedly elevated while antithyroid antibody titers are low, distinguishing it from autoimmune thyroiditis. In **infectious (suppurative) thyroiditis,** both the leukocyte count and ESR are usually elevated.

With hyperthyroidism due to Hashimoto thyroiditis or subacute thyroiditis, serum FT_4 levels tend to be proportionally higher than T_3 levels, since the hyperthyroidism is due to the passive release of stored thyroid hormone, which is predominantly T_4; this is in contrast to Graves disease and toxic nodular goiter, where T_3 is relatively more elevated. Because T_4 is less active than T_3, the hyperthyroidism seen in thyroiditis is usually less severe. Serum levels of TSH are suppressed in hyperthyroidism due to thyroiditis.

C. Imaging

The ultrasound in cases of Hashimoto thyroiditis typically shows a gland with characteristic diffuse heterogeneous density and reduced echogenicity. It helps distinguish thyroiditis from multinodular goiter or thyroid nodules that are suspicious for malignancy. It is also helpful in guiding FNA biopsy of small suspicious thyroid nodules. Color flow Doppler ultrasonography can help distinguish thyroiditis from Graves disease; in thyroiditis, vascularity is normal or reduced vascularity, whereas in Graves disease, the thyroid gland is hypervascular.

Radioiodine (RAI) uptake and scan can help distinguish thyroiditis from Graves disease; subacute thyroiditis exhibits a very low RAI uptake. However, RAI uptake may be normal or high with uneven uptake on the scan in chronic Hashimoto thyroiditis (euthyroid or hypothyroid); scanning is not useful in diagnosis.

[^{18}F] Fluorodeoxyglucose positron emission tomography (^{18}FDG-PET) scanning frequently shows diffuse thyroid uptake of isotope in cases of thyroiditis. In fact, of ^{18}FDG-PET scans done for any reason, about 3% show such uptake. However, discrete thyroid nodules can also be discovered on ^{18}FDG-PET scanning; these nodules are known as “thyroid PET incidentalomas” and 50% are malignant.

D. Fine-Needle Aspiration Biopsy

Patients with autoimmune thyroiditis who have a thyroid nodule should have an ultrasound-guided FNA biopsy, since the risk of papillary thyroid cancer is about 8% in such nodules. When infectious (suppurative) thyroiditis is suspected, an FNA biopsy with Gram stain and culture is required. FNA biopsy is usually not required for subacute thyroiditis but shows characteristic giant multinucleated cells.

Complications

Autoimmune thyroiditis may lead to hypothyroidism or transient thyrotoxicosis. Hyperthyroidism may develop, either due to the emergence of Graves disease or due to the release of stored thyroid hormone, which is caused by inflammation. Variably termed “hashitoxicosis” or “painless sporadic thyroiditis,” it is known as postpartum painless thyroiditis when it occurs in women after delivery. Perimenopausal women with high serum levels of antithyroperoxidase antibodies have a higher relative risk of depression, independent of ambient thyroid hormone levels.

In the suppurative forms of thyroiditis, any of the complications of infection may occur. Subacute and chronic thyroiditis are complicated by the effects of pressure on the neck structures: dyspnea and, in Riedel struma, vocal cord palsy. Papillary thyroid carcinoma or thyroid lymphoma may rarely be associated with chronic thyroiditis and must be considered in the diagnosis of uneven painless enlargements that continue despite treatment; such patients require FNA biopsy.

Differential Diagnosis

Thyroiditis must be considered in the differential diagnosis of all types of goiters, especially if enlargement is rapid. The very low RAI uptake in subacute thyroiditis with elevated T_4 and T_3 is helpful. Thyroid autoantibody tests have been helpful in the diagnosis of Hashimoto thyroiditis, but the tests are not specific (positive in patients with multinodular goiters, malignancy [eg, thyroid carcinoma, lymphoma], and concurrent Graves disease). The subacute and suppurative forms of thyroiditis may resemble any infectious process in or near the neck structures. Chronic thyroiditis may resemble thyroid carcinoma, especially if the enlargement is uneven and if there is pressure on surrounding structures; both disorders may be present in the same gland.

Treatment

A. Autoimmune (Hashimoto) Thyroiditis

If hypothyroidism is present, levothyroxine should be given in the usual replacement doses (0.05–0.2 mg orally daily) (See Hypothyroidism & Myxedema, below). In patients with a large goiter and normal or elevated serum TSH, an attempt is made to shrink the goiter by administering levothyroxine in doses sufficient to drive the serum TSH below the reference range while maintaining clinical euthyroidism. Suppressive doses of T_4 tend to shrink the goiter an average of 30% over 6 months. If the goiter does not regress, lower replacement doses of levothyroxine may be given. If the thyroid gland is only minimally enlarged and the patient is euthyroid, regular observation is in order, since hypothyroidism may develop subsequently—often years later.

Dietary supplementation with selenium 200 mcg/day reduces serum levels of antithyroperoxidase antibodies. However, whether selenium supplementation improves clinical outcome is unknown.

B. Subacute Thyroiditis

All treatment is empiric and must be continued for several weeks. Recurrence is common. The drug of choice is aspirin, which relieves pain and inflammation. Thyrotoxic symptoms are treated with propranolol, 10–40 mg every 6 hours. Iodinated contrast agents cause a prompt fall in serum T_3 levels and a dramatic improvement in thyrotoxic symptoms. Ipodate sodium (Bilivist, Oragrafin) or iopanoic acid (Telepaque) is given orally in doses of 500 mg orally daily until serum FT_4 levels return to normal. Transient hypothyroidism is treated with T_4 (0.05–0.1 mg orally daily) if symptomatic.

C. Infectious Thyroiditis

Treatment is with antibiotics and with surgical drainage when fluctuation is marked. Immunocompromised individuals are particularly at risk and coccidioidomycosis thyroiditis has been reported. Surgical thyroidectomy may be required.

D. Riedel Thyroiditis

The treatment of choice is tamoxifen, 20 mg orally twice daily, which must be continued for years. Tamoxifen can induce partial to complete remissions in most patients within 3–6 months. Its mode of action appears to be unrelated to its antiestrogen activity. Short-term corticosteroid treatment may be added for partial alleviation of pain and compression symptoms. Surgical decompression usually fails to permanently alleviate compression symptoms; such surgery is difficult due to dense fibrous adhesions, making surgical complications more likely. Rituximab may be useful for Riedel thyroiditis that is refractory to tamoxifen and corticosteroids.

Prognosis

Autoimmune (Hashimoto) thyroiditis is occasionally associated with other autoimmune disorders (celiac disease, diabetes mellitus, Addison disease, pernicious anemia, etc). In general, however, patients with Hashimoto thyroiditis have an excellent prognosis, since the condition either remains stable for years or progresses slowly to hypothyroidism, which is easily treated. Although 80% of women with postpartum thyroiditis subsequently recover normal thyroid function, permanent hypothyroidism eventually develops in about 50% within 7 years, more commonly in women who are multiparous or who have had a spontaneous abortion. In subacute thyroiditis, spontaneous remissions and exacerbations are common; the disease process may smolder for months. Papillary thyroid carcinoma carries a relatively good prognosis when it occurs in patients with Hashimoto thyroiditis.

Wichman J et al. Selenium supplementation significantly reduces thyroid autoantibody levels in patients with chronic autoimmune thyroiditis: a systematic review and meta-analysis. Thyroid. 2016 Dec;26(12):1681–92. [PMID: 27702392]

HYPOTHYROIDISM & MYXEDEMA

ESSENTIALS OF DIAGNOSIS

- Hashimoto thyroiditis is the most common cause of hypothyroidism.
- Fatigue, cold intolerance, constipation, weight change, depression, menorrhagia, hoarseness.
- Dry skin, bradycardia, delayed return of deep tendon reflexes.
- FT_4 level is usually low.
- TSH elevated in primary hypothyroidism.

General Considerations

Hypothyroidism is common, affecting over 1% of the general population and about 5% of individuals over age 60 years. About 85% of affected individuals are women. Thyroid hormone deficiency affects almost all body functions. The degree of severity ranges from mild and unrecognized hypothyroid states to striking myxedema. Maternal hypothyroidism during pregnancy results in offspring with IQ scores that are an average 7 points lower than those of euthyroid mothers. Congenital hypothyroidism occurs in about 1:4000 births; untreated, it causes cretinism with permanent cognitive impairment.

Hypothyroidism may be due to failure or resection of the thyroid gland itself or deficiency of pituitary TSH. The condition must be distinguished from the functional hypothyroidism that occurs in severe nonthyroidal illness, which does not require treatment with levothyroxine. Hashimoto thyroiditis is the most common cause of hypothyroidism. A hypothyroid phase also occurs in subacute (de Quervain) viral thyroiditis following initial hyperthyroidism.

Goiter may be present with thyroiditis, iodide deficiency, genetic thyroid enzyme defects, drug goitrogens (lithium, iodide, propylthiouracil or methimazole, sulfonamides, amiodarone, interferon-alpha, interferon-beta, interleukin-2), food goitrogens in iodide-deficient areas (eg, turnips, cassavas) or, rarely, peripheral resistance to thyroid hormone or infiltrating diseases (eg, cancer, sarcoidosis). Goiter is often absent in patients with autoimmune thyroiditis. Goiter is also usually absent when hypothyroidism is due to destruction of the gland by head-neck or chest-shoulder radiation therapy or ^{131}I therapy. Thyroidectomy causes hypothyroidism; after hemithyroidectomy, hypothyroidism develops in 22% of patients.

Amiodarone, because of its high iodine content, causes clinically significant hypothyroidism in about 15–20% of patients as well as thyrotoxicosis (see Amiodarone-induced thyrotoxicosis, below). Hypothyroidism occurs most often in patients with preexisting autoimmune thyroiditis and in patients who are not iodine-deficient. The T_4 level is low or low-normal, and the TSH is elevated, usually over 20 milli-international units/L. Another 17% of patients taking amiodarone are asymptomatic with normal serum T_4 levels despite elevations in serum TSH; they can be closely monitored without levothyroxine therapy. Low-dose amiodarone is less likely to cause hypothyroidism. Patients with coronary insufficiency who have amiodarone-induced symptomatic hypothyroidism are treated with just enough levothyroxine to relieve symptoms. Hypothyroidism usually resolves over several months if amiodarone is discontinued. Hypothyroidism may also develop in patients with a high iodine intake from other sources, especially if they have underlying lymphocytic thyroiditis. Some malignancies overexpress thyroid hormone inactivating enzyme (type 3 deiodinase) and cause “consumptive hypothyroidism.” This has occurred with large hemangiomas or a heavy tumor burden of colon cancer, basal cell cancer, fibrous tumors, or gastrointestinal stromal tumors (GISTs).

Chemotherapeutic agents that can cause silent thyroiditis include the following: tyrosine kinase inhibitors, denileukin diftitox, alemtuzumab, interferon-alpha, interleukin-2, thalidomide, and lenalidomide. Immune checkpoint inhibitors include pembrolizumab, ipilimumab, tremelimumab, and atezolizumab. This usually starts with hyperthyroidism (often unrecognized) and then progresses to hypothyroidism. Radioiodine-based targeted radioisotope therapy can also cause hypothyroidism.

Chronic hepatitis C is associated with an increased risk of autoimmune thyroiditis, with 21% of affected patients having antithyroid antibodies and 13% having hypothyroidism. Oral direct-acting anti–hepatitis C agents do not increase the risk of thyroid dysfunction that has been seen with interferon.

Clinical Findings

A. Symptoms and Signs

1. Common manifestations—Mild hypothyroidism often escapes detection without a screening serum TSH. Patients typically have nonspecific symptoms of hypothyroidism that include weight gain, fatigue, lethargy, depression, weakness, dyspnea on exertion, arthralgias or myalgias, muscle cramps, menorrhagia, constipation, dry skin, headache, paresthesias, cold intolerance, carpal tunnel syndrome, and Raynaud syndrome. Physical findings can include bradycardia; diastolic hypertension; thin, brittle nails; thinning of hair; peripheral edema; puffy face and eyelids; and skin pallor or yellowing (carotenemia). Delayed relaxation of deep tendon reflexes may be present. Patients often have a palpably enlarged thyroid (goiter) that arises due to elevated serum TSH levels or the underlying thyroid pathology.

2. Less common manifestations—Less common symptoms of hypothyroidism include diminished appetite and weight loss, hoarseness, decreased sense of taste and smell, and diminished auditory acuity. Some patients may complain of dysphagia or neck discomfort. Although most menstruating women have menorrhagia, some women have scant menses or amenorrhea. Physical findings may include thinning of the outer halves of the eyebrows; thickening of the tongue; hard pitting edema; and effusions into the pleural and peritoneal cavities as well as into joints. Galactorrhea may also be present. Cardiac enlargement (“myxedema heart”) and pericardial effusions may occur. Psychosis “myxedema madness” can occur from severe hypothyroidism or from toxicity of other drugs whose metabolism is slowed in hypothyroidism. Hypothermia and stupor or myxedema coma, which is often associated with infection (especially pneumonia), may develop in patients with severe hypothyroidism.

Some hypothyroid patients with Hashimoto thyroiditis have symptoms that are not due to hypothyroidism but rather to conditions associated with Hashimoto thyroiditis; these include Addison disease, hypoparathyroidism, diabetes mellitus, pernicious anemia, Sjögren syndrome, vitiligo, biliary cirrhosis, gluten sensitivity, and celiac disease.

B. Laboratory Findings

Hypothyroidism is a common disorder and thyroid function tests should be obtained for any patient with its nonspecific symptoms or signs. The single best screening test for hypothyroidism is the serum TSH (Table 26–2). The normal reference range for ultrasensitive TSH levels is generally 0.4–4.0 milli-international units/L. Over 95% of normal adults have serum TSH concentrations under 3.0 milli-international units/L. However, there is considerable controversy about what represents “normal,” such that each laboratory uses a slightly different range. The normal range of TSH varies with age; for example, the reference range for elderly patients is higher than the reference range for younger patients.

Table 26–2. Appropriate use of thyroid tests.

	Test	Comment
For screening	Serum thyroid-stimulating hormone (TSH)	Most sensitive test for primary hypothyroidism and hyperthyroidism
	Free thyroxine (FT_4)	Excellent test
For hypothyroidism	Serum TSH	High in primary and low in secondary hypothyroidism
	Antithyroperoxidase and antithyroglobulin antibodies	Elevated in Hashimoto thyroiditis
For hyperthyroidism	Serum TSH	Suppressed except in TSH-secreting pituitary tumor or pituitary hyperplasia (rare)
	Triiodothyronine (T_3) or free triiodothyronine (FT_3)	Elevated
	^{123}I uptake and scan	Increased uptake; diffuse versus "hot" foci on scan
	Antithyroperoxidase and antithyroglobulin antibodies	Elevated in Graves disease
	Thyroid-stimulating immunoglobulin (TSI)	Usually (65%) positive in Graves disease
For thyroid nodules	Fine-needle aspiration (FNA) biopsy	Best diagnostic method for thyroid cancer
	^{123}I uptake and scan	Cancer is usually "cold"; less reliable than FNA biopsy
	^{99m}Tc scan	Vascular versus avascular
	Ultrasonography	Useful to assist FNA biopsy. Useful in assessing the risk of malignancy (multinodular goiter or pure cysts are less likely to be malignant). Useful to monitor nodules and patients after thyroid surgery for carcinoma.

In primary hypothyroidism, the serum TSH is increased in a reflex effort to stimulate the failing gland, while the serum FT_4 is low or low-normal. Other laboratory abnormalities can include hypoglycemia or anemia (with normal or increased mean corpuscular volume). Hyponatremia due to syndrome of inappropriate ADH secretion (SIADH) or decreased glomerular filtration rate is common. Additional frequent findings include increased serum levels of LDL cholesterol, triglycerides, lipoprotein (a), liver enzymes, creatine kinase, or PRL. Semen analysis shows an increase in abnormal sperm morphology. In patients with autoimmune thyroiditis, titers of antibodies against thyroperoxidase and thyroglobulin are high; serum antinuclear antibodies may be present but are not usually indicative of lupus.

Subclinical hypothyroidism is defined as the state of having a normal serum FT_4 with a serum TSH that is above the reference range. It occurs most often in persons aged

65 years or older, in whom the prevalence is 13%. Subclinical hypothyroidism is often transient and the TSH normalizes spontaneously in about 35% of cases within 2 years. The likelihood of TSH normalization is higher in patients without antithyroid antibodies and those with a marginally elevated serum TSH. The term “subclinical” is somewhat misleading, since it does not refer to patients’ symptoms but rather refers only to serum hormone levels; in fact, such patients can have subtle manifestations of hypothyroidism (eg, fatigue, depression, hyperlipidemia) that may improve with a trial of levothyroxine replacement. Patients without such symptoms do not require levothyroxine therapy but must be monitored regularly for the emergence of symptoms.

A retrospective analysis of 1954 patients aged 65 years and older with subclinical hypothyroidism found a threshold serum TSH above 6.38 milli-international units/L was associated with increased mortality; however, it is uncertain whether levothyroxine therapy reduces mortality risk in this group.

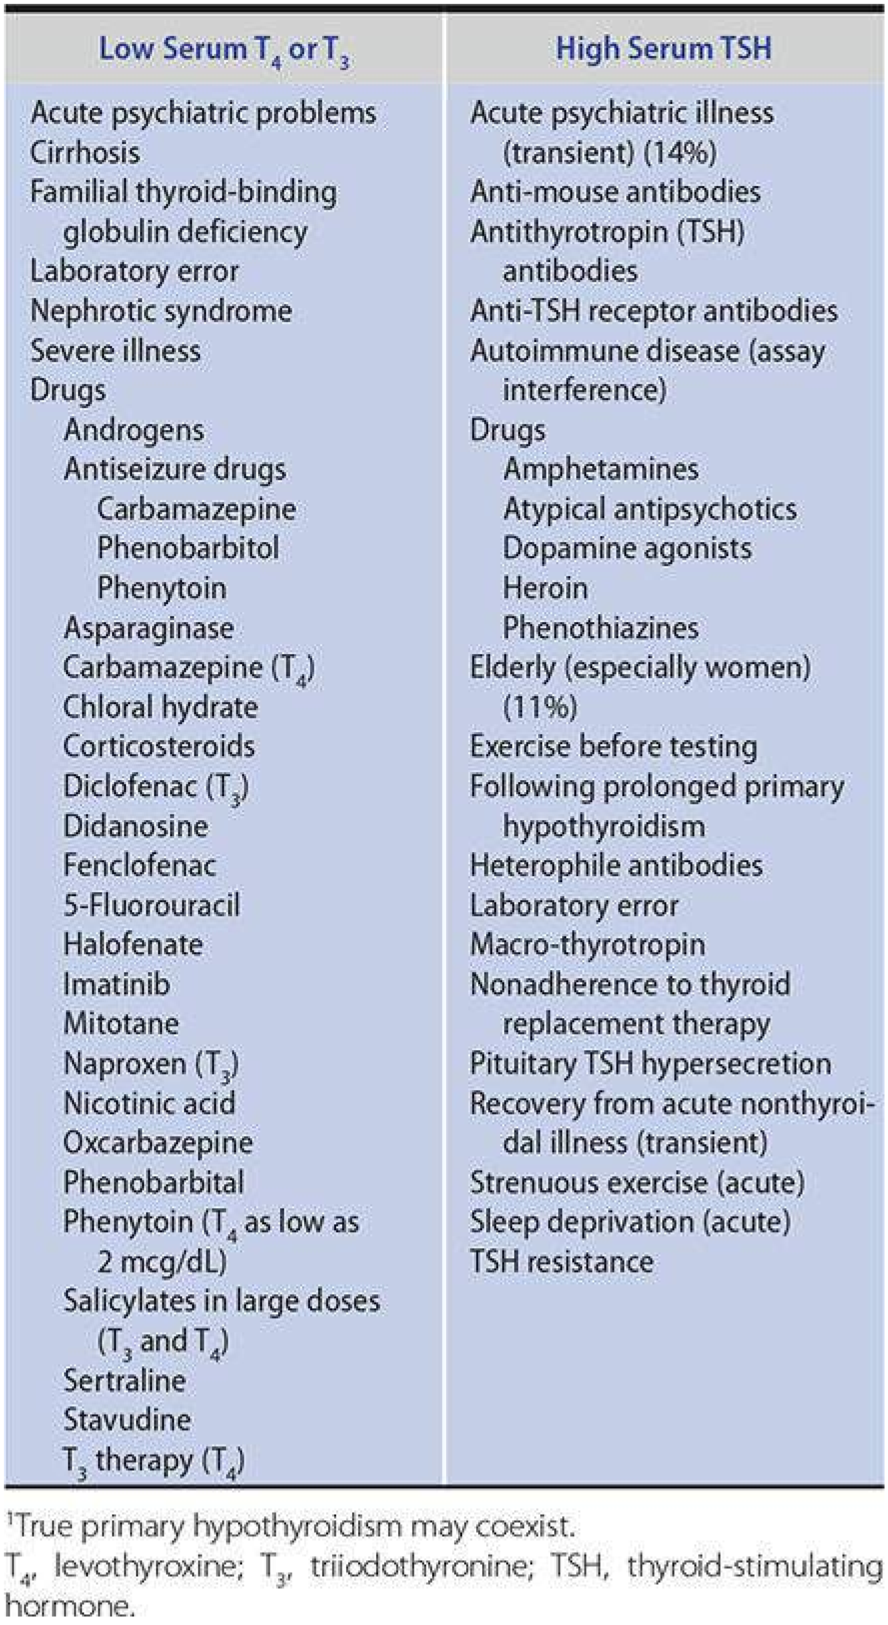
C. Imaging

Radiologic imaging is usually not necessary for patients with hypothyroidism. However, on CT or MRI, a goiter may be noted in the neck or in the mediastinum (retrosternal goiter). An enlarged thymus is frequently seen in the mediastinum in cases of autoimmune thyroiditis. On MRI, the pituitary is often quite enlarged in primary hypothyroidism, due to hyperplasia of TSH-secreting cells, which is reversible following thyroid therapy; concomitant hyperprolactinemia can lead to the mistaken diagnosis of a TSH-secreting or PRL-secreting pituitary adenoma.

Differential Diagnosis

The differential diagnosis for subclinical hypothyroidism includes antibody interference with the serum TSH assay, macro-TSH, sleep deprivation, exercise, recovery from nonthyroidal illness, acute psychiatric emergencies, and other conditions and medications that can cause a low serum T_4 or high serum TSH in the absence of hypothyroidism (Table 26–3).

Table 26–3. Factors that may cause aberrations in laboratory tests that may be mistaken for primary hypothyroidism.[1]



Low Serum T_4 or T_3

- Acute psychiatric problems
- Cirrhosis
- Familial thyroid-binding globulin deficiency
- Laboratory error
- Nephrotic syndrome
- Severe illness
- Drugs
  - Androgens
  - Antiseizure drugs
    - Carbamazepine
    - Phenobarbitol
    - Phenytoin
  - Asparaginase
  - Carbamazepine (T_4)
  - Chloral hydrate
  - Corticosteroids
  - Diclofenac (T_3)
  - Didanosine
  - Fenclofenac
  - 5-Fluorouracil
  - Halofenate
  - Imatinib
  - Mitotane
  - Naproxen (T_3)
  - Nicotinic acid
  - Oxcarbazepine
  - Phenobarbital
  - Phenytoin (T_4 as low as 2 mcg/dL)
  - Salicylates in large doses (T_3 and T_4)
  - Sertraline
  - Stavudine
  - T_3 therapy (T_4)

High Serum TSH

- Acute psychiatric illness (transient) (14%)
- Anti-mouse antibodies
- Antithyrotropin (TSH) antibodies
- Anti-TSH receptor antibodies
- Autoimmune disease (assay interference)
- Drugs
  - Amphetamines
  - Atypical antipsychotics
  - Dopamine agonists
  - Heroin
  - Phenothiazines
- Elderly (especially women) (11%)
- Exercise before testing
- Following prolonged primary hypothyroidism
- Heterophile antibodies
- Laboratory error
- Macro-thyrotropin
- Nonadherence to thyroid replacement therapy
- Pituitary TSH hypersecretion
- Recovery from acute nonthyroidal illness (transient)
- Strenuous exercise (acute)
- Sleep deprivation (acute)
- TSH resistance

[1] True primary hypothyroidism may coexist.

T_4, levothyroxine; T_3, triiodothyronine; TSH, thyroid-stimulating hormone.

Euthyroid sick syndrome should be considered in patients without known thyroid disease who are found to have a low serum FT_4 with a serum TSH that is not elevated. This syndrome can be seen in patients with severe illness, caloric deprivation, or major surgery. Serum TSH tends to be suppressed in severe nonthyroidal illness, making the diagnosis of concurrent primary hypothyroidism quite difficult, although the presence of a goiter suggests the diagnosis.

The clinician must decide whether such severely ill patients (with a low serum T_4 but no elevated TSH) might have hypothyroidism due to hypopituitarism. Patients without symptoms of prior brain lesion or hypopituitarism are very unlikely to suddenly develop hypopituitarism during an unrelated illness. Patients with diabetes insipidus, hypopituitarism, or other signs of a central nervous system (CNS) lesion may be given T_4 empirically.

Patients receiving prolonged dopamine infusions can develop true secondary hypothyroidism caused by dopamine's direct suppression of TSH-secreting cells.

Complications

Patients with severe hypothyroidism have an increased susceptibility to bacterial pneumonia. Megacolon has been described in long-standing hypothyroidism. Organic psychoses with paranoid delusions may occur ("myxedema madness"). Rarely, adrenal crisis may be precipitated by thyroid therapy. Hypothyroidism is a rare cause of infertility, which may respond to thyroid replacement. Untreated hypothyroidism during pregnancy often results in miscarriage. Preexistent coronary artery disease and heart failure may be exacerbated by levothyroxine therapy.

Myxedema crisis refers to severe, life-threatening manifestations of hypothyroidism. Myxedema crisis particularly affects elderly women and can occur spontaneously in severely hypothyroid patients with prolonged exposure to the cold, with resultant hypothermia. It can also be induced by a stroke, heart failure, infection (particularly pneumonia), or trauma. Metabolism of drugs is slowed in hypothyroidism and myxedema crisis is often precipitated by the administration of sedatives, antidepressants, hypnotics, anesthetics, or opioids. The drugs further impair cognition and respiratory drive and can precipitate respiratory arrest. Affected patients have impaired cognition, ranging from confusion to somnolence to coma (myxedema coma). Convulsions and abnormal CNS signs may occur. Patients have profound hypothermia, hypoventilation, hyponatremia, hypoglycemia, hypoxemia, hypercapnia, and hypotension. Rhabdomyolysis and acute kidney injury may occur. The mortality rate is high.

Treatment

Before beginning therapy with thyroid hormone, the hypothyroid patient requires at least a clinical assessment for adrenal insufficiency and angina. The presence of either condition requires further evaluation and management.

A. Treatment for Hypothyroidism

Synthetic levothyroxine is the preferred preparation for treating hypothyroid patients. However, some clinicians prescribe mixtures of levothyroxine and triiodothyronine for certain patients. Otherwise healthy young and middle-aged adults with hypothyroidism may be treated initially with levothyroxine in average doses of about 1.6 mcg/kg/day. Lower doses can be used for very mild hypothyroidism, while full doses are given for more symptomatic hypothyroidism. During pregnancy, women with mild hypothyroidism may be treated with initial levothyroxine doses of about 75–100 mcg daily. Pregnant women with overt hypothyroidism or myxedema should be treated immediately with levothyroxine at full replacement doses of 1.6 mcg/kg/day (about 100–150 mcg daily). Thyroid function testing is repeated every 4–6 weeks during pregnancy, with levothyroxine doses being adjusted to normalize the serum TSH and restore euthyroidism. For initial titration, the levothyroxine dosage may be increased according to clinical response and serum TSH, measuring serum TSH every 4–6 weeks and trying to keep the serum TSH level between 0.4 milli-international units/L and 2.0 milli-international units/L. However, patients receiving levothyroxine replacement, with serum TSH levels within the reference range, have higher average levels of LDL cholesterol compared to matched euthyroid controls. Also, some treated patients continue to have subjective symptoms suggestive of mild hypothyroidism, despite normal serum TSH levels. Such patients may benefit from a carefully increased dose of levothyroxine. Bedtime levothyroxine administration results in somewhat higher serum T_4 and lower TSH levels than morning administration. Therefore, the administration timing for levothyroxine should be kept constant. After beginning daily administration, significant increases in serum T_4 levels are seen within 1–2 weeks, and near-peak levels are seen within 3–4 weeks.

Patients with stable coronary artery disease or those who are over age 60 years are treated with smaller initial doses of levothyroxine, 25–50 mcg orally daily; higher initial doses may be used if such patients are severely hypothyroid. The dose can be increased by 25 mcg every 1–3 weeks until the patient is euthyroid. Ideally, patients with hypothyroidism and unstable coronary artery disease or uncontrolled atrial fibrillation should begin levothyroxine replacement following medical or interventional therapy.

Myxedema crisis requires larger initial doses of levothyroxine intravenously, since myxedema itself can interfere with intestinal absorption of oral levothyroxine. Levothyroxine sodium 500 mcg is given intravenously as a loading dose, followed by 50–100 mcg intravenously daily; the lower dose is given to patients with suspected coronary artery disease. In patients with myxedema coma, liothyronine (T_3, Triostat) can be given intravenously with a loading dose of 10–20 mcg, followed by 10 mcg every 4–6 hours for the first 48 hours. The hypothermic patient is warmed only with blankets, since faster warming can precipitate cardiovascular collapse. Hypoglycemic patients are given 5% dextrose intravenously. Hyponatremic patients with a serum sodium 120–130 mEq/mL are administered 0.9% NaCl intravenously, while patients with a serum sodium below 120 mEq/mL are treated with boluses of 100 mL of 3% NaCl intravenously with intravenous furosemide 20–40 mg to promote water diuresis; serum sodium levels must be followed closely and boluses of 3% NaCl can be repeated about every 6 hours until the serum sodium rises to 120 mmol/L or higher. When giving intravenous saline to myxedematous patients, care must be taken to avoid fluid overload.

Patients with hypercapnia require mechanical assistance with ventilation. Opioid medications must be stopped or used in very low doses. Infections must be detected and treated aggressively. Patients in whom concomitant adrenal insufficiency is suspected are treated with hydrocortisone, 100 mg intravenously, followed by 25–50 mg every 8 hours.

B. Monitoring and Optimizing Treatment of Hypothyroidism

Regular clinical and laboratory monitoring is critical to determine the optimal levothyroxine dose for each patient. The initial goal should be to normalize the serum TSH within 1–2 months of commencing thyroid replacement therapy. The patient should be prescribed sufficient levothyroxine to restore a clinically euthyroid state; this can usually be attained by maintaining the serum TSH, FT_4, and FT_3 within their reference ranges. However, when patients take levothyroxine replacement in doses sufficient to normalize serum TSH levels, their serum FT_3 levels are lower and serum FT_4 levels are higher, on average, than matched euthyroid individuals not taking levothyroxine. Perhaps for that reason, a significant number of patients taking levothyroxine continue to feel hypothyroid while taking levothyroxine, despite having a normal serum TSH. Unless contraindicated by unstable angina, such patients may be carefully administered a slightly higher dose of levothyroxine that suppresses the serum TSH while achieving clinical euthyroidism and a serum FT_3 near the low-normal range. For most patients with hypothyroidism, an ideal stable maintenance dose of levothyroxine can usually be found.

Different levothyroxine preparations vary in their bioavailability by up to 14% and such differences may have a subtle but significant clinical impact. It is optimal for patients to consistently take the same manufacturer’s brand of levothyroxine.

Pregnancy usually increases the levothyroxine dosage requirement; an increase in levothyroxine requirement has been noted as early as the fifth week of pregnancy. Adequate levothyroxine is critical to the health of the fetus. Therefore, it is prudent to increase levothyroxine dosages by approximately 20–30% as soon as pregnancy is confirmed. The fetus is at least partially dependent on maternal T_4 for its CNS development—particularly in the second trimester. By mid-pregnancy, women require an average of 47% increase in their levothyroxine dosage. Postpartum, levothyroxine replacement requirement ordinarily returns to prepregnancy level.

Decreased levothyroxine dose requirements occur in women after delivery, after bilateral oophorectomy or natural menopause, after cessation of oral estrogen replacement, or during therapy with GnRH agonists. Levothyroxine dosage may need to be titrated downward for patients who start taking teduglutide for short bowel syndrome.

1. Elevated serum TSH level—This usually indicates underreplacement with levothyroxine. However, before increasing the T_4 dosage, it is important to confirm that the patient is taking the levothyroxine as directed and does not have coronary insufficiency.

Increased levothyroxine dosage requirements (low serum T_4 levels) can occur with drugs that increase the hepatic metabolism of levothyroxine (Table 26–3). Amiodarone can increase or decrease levothyroxine dose requirements. Malabsorption of levothyroxine can be caused by coadministration of binding substances, such as iron (eg, in multivitamins); fiber; raloxifene; sucralfate; aluminum hydroxide antacids; sevelemer; orlistat; soy milk; bile acid–binding resins (cholestyramine and colesevelam); and calcium, magnesium, and soy protein supplements.

Proton pump inhibitors interfere slightly with the absorption of levothyroxine. Gastrointestinal disorders can interfere with levothyroxine absorption, including celiac disease, inflammatory bowel disease, lactose intolerance, Helicobacter pylori gastritis, and atrophic gastritis. Nephrotic syndrome can increase the required dose of oral levothyroxine. Women with hypothyroidism may require increased doses of levothyroxine after commencing oral estrogen therapy.

Serum TSH may be elevated transiently in acute psychiatric illness, with antipsychotics and phenothiazines, and during recovery from nonthyroidal illness. Autoimmune disease can cause false elevations of TSH by interfering with the assay. Very rarely, a high TSH can be caused by a thyrotropin-secreting pituitary tumor or hyperplasia.

2. Normal serum TSH level—Most patients may be given levothyroxine in doses sufficient to achieve a serum TSH in the low-normal range. However, for patients with coronary artery disease or recurrent atrial fibrillation, it may be prudent to administer lower doses of levothyroxine to keep their serum TSH in the high-normal range or even at a slightly elevated level.

About 10% of otherwise healthy treated hypothyroid patients (taking levothyroxine with a normal serum TSH) continue to have hypothyroid-type symptoms, such as lethargy, weight gain, depression, or cognitive problems. An even larger percentage has been found to have subtle but significantly reduced psychological wellbeing, compared to gender-matched and age-matched euthyroid controls. Such patients must be assessed for concurrent conditions, such as an adverse drug reaction, Addison disease, depression, hypogonadism, anemia, celiac disease, or gluten sensitivity. If such conditions are not present or are treated and hypothyroid-type symptoms persist, a serum T_3 or free T_3 level is often helpful. Low serum T_3 levels may reflect inadequate peripheral deiodinase activity to convert inactive T_4 to active T_3. Such patients may be given a careful clinical trial of a slightly higher dose of levothyroxine that results in a low serum TSH and a low-normal serum T_3 or free T_3.

For such patients, some clinicians have found success with other strategies, such as using desiccated natural porcine thyroid preparations containing both T_4 and T_3 (eg, Armour Thyroid, Nature-Throid, NP Thyroid). For product conversion purposes, 100 mcg of levothyroxine is equivalent to about 65 mg (1 grain) of desiccated thyroid. The use of desiccated thyroid preparations has been discouraged by several professional medical societies, but some patients prefer them.

3. Low or suppressed serum TSH level—A serum TSH level-below the reference range (adults 0.4–4.0 milli-international units/L) is either “low” (0.1–0.39 milli-international units/L) or “suppressed” (less than 0.1 milli-international units/L). Clinically euthyroid patients receiving levothyroxine who have “low” TSH levels do not have increased morbidity. However, a “suppressed” serum TSH often indicates over- replacement with levothyroxine, and such patients may have symptoms of hyperthyroidism and have an increased risk for atrial fibrillation, osteoporosis, and clinical hyperthyroidism. When the serum TSH is suppressed, the dosage of levothyroxine is reduced. However, some patients feel unmistakably hypothyroid while taking the reduced dose of levothyroxine and have low serum T_3 or free T_3 levels. For such patients, a higher levothyroxine dose may be resumed with close surveillance for atrial fibrillation, osteoporosis, and manifestations of subtle hyperthyroidism. A suppressed serum TSH can also occur with hypopituitarism, severe nonthyroidal illness, and certain medications (eg, nonsteroidal anti-inflammatory drugs [NSAIDs], opioids, nifedipine, verapamil, and high-dose [short-term] corticosteroids).

Prognosis

Patients with mild hypothyroidism caused by Hashimoto thyroiditis have a remission rate of 11%. Hypothyroidism caused by interferon-alpha resolves within 17 months of stopping the drug in 50% of patients. With levothyroxine treatment of hypothyroidism, striking transformations take place both in appearance and mental function. Return to a normal state is usually the rule, but relapses will occur if treatment is interrupted.

However, untreated patients with myxedema crisis have a mortality rate approaching 100%; even with optimal treatment, the mortality rate is 20–50%.

When to Refer

- Difficulty titrating levothyroxine replacement to normal TSH or clinically euthyroid state.
- Any patient with significant coronary artery disease needing levothyroxine therapy.

When to Admit

- Suspected myxedema crisis.
- Hypercapnia.

HYPERTHYROIDISM (Thyrotoxicosis)

ESSENTIALS OF DIAGNOSIS

- Sweating, weight loss or gain, anxiety, palpitations, loose stools, heat intolerance, menstrual irregularity.
- Tachycardia; warm, moist skin; stare; tremor.
- Graves disease is most common cause of hyperthyroidism; palpable goiter (sometimes with bruit) seen in most patients; ophthalmopathy also common.
- Suppressed TSH in primary hyperthyroidism; usually increased T_4, FT_4, T_3, FT_3.

General Considerations

The term "thyrotoxicosis" refers to the clinical manifestations associated with elevated serum levels of T_4 or T_3 that are excessive for the individual (hyperthyroidism). Serum TSH levels are suppressed in primary hyperthyroidism. However, certain drugs and conditions can affect laboratory tests and lead to the erroneous diagnosis of hyperthyroidism in euthyroid individuals (Table 26–4). The causes of hyperthyroidism are many and diverse, as described below.

Table 26–4. Factors that can cause aberrations in laboratory tests that may be mistaken for spontaneous clinical primary hyperthyroidism.[1]

High Serum T_4 or T_3	Low Serum TSH
Laboratory error Collection vial contains gel barrier for T_3 Acute psychiatric problems (30%) Acute medical illness (eg, acute intermittent porphyria) Acute or chronic active hepatitis, primary biliary cirrhosis AIDS (increased thyroid-binding globulin) Autoimmunity Familial thyroid-binding abnormalities Familial resistance to thyroid (Refetoff syndrome) Pregnancy: morning sickness, hyperemesis gravidarum Drugs Amiodarone Amphetamines Biotin supplements Clofibrate Estrogens (oral) Heparin (dialysis method) Heroin Methadone Perphenazine Tamoxifen Thyroid hormone therapy (excessive or factitious)	Laboratory error Autonomous thyroid or thyroid nodule Biotin supplements Corticosteroid administration (acute) Drugs Amphetamines Calcium channel blockers (nifedipine, verapamil) Dopamine Dopamine agonists Thyroid hormone Elderly euthyroid hCG-secreting trophoblastic tumors Hypopituitarism Nonthyroidal illness (severe) Pregnancy (especially with morning sickness) Suppression after recent therapy for hyperthyroidism TSH variants not detected by commercial assays

[1] True clinical hyperthyroidism may coexist.

hCG, human chorionic gonadotropin; T_4, levothyroxine; T_3, triiodothyronine; TSH, thyroid-stimulating hormone.

A. Graves Disease

Graves disease (known as Basedow disease in Europe) is the most common cause of thyrotoxicosis. It is an autoimmune disorder affecting the thyroid gland, characterized by an increase in synthesis and release of thyroid hormones; autoantibodies known as thyroid-stimulating immunoglobulins (TSI) or TSH receptor antibodies bind to the TSH receptor in thyroid cell membranes and stimulate the gland to hyperfunction.

Graves disease is much more common in women than in men (8:1), and its onset is usually between the ages of 20 and 40 years. It may be accompanied by infiltrative ophthalmopathy (Graves exophthalmos) and, less commonly, by infiltrative dermopathy (pretibial myxedema). The thymus gland is typically enlarged and serum antinuclear antibody levels are usually elevated. Many patients with Graves disease have a family history of either Graves disease or autoimmune (Hashimoto) thyroiditis.

Dietary iodine supplementation can trigger Graves disease. An increased incidence of Graves disease occurs in countries that have embarked on national programs to fortify commercial salt with potassium iodide; the increase in Graves disease lasts about 4 years. Similarly, patients being treated with potassium iodide or amiodarone (which contains iodine) have an increased risk of developing Graves disease.

Chemotherapy with immune checkpoint inhibitors (ipilimumab, pembrolizumab, tremelimumab, and atezolizumab) can precipitate Graves disease, which must be distinguished from hyperthyroidism from destructive autoimmune thyroiditis (silent thyroiditis), which can be caused by these same medications.

Patients with Graves disease have an increased risk of other systemic autoimmune disorders, including Sjögren syndrome, celiac disease, pernicious anemia, Addison disease, alopecia areata, vitiligo, type 1 diabetes mellitus, hypoparathyroidism, myasthenia gravis, and cardiomyopathy.

B. Toxic Multinodular Goiter and Thyroid Nodules

Autonomous hyperfunctioning thyroid nodules that produce hyperthyroidism are known as toxic multinodular goiter (Plummer disease) and are more prevalent among older adults and in iodine-deficient regions. A single hyperfunctioning nodule can also produce hyperthyroidism. Toxic multinodular goiter and Graves disease may sometimes coexist in the same gland (Marine-Lenhart syndrome). Thyroid cancer is found in about 4.7% of patients with toxic multinodular goiter.

C. Postpartum, Subacute, and Silent Thyroiditis

These conditions cause thyroid inflammation with release of stored hormone. They all produce a variable triphasic course: variable hyperthyroidism is followed by transient euthyroidism, and progresses to hypothyroidism.

Postpartum thyroiditis refers to autoimmune thyroiditis that occurs in the first 12 months postpartum and occasionally after miscarriages. See Thyroiditis, above. About 22% of affected women experience hyperthyroidism followed by hypothyroidism, whereas 30% of such women have isolated thyrotoxicosis and 48% have isolated hypothyroidism. The thyrotoxic phase typically occurs 2–6 weeks postpartum and lasts 2–3 months. Over 80% have antithyroid antibodies. Most women progress to a hypothyroid phase that usually lasts a few months but that can be permanent.

Subacute thyroiditis is also known as “de Quervain” or “granulomatous” thyroiditis. It is typically caused by various viral infections. Women are affected four times more frequently than men. Patients typically experience a viral upper respiratory infection and develop an enlarged and extremely painful thyroid. About 50% of affected patients experience a symptomatic thyrotoxic phase that lasts 3–6 weeks. It is important to differentiate subacute thyroiditis from infectious (suppurative bacterial) thyroiditis. About 10% remain hypothyroid after 1 year. The recurrence rate is 1–4%.

Silent thyroiditis is also known as subacute lymphocytic thyroiditis or "Hashitoxicosis." It can occur spontaneously; women are affected four times more frequently than men. About 50% have antithyroid antibodies. Silent thyroiditis can also be caused by chemotherapeutic agents (such as tyrosine kinase inhibitors; denileukin diftitox; alemtuzumab; interferon-alpha; interleukin-2; and immune checkpoint inhibitors). Other drugs can cause silent thyroiditis, including lithium and amiodarone. In those with spontaneous silent thyroiditis, about 10–20% remain hypothyroid after 1 year. There is a recurrence rate of 5–10%; this rate is higher in Japan.

D. Medication-Induced Hyperthyroidism

1. Amiodarone-induced thyrotoxicosis—Amiodarone is 37% iodine by weight. The half-life of amiodarone and its metabolites is about 100 days. In the short term, amiodarone normally increases the serum TSH, though usually not over 20 milli-international units/L (see Thyroiditis, above). Serum T_4 and FT_4 rise about 40% and may become frankly elevated in clinically euthyroid patients. Meanwhile, serum T_3 levels decline. Due to these short-term changes, it is best to not check thyroid function tests during the first 3 months of therapy with amiodarone, unless clinically indicated. After about 3 months, the serum TSH usually normalizes. Since serum T_4 levels can be misleadingly high, the serum TSH level must be suppressed to diagnose amiodarone-induced thyrotoxicosis. With amiodarone-induced thyrotoxicosis, the serum T_3 or FT_3 is usually high or high-normal. In the United States, amiodarone causes thyrotoxicosis in about 3% of patients taking the drug. In Europe and iodine-deficient geographic areas, amiodarone induces thyrotoxicosis in about 20%. Thyrotoxicosis can occur suddenly at any time during treatment and may even develop several months after it has been discontinued. The manifestations of amiodarone-induced thyrotoxicosis can be missed, particularly since amiodarone tends to cause bradycardia. Therefore, thyroid function tests (TSH, FT_4, T_3) should be checked before starting amiodarone, again at 3–6 months, and then every 6 months (or sooner if clinically indicated).

Amiodarone-induced thyrotoxicosis is categorized as type 1 or type 2; about 27% are mixed type 1–2. Type 1 is caused by the active production of excessive thyroid hormone. Type 2 is caused by thyroiditis with the passive release of stored thyroid hormone.

2. Iodine-induced hyperthyroidism—This is also known as Jod-Basedow disease. The recommended iodine intake for nonpregnant adults is 150 mcg/day. Higher iodine intake can precipitate hyperthyroidism in patients with nodular goiters, autonomous thyroid nodules, or asymptomatic Graves disease, and less commonly in patients with no detectable underlying thyroid disorder. Common sources of excess iodine include intravenous iodinated radiocontrast dye, certain foods (eg, kelp, nori), topical iodinated antiseptics (eg, povidine iodine), and medications (eg, amiodarone or potassium iodide). Intravenous iodinated radiocontrast dye can rarely induce a painful, destructive subacute thyroiditis, similar to type 2 amiodarone-induced thyrotoxicosis.

3. Tyrosine kinase inhibitors—Silent thyroiditis that releases stored thyroid hormone, resulting in hyperthyroidism, develops in about 3.2% of patients receiving chemotherapy with tyrosine kinase inhibitors (eg, axitinib, sorafenib, sunitinib). While this hyperthyroidism may be subclinical, thyrotoxic crisis has been reported. Hypothyroidism usually follows hyperthyroidism and overall occurs in 19% of patients taking these drugs.

4. Immune checkpoint inhibitor cancer therapy—Immune checkpoint inhibitor therapy directed against either PD-1/PD-L1 or CTLA-4/B7-1/B7-2 can be effective against certain malignancies but frequently precipitates autoimmune adverse reactions. Thyroid autoimmunity commonly causes thyroiditis, hypothyroidism (primary or secondary), or hyperthyroidism from either passive release of thyroid hormone or active production of thyroid hormone (Graves disease), in whom ophthalmopathy has been observed.

E. Pregnancy, hCG-Secreting Trophoblastic Tumors, and Testicular Choriocarcinoma

Human chorionic gonadotropin (hCG) can bind to the thyroid's TSH receptors, so very high levels of serum hCG, particularly during the first 4 months of pregnancy, may cause sufficient receptor activation to cause hyperthyroidism. About 18% of pregnant women have a low serum TSH during pregnancy, but only about 10% of such women have clinical hyperthyroidism that requires treatment. Pregnant women are more likely to have hCG-induced thyrotoxicosis if they have high levels of serum asialo-hCG, a subfraction of hCG that has a greater affinity for TSH receptors. Such women are also more likely to suffer from hyperemesis gravidarum. This condition must be distinguished from true Graves disease in pregnancy, which usually predates conception and may be associated with high serum levels of TSI and antithyroid antibodies or with exophthalmos.

High levels of hCG can also cause thyrotoxicosis in some cases of pregnancies with gestational trophoblastic disease (molar pregnancy, choriocarcinoma). Some such pregnancies have produced thyrotoxic crisis. Men have developed hyperthyroidism from high levels of serum hCG secreted by a testicular choriocarcinoma.

F. Rare Causes of Hyperthyroidism

Thyrotoxicosis factitia is due to intentional or accidental ingestion of excessive amounts of exogenous thyroid hormone. Struma ovarii refers to thyroid tissue contained in about 3% of ovarian dermoid tumors and teratomas. Pituitary TSH hypersecretion by a pituitary thyrotrophe tumor or hyperplasia can rarely cause hyperthyroidism. Serum TSH is elevated or inappropriately normal in the presence of true thyrotoxicosis. Pituitary hyperplasia may be detected on an MRI as a pituitary enlargement without a discrete adenoma being visible. Metastatic functioning thyroid carcinoma can cause hyperthyroidism in patients with a heavy tumor burden. Recombinant human thyroid-stimulating hormone (rhTSH) can rarely induce hyperthyroidism when it is given prior to radioiodine therapy or scanning for metastatic differentiated thyroid cancer.

Clinical Findings

A. Symptoms and Signs

Thyrotoxicosis due to any cause can produce nervousness, restlessness, heat intolerance, increased sweating, palpitations, pruritus, fatigue, muscle weakness, muscle cramps, frequent bowel movements, weight change (usually loss), or menstrual irregularities. There may be fine resting finger tremors, moist warm skin, fever, hyperreflexia, fine hair, and onycholysis. Angina or atrial fibrillation may also be present, sometimes in the absence of other thyrotoxic symptoms **(apathetic hyperthyroidism).** Women with **postpartum thyroiditis** are often asymptomatic or experience only minor symptoms, such as palpitations, heat intolerance, and irritability. Chronic thyrotoxicosis may cause osteoporosis. Even subclinical hyperthyroidism (suppressed serum TSH with normal FT_4) may increase the risk of nonvertebral fractures. Clubbing and swelling of the fingers (acropachy) develop rarely. Tetany is a rare presenting symptom; hyperthyroidism causes an increased renal excretion of magnesium, resulting in functional hypoparathyroidism and hypocalcemia.

Thyroid examination in patients with Graves disease usually reveals a diffusely enlarged thyroid, frequently asymmetric, often with a bruit. However, there may be no palpable thyroid enlargement. The thyroid gland in subacute thyroiditis is usually moderately enlarged and tender. There is often dysphagia and pain that can radiate to the jaw or ear. In patients with toxic multinodular goiter, the thyroid usually has palpable nodules. Patients with silent thyroiditis or postpartum thyroiditis have either no palpable goiter or a small, nontender goiter. **Cardiopulmonary manifestations** of thyrotoxicosis commonly include a forceful heartbeat, premature atrial contractions, and sinus tachycardia. Patients often have exertional dyspnea. Atrial fibrillation or atrial tachycardia occurs in about 8% of patients with thyrotoxicosis, more commonly in men, older adults, and those with ischemic or valvular heart disease. The ventricular response from the atrial fibrillation may be difficult to control. Thyrotoxicosis itself can cause a thyrotoxic cardiomyopathy, and the onset of atrial fibrillation can precipitate heart failure. Echocardiogram reveals pulmonary hypertension in 49% of patients with hyperthyroidism; of these, 71% have pulmonary artery hypertension while 29% have pulmonary venous hypertension. Even "subclinical hyperthyroidism" increases the risk for atrial fibrillation and overall mortality. Hemodynamic abnormalities and pulmonary hypertension are reversible with restoration of euthyroidism.

Thyrotoxic crisis or "storm" is an extreme form of severe thyrotoxicosis that is an immediate threat to life. It may be triggered by stressful illness, thyroid surgery, or RAI administration. Its manifestations typically include marked agitation or delirium, very high fever, severe tachycardia, vomiting, diarrhea, and dehydration. Cardiac arrhythmias, heart failure, and myocardial infarction are possible complications.

Eye manifestations that occur with hyperthyroidism of any etiology include: upper eyelid retraction, lid lag with downward gaze, and a staring appearance. See Thyroid Eye Disease, Chapter 7. Thyroid-associated ophthalmopathy with exophthalmos is clinically apparent in 20–40% of patients with Graves disease and some cases of amiodarone-induced thyrotoxicosis. Aggravation of Graves eye disease has occurred after treatment with radioiodine or during therapy with thiazolidinediones (eg, pioglitazone). About 5–10% of patients experience more severe exophthalmos, with the eye being pushed forward by increased retro-orbital fat and eye muscles that have been thickened by lymphocytic infiltration. Such patients can experience diplopia from extraocular muscle entrapment. The severity of eye disease is not closely correlated with the severity of thyrotoxicosis.

Exophthalmometry should be performed on all patients with Graves disease to document their degree of exophthalmos and detect progression of orbitopathy. The protrusion of the eye beyond the orbital rim is measured with a prism instrument (Hertel exophthalmometer). Maximum normal eye protrusion varies between kindreds and races, being about 24 mm for blacks, 20 mm for whites, and 18 mm for Asians.

It is important to determine whether thyroid-associated orbitopathy is in an acute stage of inflammation versus a stable "burned out" stage with exophthalmos. It is also important to distinguish active eye disease from congenital proptosis or asymmetry in orbital protrusion.

Graves dermopathy (pretibial myxedema) occurs in about 3% of patients with Graves disease. It usually affects the pretibial region, but can also affect the dorsal forearms and wrists and dorsum of the feet. It is more common in patients with high levels of serum TSI and severe Graves ophthalmopathy. Glycosaminoglycans accumulation and lymphoid infiltration occur in affected skin, which becomes erythematous with a thickened, rough texture. Elephantiasis of the legs is a rare complication.

Thyroid acropachy is an extreme and unusual manifestation of Graves disease. It presents with digital clubbing, swelling of fingers and toes, and radiographic findings of periostitis involving phalangeal and metacarpal bones. Extremity skin can become very thickened, resembling elephantiasis. Thyroid acropachy is ordinarily associated with ophthalmopathy and thyroid dermopathy. Most affected patients are smokers.

Hyperthyroidism during pregnancy has a prevalence of about 0.2%. It may commence before conception or emerge during pregnancy, particularly the first trimester. Pregnancy can have a beneficial effect on the thyrotoxicosis of Graves disease, with decreasing antibody titers and decreasing serum T_4 levels as the pregnancy advances; about 30% of affected women experience a remission by late in the second trimester. However, undiagnosed or undertreated hyperthyroidism in pregnancy carries an increased risk of miscarriage, preeclampsia-eclampsia, preterm delivery, abruptio placenta, maternal heart failure, and thyrotoxic crisis (thyroid storm) (see Thyroid Disease, Chapter 19). Such thyrotoxic crisis can be precipitated by trauma, infection, surgery, or delivery and confers a fetal/maternal mortality rate of about 25%.

Hypokalemic periodic paralysis occurs in about 15% of Asian or Native American men with thyrotoxicosis. It usually presents abruptly with symmetric flaccid paralysis (and few thyrotoxic symptoms), often after intravenous dextrose, oral carbohydrate, or vigorous exercise. Attacks last 7–72 hours.

B. Laboratory Findings

Serum FT_4, T_3, FT_3, T_4, thyroid resin uptake, and FT_4 index are all usually increased. Sometimes the FT_4 level may be normal but with an elevated serum T_3 (T_3 toxicosis). The severity of the elevation of serum FT_4 and FT_3 levels does not always correlate with the severity of thyrotoxic manifestations; patients with thyrotoxic crisis tend to have serum thyroid levels that are not significantly higher than those with less pronounced symptoms. Serum T_3 can be misleadingly elevated when blood is collected in tubes using a gel barrier, which causes certain immunoassays to report falsely elevated serum total T_3 levels in 24% of normal patients. Serum T_4 or T_3 can be elevated in other nonthyroidal conditions (Table 26–4).

Serum TSH is suppressed in hyperthyroidism (except in the very rare cases of pituitary inappropriate secretion of thyrotropin). Serum TSH may be misleadingly low in other nonthyroidal conditions (Table 26–4). The term **"subclinical hyperthyroidism"** is used to describe asymptomatic individuals with a low serum TSH but normal serum levels of FT_4 and T_3.

Hyperthyroidism can cause hypercalcemia, increased liver enzymes, increased alkaline phosphatase, anemia, and decreased neutrophils. Hypokalemia and hypophosphatemia occur in thyrotoxic periodic paralysis. Hyperthyroidism also increases urinary magnesium excretion, which can lead to hypomagnesemia, resulting in functional hypoparathyroidism with hypocalcemia.

Problems of diagnosis occur in patients with acute psychiatric disorders; about 30% of these patients have elevated serum T_4 levels without clinical thyrotoxicosis. The TSH is not usually suppressed, distinguishing psychiatric disorder from true hyperthyroidism. T_4 levels return to normal gradually.

In **Graves disease**, serum TSI (TSHrAb) is usually detectable (65%). Antithyroperoxidase or antithyroglobulin antibodies are usually elevated but are nonspecific. Serum antinuclear antibodies are also usually elevated without any evidence of SLE or other rheumatologic disease.

With **subacute thyroiditis**, patients often have an increased WBC, ESR, and C-reactive protein. About 25% have antithyroid antibodies (usually in low titer) and serum TSI (TSHrAb) levels are normal. Patients with iodine-induced hyperthyroidism also have undetectable serum TSI (or TSHrAb), an absence of serum antithyroperoxidase antibodies, and an elevated urinary iodine concentration. In thyrotoxicosis factitia, serum thyroglobulin levels are low, distinguishing it from other causes of hyperthyroidism.

With **hyperthyroidism during pregnancy**, women have an elevated serum total T_4 and FT_4 while the TSH is suppressed. However, about 18% of normal pregnant women have a low serum TSH. An apparent lack of full TSH suppression in hyperthyroidism can be seen due to misidentification of hCG as TSH in certain assays. The serum FT_4 assay is difficult in pregnancy. Although the serum T_4 is elevated in most pregnant women, values over 20 mcg/dL (257 nmol/L) are encountered only in hyperthyroidism. On treatment, serum total T_4 levels during pregnancy should be kept at about 1.5 × the pre-pregnancy level. The T_3 resin uptake, which is low in normal pregnancy because of high thyroxine-binding globulin (TBG) concentration, is normal or high in thyrotoxic persons.

Since high levels of T_4 and FT_4 are normally seen in patients taking **amiodarone, a** suppressed TSH must be present along with a greatly elevated T_4 (greater than 20 mcg/dL [257 nmol/L]) or T_3 (greater than 200 ng/dL [3.1 nmol/L]) in order to diagnose hyperthyroidism. In type 1 amiodarone-induced thyrotoxicosis, the presence of proptosis and serum TSI (TSHrAb) is diagnostic. In type 2 amiodarone-induced thyrotoxicosis, serum levels of interleukin-6 (IL-6) are usually quite elevated.

C. Radioisotope Uptake and Imaging

Note: All radioisotope testing is contraindicated during pregnancy or breastfeeding.

Radioiodine (RAI) uptake and scanning can be helpful in determining the cause of hyperthyroidism. RAI uptake and scanning is not necessary for diagnosis in patients with obvious Graves disease who have elevated serum TSI or associated Graves ophthalmopathy. Women should ideally have the RAI scan extended to include the pelvis in order to screen for concomitant struma ovarii (rare). A high RAI uptake is seen in Graves disease and toxic nodular goiter. Patients with type 1 amiodarone-induced thyrotoxicosis have RAI uptake that is usually detectable. A low RAI uptake is also characteristic of iodine-induced hyperthyroidism and thyroiditis (subacute, silent, or postpartum), distinguishing them from Graves disease. In type 2 amiodarone-induced thyrotoxicosis, thyroid RAI uptake is usually below 3%.

Patients with Graves disease have increased or normal uptake of **technetium (Tc-99m) pertechnetate**, whereas those with thyrotoxicosis from thyroiditis (silent, subacute, postpartum) have reduced uptake. Technetium (Tc-99m) pertechnetate mimics radioiodine scanning but is more convenient, costs less, and confers less radiation exposure.

Thyroid ultrasound can be helpful in patients with hyperthyroidism, particularly in patients with palpable thyroid nodules. Thyroid ultrasound shows a variably heterogeneous, hypoechoic gland in thyroiditis. Color flow Doppler sonography is helpful to distinguish type 1 amiodarone-induced thyrotoxicosis (normal to increased blood flow velocity and vascularity) from type 2 amiodarone-induced thyrotoxicosis (reduced vascularity).

99mTc-sestamibi scanning usually shows normal or increased uptake with type 1 amiodarone-induced thyrotoxicosis and decreased uptake in type 2.

MRI and CT scanning of the orbits are the imaging methods of choice to visualize Graves ophthalmopathy affecting the extraocular muscles. Imaging is required only in severe or unilateral cases or in euthyroid exophthalmos that must be distinguished from orbital pseudotumor, tumors, and other lesions.

Differential Diagnosis

True thyrotoxicosis must be distinguished from those conditions that elevate serum T_4 and T_3 or suppress serum TSH without affecting clinical status (see Table 26–4). Serum TSH is commonly suppressed in early pregnancy and only about 10% of pregnant women with a low TSH have clinical hyperthyroidism.

Some states of hypermetabolism without thyrotoxicosis—notably severe anemia, leukemia, polycythemia, cancer, and pheochromocytoma—rarely cause confusion.

Acromegaly may also produce tachycardia, sweating, and thyroid enlargement. Appropriate laboratory tests will easily distinguish these entities.

The differential diagnosis for thyroid-associated ophthalmopathy includes an orbital tumor (eg, lymphoma) or pseudotumor. Ocular myasthenia gravis is another autoimmune condition that occurs more commonly in Graves disease but is usually mild, often with unilateral eye involvement. Acetylcholinesterase receptor antibody (AChR Ab) levels are elevated in only 36% of such patients, and a thymoma is present in 9%.

Diabetes mellitus and Addison disease may coexist with thyrotoxicosis and can aggravate the weight loss, fatigue, and muscle weakness seen with hyperthyroidism.

Complications

Hypercalcemia, osteoporosis, and nephrocalcinosis may occur in hyperthyroidism. Decreased libido, erectile dysfunction, diminished sperm motility, and gynecomastia may be noted in men. Other complications include cardiac arrhythmias and heart failure, thyroid crisis, ophthalmopathy, dermopathy, and thyrotoxic hypokalemic periodic paralysis.

Treatment

A. Treatment of Graves Disease

1. Propranolol—Propranolol is generally used for symptomatic relief of tachycardia, tremor, diaphoresis, and anxiety until the hyperthyroidism is resolved. It is the initial treatment of choice for thyrotoxic crisis and effectively treats thyrotoxic hypokalemic periodic paralysis. Propranolol has no effect on thyroid hormone secretion. Treatment is usually begun with propranolol ER 60 mg orally once or twice daily, with dosage increases every 2–3 days to a maximum daily dose of 320 mg. Propranolol ER is initially given every 12 hours for patients with severe hyperthyroidism, due to accelerated metabolism of the propranolol; it may be given once daily as hyperthyroidism improves.

2. Thiourea drugs—Methimazole or propylthiouracil is generally used for young adults or patients with mild thyrotoxicosis, small goiters, or fear of isotopes. See Treatment of Hyperthyroidism during Pregnancy-Planning, Pregnancy, and Lactation, below. Elderly patients usually respond particularly well. These drugs are also useful for preparing hyperthyroid patients for surgery and elderly patients for RAI treatment. When thiourea therapy is discontinued, there is a high recurrence rate for hyperthyroidism (about 50%). A better likelihood of long-term remission is seen in patients with small goiters, mild hyperthyroidism, those requiring small doses of thiourea, and those with serum TSI

(TSHrAb) less than 2 milli-units/L. Patients whose antithyroperoxidase and antithyroglobulin antibodies remain low after 2 years of therapy have been reported to have only a 10% rate of relapse. Some clinicians advocate RAI or surgery for patients with Graves disease who continue to require thiourea therapy after 1 year. However, there should be no rush to discontinue thiourea therapy that may be continued long term for patients who are tolerating it well.

All patients receiving thiourea therapy must be informed of the danger of agranulocytosis or pancytopenia and the need to stop the drug and seek medical attention immediately with the onset of any infection or unusual bleeding. Agranulocytosis (defined as an absolute neutrophil count below 500/mcL) or pancytopenia usually occurs abruptly in about 0.4% of patients taking either methimazole or propylthiouracil. Over 70% of agranulocytosis cases occur within the first 60 days and nearly 85% within 90 days of commencing therapy, but continued long-term vigilance for this side effect is required. About half the cases are discovered because of fever, pharyngitis, or bleeding, but the other cases are discovered with routine complete blood counts. There is a genetic tendency to develop agranulocytosis with thiourea therapy; if a close relative has had this adverse reaction, other therapies should be considered. Agranulocytosis generally remits spontaneously with discontinuation of the thiourea and during antibiotic treatment. Recovery has not been improved by filgrastim (granulocyte colony-stimulating factor [G-CSF]). Surveillance of the WBC can be done when blood is drawn to check thyroid levels during the first few months of treatment. Such surveillance may be helpful, since some cases of agranulocytosis occur gradually and many cases may be discovered while the patient is still asymptomatic.

Other side effects common to thiourea drugs include pruritus, allergic dermatitis, nausea, and dyspepsia. Antihistamines may control mild pruritus without discontinuation of the drug. Since the two thiourea drugs are similar, patients who have a major allergic reaction to one should not be given the other.

The patient may become clinically hypothyroid for 2 weeks or more before TSH levels rise, the pituitary gland having been suppressed by the preceding hyperthyroidism. Therefore, the patient’s changing thyroid status is best monitored clinically and with serum FT_4 levels. Rapid growth of the goiter usually occurs if prolonged hypothyroidism is allowed to develop; the goiter may sometimes become massive but usually regresses rapidly with reduction or cessation of thiourea therapy or with thyroid hormone replacement.

A. METHIMAZOLE—Except during the first trimester of pregnancy, methimazole is generally preferred over propylthiouracil, since methimazole is more convenient to use and is less likely to cause fulminant hepatic necrosis. Methimazole therapy is also less likely to cause ^{131}I treatment failure. Methimazole is given orally in initial doses of 30–60 mg once daily. Some patients with very mild hyperthyroidism may respond well to smaller initial doses of methimazole (10–20 mg daily). Methimazole may also be administered twice daily to reduce the likelihood of gastrointestinal upset. Rare complications peculiar to methimazole include serum sickness, cholestatic jaundice, alopecia, nephrotic syndrome, hypoglycemia, and loss of taste. Methimazole use in pregnancy has been associated with an increased risk of major fetal anomalies (4.1% vs 2.1% in controls). If methimazole is used during pregnancy or breastfeeding, the dose should not exceed 20 mg daily. The dosage is reduced as manifestations of hyperthyroidism resolve and as the FT_4 level falls toward normal. For patients receiving ^{131}I therapy, methimazole is discontinued 4 days prior to receiving the ^{131}I and is resumed at a lower dose 3 days afterward to avoid recurrence of hyperthyroidism. Following ^{131}I therapy, the dose of methimazole is gradually reduced according to frequent thyroid function testing; most patients are able to discontinue methimazole within 1–3 months following RAI therapy.

B. PROPYLTHIOURACIL—Initially, propylthiouracil is given orally in doses of 300–600 mg daily in four divided doses. The dosage and frequency of administration are reduced as symptoms of hyperthyroidism resolve and the FT_4 level approaches normal. Rare complications peculiar to propylthiouracil include arthritis, lupus, aplastic anemia, thrombocytopenia, and hypoprothrombinemia. With propylthiouracil, acute hepatitis occurs rarely and is treated with prednisone. Acute liver failure occurs in about 1 in 10,000 patients, making this a second-line drug, usually reserved for pregnancy, since it is not known to cause fetal anomalies. During pregnancy, the dose of propylthiouracil is kept below 200 mg/day to avoid goitrous hypothyroidism in the infant; the patient may be switched to methimazole in the second trimester.

3. Iodinated contrast agents—These agents provide effective temporary treatment for thyrotoxicosis of any cause. Iopanoic acid (Telepaque) or ipodate sodium (Bilivist, Oragrafin) is given orally in a dosage of 500 mg twice daily for 3 days, then 500 mg once daily. These agents inhibit peripheral 5′-monodeiodination of T_4, thereby blocking its conversion to active T_3. Within 24 hours, serum T_3 levels fall an average of 62%. For patients with Graves disease, methimazole is begun first to block iodine organification; the next day, ipodate sodium or iopanoic acid may be added. The iodinated contrast agents are particularly useful for patients who are symptomatically very thyrotoxic. They offer a therapeutic option for patients with T_4 overdosage, subacute thyroiditis, and amiodarone-induced thyrotoxicosis; for those intolerant to thioureas; and for newborns with thyrotoxicosis (due to maternal Graves disease). Treatment periods of 8 months or more are possible, but efficacy tends to wane with time. In Graves disease, thyroid RAI uptake may be suppressed during treatment but typically returns to pretreatment uptake by 7 days after discontinuation of the drug, allowing ^{131}I treatment.

4. Lithium carbonate—Thioureas are greatly preferred over lithium for the medical treatment of hyperthyroidism in Graves disease. However, lithium may be used effectively in cases of methimazole or propylthiouracil-induced hepatic toxicity or leukopenia, while the patient receives supportive treatment. The regimen for lithium carbonate is 500–750 mg/day orally in divided doses. Lithium should not be used during pregnancy. Most patients require concurrent treatment with propranolol and sometimes prednisone.

5. Radioactive iodine (^{131}I, RAI)—The administration of ^{131}I is an excellent method of destroying overactive thyroid tissue (either diffuse or toxic nodular goiter). Adolescent and adult patients who have been treated with RAI in adulthood do not have an increased risk of subsequent thyroid cancer, leukemia, or other malignancies. Children born to parents previously treated with ^{131}I show no increase in rates of congenital abnormalities.

Precautions: Because radiation is harmful to the fetus and children, RAI should not be given to pregnant or lactating women or to mothers who lack childcare. Women are advised to avoid pregnancy for at least 4 months following ^{131}I therapy. A pregnancy test should be obtained within 48 hours before therapy for any woman with childbearing potential. Men have been found to have abnormal spermatozoa for up to 6 months following ^{131}I therapy and are advised to use contraceptive methods during that time.

Patients may receive ^{131}I while being symptomatically treated with propranolol ER, which is then reduced in dosage as hyperthyroidism resolves. A higher rate of ^{131}I treatment failure has been reported in patients with Graves disease who have been receiving methimazole or propylthiouracil. However, therapy with ^{131}I will usually be effective if the methimazole is discontinued at least 3–4 days before RAI therapy and if the therapeutic dosage of ^{131}I is adjusted (upward) according to RAI uptake on the pretherapy scan. Prior to ^{131}I therapy, patients are instructed against receiving intravenous iodinated contrast and should consume a low-iodine diet.

The presence of Graves ophthalmopathy is a relative contraindication to ^{131}I therapy. Following ^{131}I treatment for hyperthyroidism, Graves ophthalmopathy appears or worsens in 15% of patients (23% in smokers and 6% in nonsmokers) and improves in none, whereas during treatment with methimazole, ophthalmopathy worsens in 3% and improves in 2% of patients. Among patients receiving prednisone following ^{131}I treatment, preexistent ophthalmopathy worsens in none and improves in 67%. Therefore, patients with Graves ophthalmopathy who are to be treated with radioiodine should be considered for prophylactic prednisone (20–40 mg/day) for 2 months following administration of ^{131}I, particularly in patients who have severe orbital involvement.

Smoking increases the risk of having a flare in ophthalmopathy following ^{131}I treatment and also reduces the effectiveness of prednisone treatment. Patients who smoke are strongly encouraged to quit prior to RAI treatment. Smokers receiving RAI should be considered for prophylactic prednisone (see above).

FT_4 levels may sometimes drop within 2 months after ^{131}I treatment, but then rise again to thyrotoxic levels, at which time thyroid RAI uptake is low. This phenomenon is caused by a release of stored thyroid hormone from injured thyroid cells and does not indicate a treatment failure. In fact, serum FT_4 then falls abruptly to hypothyroid levels.

There is a high incidence of hypothyroidism in the months to years after ^{131}I, even when low activities are given. Patients with Graves disease treated with ^{131}I also have an increased lifetime risk of developing hyperparathyroidism, particularly when radioiodine therapy was administered in childhood or adolescence. Lifelong clinical follow-up is mandatory, with measurements of serum TSH, FT_4, and calcium when indicated.

6. Thyroid surgery—Surgery may be indicated for patients with Graves disease who do not wish to have radioiodine therapy, for those with an intolerance to thioureas, and women planning pregnancy in the near future. The surgical procedure of choice is a total resection of one lobe and a subtotal resection of the other lobe, leaving about 4 g of thyroid tissue (Hartley–Dunhill operation). Total thyroidectomy of both lobes poses an increased risk of hypoparathyroidism and damage to the recurrent laryngeal nerves. See below for surgical treatment of Graves disease during pregnancy.

Patients are ordinarily rendered euthyroid preoperatively with a thiourea drug. Propranolol ER is given orally at initial doses of 60–80 mg twice daily and increased every 2–3 days until the heart rate is less than 90 beats per minute. Propranolol is continued until the serum T_3 (or free T_3) is normal preoperatively. If a patient undergoes surgery while thyrotoxic, larger doses of propranolol are given perioperatively to reduce the likelihood of thyroid crisis. Ipodate sodium or iopanoic acid (500 mg orally twice daily) may be used in addition to a thiourea to accelerate the decline in serum T_3. The patient should be euthyroid by the time of surgery.

To reduce thyroid vascularity preoperatively, the patient may be treated for 3–10 days preoperatively with oral potassium iodide 25–50 mg (eg, ThyroShield 65 mg/mL, 0.5 mL, or SSKI 1 g/mL, 1 drop) three times daily. However, preoperative potassium iodide often increases the volume of the thyroid, so the requirement for preoperative potassium iodide for Graves disease is debatable. Preoperative iodide supplementation is not recommended prior to surgery for multinodular goiter. Alternatively, iodinated radiocontrast agents (eg, iopanoic acid 500 mg orally twice daily) may be given for 1 week preoperatively.

Surgical morbidity includes possible damage to a recurrent laryngeal nerve, with resultant vocal cord paralysis. If both recurrent laryngeal nerves are damaged, airway obstruction may develop, and the patient may require intubation and tracheostomy. Hypoparathyroidism also occurs; serum calcium levels must be checked postoperatively. Patients should be admitted for thyroidectomy surgery for at least an overnight observation period.

B. Treatment of Toxic Solitary Thyroid Nodules

Toxic solitary thyroid nodules are usually benign but may rarely be malignant. If a nonsurgical therapy is elected, the nodule should be evaluated with a fine-needle aspiration (FNA) biopsy. **Medical therapy** for hyperthyroidism caused by a single hyperfunctioning thyroid nodule may be treated symptomatically with propranolol ER and methimazole or propylthiouracil, as in Graves disease (see above). Patients who tolerate methimazole well may elect to continue it for long-term therapy. The dose of methimazole should be adjusted to keep the TSH slightly suppressed, so the risk of TSH-stimulated growth of the nodule is reduced. **Surgery** is usually recommended for patients under age 40 years, for healthy older patients with toxic solitary thyroid nodules, and for nodules that are suspicious for malignancy. Patients are made euthyroid with a thiourea preoperatively and given several days of iodine, ipodate sodium, or iopanoic acid before surgery. Postoperative hypothyroidism usually resolves spontaneously, but permanent hypothyroidism occurs in about 14% of patients by 6 years after surgery. **Radioiodine (^{131}I) therapy** may be offered to patients with a toxic solitary nodule who are over age 40 or in poor health. A pregnancy test should be obtained within 48 before therapy for any premenopausal woman. RAI should not be given to women with Graves disease within 3 months prior to a planned conception. If the patient has been receiving methimazole preparatory to ^{131}I, the TSH should be kept slightly suppressed in order to reduce the uptake of ^{131}I by the normal thyroid. Nevertheless, permanent hypothyroidism occurs in about one-third of patients by 8 years after ^{131}I therapy. The nodule remains palpable in 50% and may grow in 10% of patients after ^{131}I.

C. Treatment of Toxic Nodular Goiter

Medical therapy for patients with toxic nodular goiter consists of propranolol ER (while hyperthyroid) and a thiourea, as in Graves disease. Thioureas (methimazole or propylthiouracil) reverse hyperthyroidism but do not shrink the goiter. There is a 95% recurrence rate if the drug is stopped.

Surgery is the definitive treatment for patients with large toxic nodular goiter, following therapy with a thiourea to render them euthyroid. Surgery is particularly indicated to relieve pressure symptoms or for cosmetic indications. Patients with toxic nodular goiter are not treated preoperatively with potassium iodide. Total or near-total thyroidectomy is recommended, since surgical pathology reveals unsuspected differentiated thyroid cancer in 18.3% of cases.

Radioiodine (RAI, ^{131}I) therapy may be used to treat patients with toxic nodular goiter. See **Precautions** for RAI use, above. Any suspicious nodules should be evaluated beforehand for malignancy with FNA cytology. Patients are rendered euthyroid with methimazole, which is stopped 3–4 days before a repeat RAI therapy.

Meanwhile, the patient follows a low-iodine diet in order to enhance the thyroid gland's uptake of RAI, which may be relatively low in this condition (compared to Graves disease). Relatively high doses of ^{131}I are usually required; hypothyroidism or recurrent thyrotoxicosis typically occurs, so patients must be monitored closely. Peculiarly, in about 5% of patients with diffusely nodular toxic goiter, the administration of ^{131}I therapy may induce Graves disease. Also, Graves eye disease has occurred rarely following ^{131}I therapy for multinodular goiter.

D. Treatment of Hyperthyroidism from Thyroiditis

Patients with thyroiditis (subacute, postpartum, or silent) are treated with propranolol during the hyperthyroid phase, which usually subsides spontaneously within weeks to months. For symptomatic relief, begin propranolol ER 60–80 mg twice daily and increase every 3 days until the heart rate is less than 90 beats per minute. Ipodate sodium or iopanoic acid, 500 mg orally daily, promptly corrects elevated T_3 levels and is continued for 15–60 days until the serum FT_4 level normalizes. Thioureas are ineffective, since thyroid hormone production is actually low in this condition. Patients are monitored carefully for the development of hypothyroidism and treated with levothyroxine as needed. With subacute thyroiditis, pain can usually be managed with NSAIDs and corticosteroids, but opioid analgesics are sometimes required.

E. Treatment of Hyperthyroidism During Pregnancy-Planning, Pregnancy, and Lactation

Both men and women with Graves disease who are planning pregnancy should not have RAI treatment within about 4 months of conception. Women who are planning to become pregnant are encouraged to consider definitive therapy with RAI or surgery well before conception. See **Precautions** for RAI use, above. Dietary iodine must not be restricted for such women. There is an increased risk of fetal anomalies associated with methimazole in the first trimester. Therefore, women who are being treated with a thiourea should be treated with propylthiouracil through the first trimester and then switched to methimazole (see Thiourea drugs, above). Thiourea should be given in the smallest dose possible, permitting mild subclinical hyperthyroidism to occur, since it is usually well tolerated. About 30% of women with Graves disease experience a remission by the late second trimester.

Both propylthiouracil and methimazole cross the placenta and can induce hypothyroidism, with fetal TSH hypersecretion and goiter. Fetal ultrasound at 20–32 weeks gestation can visualize any fetal goiter, allowing fetal thyroid dysfunction to be diagnosed and treated. Thyroid hormone administration to the mother does not prevent hypothyroidism in the fetus, since T_4 and T_3 do not freely cross the placenta. Fetal hypothyroidism is rare if the mother's hyperthyroidism is controlled with small daily doses of propylthiouracil (50–150 mg/day orally) or methimazole (5–15 mg/day orally). Serum total T_4 levels during pregnancy should be kept at about 1.5 × the prepregnancy level. Maternal serum TSI levels over 500% at term predict an increased risk of neonatal Graves disease in the infant.

Subtotal thyroidectomy is indicated for pregnant women with Graves disease or for fertile women of reproductive age who are sexually active and decline contraceptives, under the following circumstances: (1) severe adverse reaction to thioureas; (2) high dosage requirement for thioureas (methimazole greater than or equal to 30 mg/day or propylthiouracil greater than or equal to 450 mg/day); or (3) uncontrolled hyperthyroidism due to nonadherence to thiourea therapy. Surgery is best performed during the second trimester.

Both methimazole and propylthiouracil are secreted in breast milk, but not in amounts that affect the infant's thyroid hormone levels. No adverse reactions to these drugs (eg, rash, hepatic dysfunction, leukopenia) have been reported in breast-fed infants. Recommended doses are less than or equal to 20 mg orally daily for methimazole and less than or equal to 450 mg orally (in divided doses) daily for propylthiouracil. It is recommended that the medication be taken just after breastfeeding.

F. Treatment of Amiodarone-Induced Thyrotoxicosis

Patients with either type 1 or type 2 amiodarone-induced thyrotoxicosis require treatment with propranolol ER for symptomatic relief and methimazole 30 mg orally daily. After two doses of methimazole, iopanoic acid or sodium ipodate may be added to the regimen to further block conversion of T_4 to T_3; the recommended dosage for each is 500 mg orally twice daily for 3 days, followed by 500 mg once daily until thyrotoxicosis is resolved. If iopanoic acid or sodium ipodate is not available, the alternative is potassium perchlorate; it is given in doses of less than or equal to 1000 mg daily (in divided doses) for a course not to exceed 30 days in order to avoid the complication of aplastic anemia. Amiodarone may be withdrawn but this does not have a significant therapeutic impact for several months because of its long half-life. For patients with type 1 amiodarone-induced thyrotoxicosis, therapy with ^{131}I may be successful, but only for those with sufficient RAI uptake. Patients with clear-cut type 2 amiodarone-induced thyrotoxicosis are usually also treated with prednisone at an initial dose of about 0.5–0.7 mg/kg orally daily; that dose of prednisone is continued for about 2 weeks and then slowly tapered and finally withdrawn after about 3 months. Subtotal thyroidectomy should be considered for patients with amiodarone-induced thyrotoxicosis that is resistant to treatment.

G. Treatment of Complications

1. Thyroid-associated orbitopathy—^{131}I treatment can "flare" thyroid-associated orbitopathy (see Radioactive iodine, above). Thyroid-associated orbitopathy can also be aggravated by thiazolidinediones (eg, pioglitazone, rosiglitazone); these oral diabetic agents should be avoided or withdrawn in patients with Graves disease. Patients with mild orbitopathy may be treated with selenium 100 mcg orally twice daily, which may slow its progression.

For active thyroid-associated orbitopathy, therapy with intravenous methylprednisolone, begun promptly, is superior to oral prednisone. Methylprednisolone is given in intravenous pulses, 500 mg weekly for 6 weeks, and then 250 mg weekly for 6 weeks. Oral prednisone, if chosen for treatment, must be given promptly in doses of 40–60 mg/day orally, with dosage reduction over several weeks. Higher initial prednisone doses of 80–120 mg/day are used when there is optic nerve compression. Prednisone alleviates acute eye symptoms in 64% of nonsmokers but in only 14% of smokers.

Patients with corticosteroid-resistant acute Graves ophthalmopathy may also be treated with monoclonal antibody drugs that reduce immune-mediated inflammation. Teprotumumab, an experimental drug, or tocilizumab are administered intravenously, whereas rituximab may be given by retro-orbital injections.

Progressive active exophthalmos may be treated with retrobulbar radiation therapy over 2 weeks to the extraocular muscles, avoiding the cornea and lens. Prednisone in high doses is given concurrently. Patients who respond well to orbital radiation include those with signs of acute inflammation, recent exophthalmos (less than 6 months), or optic nerve compression. Patients with chronic proptosis and orbital muscle restriction respond less well. Retrobulbar radiation does not cause cataracts or tumors; however, it can cause radiation-induced retinopathy (usually subclinical) in about 5% of patients overall, mostly in patients with diabetes.

For severe cases, orbital decompression surgery may save vision, though diplopia often persists postoperatively. General eye protective measures include wearing glasses to protect the protruding eye and taping the lids shut during sleep if corneal drying is a problem. Methylcellulose drops and gels ("artificial tears") may also help. Tarsorrhaphy or canthoplasty can frequently help protect the cornea and provide improved appearance. Hypothyroidism and hyperthyroidism must be treated promptly.

2. Cardiac complications—

A. SINUS TACHYCARDIA—Treatment consists of treating the thyrotoxicosis. A beta-blocker such as propranolol is used in the interim unless there is an associated cardiomyopathy.

B. ATRIAL FIBRILLATION—Hyperthyroidism must be treated immediately. Other drugs, including digoxin, beta-blockers, and anticoagulants, may be required. Electrical cardioversion is unlikely to convert atrial fibrillation to normal sinus rhythm while the patient is thyrotoxic. Spontaneous conversion to normal sinus rhythm occurs in 62% of patients with return of euthyroidism, but that likelihood decreases with age. Following conversion to euthyroidism, there is a 60% chance that atrial fibrillation will recur, despite normal thyroid function tests. Those with persistent atrial fibrillation may have elective cardioversion following anticoagulation 4 months after resolution of hyperthyroidism.

(1) Digoxin—Digoxin is used to slow a fast ventricular response to thyrotoxic atrial fibrillation; it must be used in larger than normal doses. Digoxin doses are reduced as hyperthyroidism is corrected.

(2) Beta-blockers—Beta-blockers may also reduce the ventricular rate, but they must be used with caution—particularly in patients with heart failure with reduced ejection fraction—since their negative inotropic effect may precipitate overt heart failure. Therefore, an initial trial of a short-duration beta-blocker should be considered, such as esmolol intravenously. If a beta-blocker is used, doses of digoxin must be reduced.

(3) Anticoagulants—The doses of warfarin required in thyrotoxicosis are smaller than normal because of an accelerated plasma clearance of vitamin K–dependent clotting factors. Higher warfarin doses are usually required as hyperthyroidism subsides. Dabigatran malabsorption has been reported in thyrotoxicosis-induced diarrhea.

C. HEART FAILURE—Thyrotoxicosis can cause high-output heart failure due to extreme tachycardia, cardiomyopathy, or both. Very aggressive treatment of the hyperthyroidism is required in either case.

Heart failure may also occur as a result of low-output dilated cardiomyopathy. It is uncommon and may be caused by an idiosyncratic severe toxic effect of hyperthyroidism upon certain hearts. Cardiomyopathy may occur at any age and without preexisting cardiac disease. See Chapter 10 for treatment of heart failure and dilated cardiomyopathy. The patient should be rendered euthyroid. However, the heart failure usually persists despite correction of the hyperthyroidism.

D. APATHETIC HYPERTHYROIDISM—Apathetic hyperthyroidism may present with angina pectoris. Treatment is directed at reversing the hyperthyroidism as well as providing standard antianginal therapy. PCI or CABG can often be avoided by prompt diagnosis and treatment.

3. Thyroid crisis or "storm"—A thiourea drug is given (eg, methimazole, 15–25 mg orally every 6 hours, or propylthiouracil, 150–250 mg orally every 6 hours). Ipodate sodium (500 mg/day orally) can be helpful if begun 1 hour after the first dose of thiourea. Iodide is given 1 hour later as potassium iodide (10 drops three times daily orally). Propranolol is given (cautiously in the presence of heart failure; see above) in a dosage of 0.5–2 mg intravenously every 4 hours or 20–120 mg orally every 6 hours. Hydrocortisone is usually given in doses of 50 mg orally every 6 hours, with rapid dosage reduction as the clinical situation improves. Aspirin is avoided since it displaces T_4 from thyroxine-binding globulin (TBG), raising FT_4 serum levels. Definitive treatment with ^{131}I or surgery is delayed until the patient is euthyroid.

4. Hyperthyroidism from postpartum thyroiditis—Propranolol ER is given during the hyperthyroid phase followed by levothyroxine during the hypothyroidism phase.

5. Graves dermopathy—Treatment involves application of a topical corticosteroid (eg, fluocinolone) with nocturnal plastic occlusive dressings. Compression stockings may improve any associated edema.

6. Thyrotoxic hypokalemic periodic paralysis—Sudden symmetric flaccid paralysis, along with hypokalemia and hypophosphatemia, can occur with hyperthyroidism despite few, if any, of the classic signs of thyrotoxicosis. It is most prevalent in Asian and Native Americans with hyperthyroidism and is 30 times more common in men than women. Therapy with oral propranolol, 3 mg/kg in divided doses, normalizes the serum potassium and phosphate levels and reverses the paralysis within 2–3 hours. No intravenous potassium or phosphate is ordinarily required. Intravenous dextrose and oral carbohydrate aggravate the condition and are to be avoided. Therapy is continued with propranolol, 60–80 mg orally every 8 hours (or sustained-action propranolol ER daily at equivalent daily dosage), along with a thiourea drug such as methimazole to treat the hyperthyroidism.

7. Thyroid acropachy—This rare complication of Graves disease is often mild and may not require therapy. More severe cases are treated with systemic immunosuppressant therapy that may include intravenous immune globulin and rituximab.

Prognosis

Mild or subclinical **Graves disease** may sometimes subside spontaneously. Graves disease that presents in early pregnancy has a 30% chance of spontaneous remission before the third trimester. The ocular, cardiac, and psychological complications can become serious and persistent even after treatment. Permanent hypoparathyroidism and vocal cord palsy are risks of surgical thyroidectomy. Recurrences are common following thiourea therapy but also occur after low-dose ^{131}I therapy or subtotal thyroidectomy. With adequate treatment and long-term follow-up, the results are usually good. However, despite treatment for their hyperthyroidism, women experience an increased long-term risk of death from thyroid disease, cardiovascular disease, stroke, and fracture of the femur. Posttreatment hypothyroidism is common. It may occur within a few months or up to several years after RAI therapy or subtotal thyroidectomy. Malignant exophthalmos has a poor prognosis unless treated aggressively. Patients with thyrotoxic crisis have a high mortality rate despite treatment.

Subclinical hyperthyroidism generally subsides spontaneously. Progression to symptomatic thyrotoxicosis occurs at a rate of 1–2% per year in patients without a goiter and at a rate of 5% per year in patients with a multinodular goiter. Most patients do well without treatment and the serum TSH usually reverts to normal within 2 years. Most such patients do not have accelerated bone loss. However, if a baseline bone density shows significant osteopenia, bone densitometry may be performed periodically. In persons over age 60 years, serum TSH is suppressed (less than 0.1 milli-international units/L) in 3% and mildly low (0.1–0.4 milli-international units/L) in 9%. The chance of developing atrial fibrillation is 2.8% yearly in elderly patients with very low TSH and 1.1% yearly in those with mildly low TSH. Asymptomatic persons with very low TSH are monitored closely but are not treated unless atrial fibrillation or other manifestations of hyperthyroidism develop.

When to Admit

- Thyroid crisis.
- Hyperthyroidism-induced atrial fibrillation with severe tachycardia.
- Thyroidectomy.

THYROID NODULES & MULTINODULAR GOITER

ESSENTIALS OF DIAGNOSIS

- Single or multiple thyroid nodules are commonly palpated by the patient or clinician or discovered incidentally on imaging studies.
- Thyroid function tests recommended.
- FNA cytology for thyroid nodules 1 cm or larger in diameter or for smaller nodules when prior head-neck or chest-shoulder radiation.
- Ultrasound guidance improves FNA diagnosis for palpable and nonpalpable nodules.
- Clinical follow-up required.

General Considerations

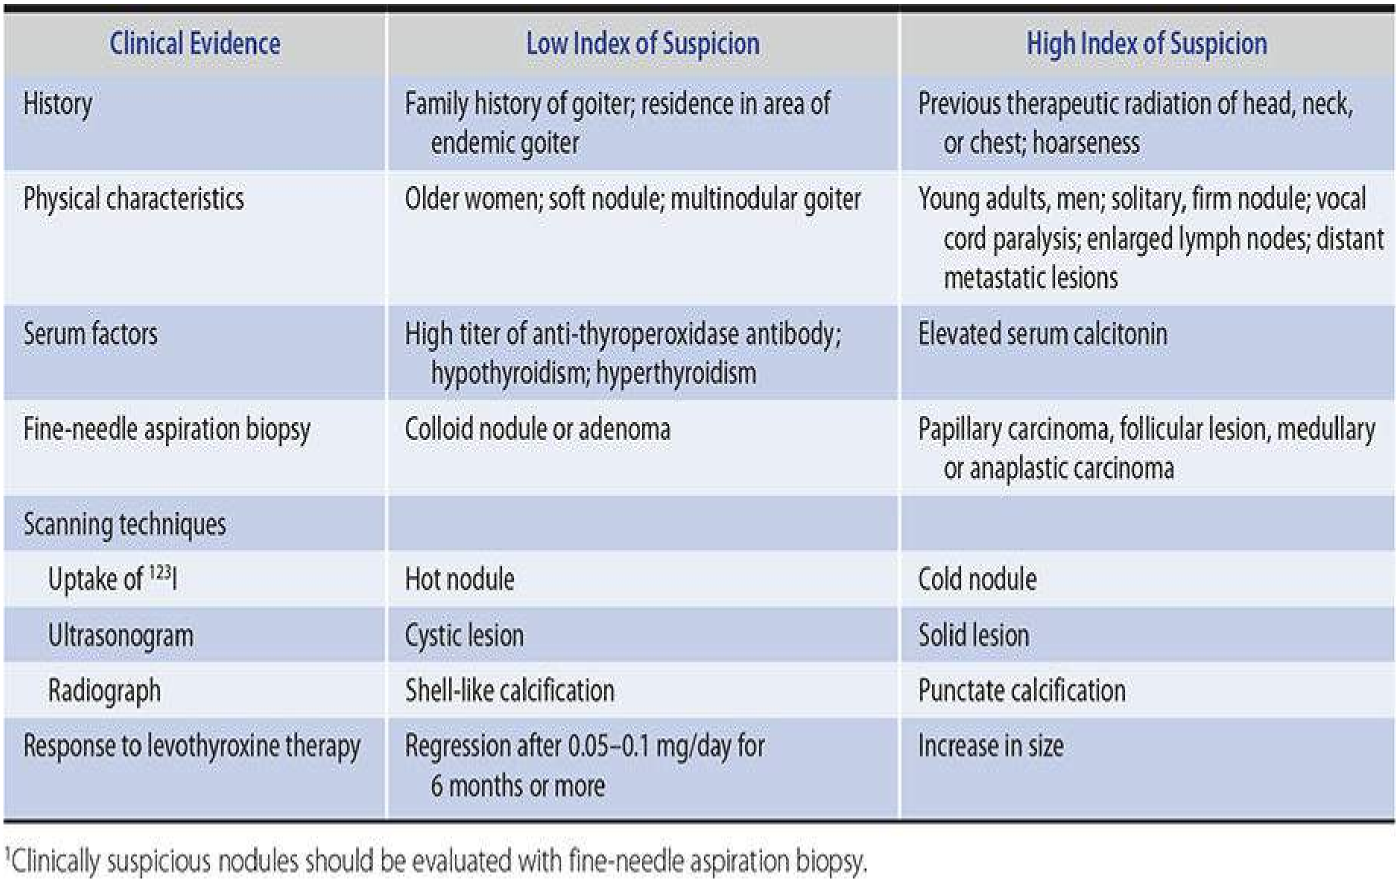
Thyroid nodules are extremely common. Palpable nodules occur in 4–7% of all adults in the United States. They are much more common in women than men and become more prevalent with age. About 90% of palpable thyroid nodules are benign adenomas, colloid nodules, or cysts, but some are primary thyroid malignancies or (less frequently) metastatic malignancy. The general use of scanning also incidentally detects nonpalpable thyroid nodules. On MRI, incidental small thyroid nodules are found in about 50% of adults. Thyroid nodules 1 cm or larger in diameter warrant follow-up and further testing for function and malignancy. An occasional nodule smaller than 1 cm in diameter requires follow-up if it has high-risk characteristics on ultrasound or if the patient is at high-risk for thyroid cancer due to prior head-neck radiation therapy during childhood. Thyroid nodules that are incidentally discovered with increased standard uptake value (SUV) on ^{18}FDG-PET scanning have a 33% risk for being malignant and require FNA cytology.

Most patients with a thyroid nodule are euthyroid, but there is a high incidence of hypothyroidism or hyperthyroidism. Patients with multiple thyroid nodules have the same overall risk of thyroid cancer as patients with solitary nodules. The risk of a thyroid nodule being malignant is higher in men and among patients with a history of head-neck radiation, total body radiation for bone marrow transplantation, exposure to radioactive fallout as a child or teen, a family history of thyroid cancer or a thyroid cancer syndrome (eg, Cowden syndrome, multiple endocrine neoplasia type 2, familial polyposis, Carney syndrome), or a personal history of another malignancy. The risk of malignancy is also higher for large solitary nodules and if there is hoarseness or vocal fold paralysis, adherence to the trachea or strap muscles, cervical lymphadenopathy. The presence of Hashimoto thyroiditis does not reduce the risk of malignancy; a nodule of 1 cm or larger in a gland with thyroiditis carries an 8% chance of malignancy.

Clinical Findings

Table 26–5 illustrates the approach to the evaluation of thyroid nodules based on the index of suspicion for malignancy.

Table 26–5. Clinical evaluation of thyroid nodules.[1]



Clinical Evidence	Low Index of Suspicion	High Index of Suspicion
History	Family history of goiter; residence in area of endemic goiter	Previous therapeutic radiation of head, neck, or chest; hoarseness
Physical characteristics	Older women; soft nodule; multinodular goiter	Young adults, men; solitary, firm nodule; vocal cord paralysis; enlarged lymph nodes; distant metastatic lesions
Serum factors	High titer of anti-thyroperoxidase antibody; hypothyroidism; hyperthyroidism	Elevated serum calcitonin
Fine-needle aspiration biopsy	Colloid nodule or adenoma	Papillary carcinoma, follicular lesion, medullary or anaplastic carcinoma
Scanning techniques		
Uptake of ^{123}I	Hot nodule	Cold nodule
Ultrasonogram	Cystic lesion	Solid lesion
Radiograph	Shell-like calcification	Punctate calcification
Response to levothyroxine therapy	Regression after 0.05–0.1 mg/day for 6 months or more	Increase in size

[1]Clinically suspicious nodules should be evaluated with fine-needle aspiration biopsy.

A. Symptoms and Signs

Most small thyroid nodules cause no symptoms. They may sometimes be detected only by having the patient swallow during careful inspection and palpation of the thyroid.

A thyroid nodule or multinodular goiter can grow to become visible and of concern to the patient. Particularly large nodular goiters can become a cosmetic embarrassment. Nodules can grow large enough to cause discomfort, hoarseness, or dysphagia. Nodules that cause ipsilateral recurrent laryngeal nerve palsy are more likely to be malignant. Retrosternal large multinodular goiters can cause dyspnea due to tracheal compression. Large substernal goiters may cause superior vena cava syndrome, manifested by facial erythema and jugular vein distention that progress to cyanosis and facial edema when both arms are kept raised over the head.

Depending on their cause, goiters and thyroid nodules may be associated with hypothyroidism (Hashimoto thyroiditis, endemic goiter) or hyperthyroidism (Graves disease, toxic nodular goiter, subacute thyroiditis, and thyroid cancer with metastases).

B. Laboratory Findings

A serum TSH and FT_4 determine if the thyroid is hyperfunctioning. Patients with a subnormal serum TSH must have a radionuclide (^{123}I or ^{99m}Tc pertechnetate) thyroid scan to examine whether the nodule is hyperfunctioning; hyperfunctioning nodules are usually benign but not reliably so. Very high levels of antithyroperoxidase antibodies and antithyroglobulin antibodies are found in Hashimoto thyroiditis. However, thyroiditis frequently coexists with malignancy, so suspicious nodules should always be biopsied. Serum calcitonin is obtained if a medullary thyroid carcinoma is suspected in a patient with a family history of medullary thyroid carcinoma or MEN types 2 or 3.

C. Imaging

Neck ultrasonography should be performed (see Fine-Needle Aspiration of Thyroid Nodules, below). Malignant nodules are more likely to grow more than 2 mm/year. Ultrasonography is preferred over CT and MRI. CT scanning is helpful for larger thyroid nodules and multinodular goiter; it can determine the degree of tracheal compression and the degree of extension into the mediastinum.

RAI (^{123}I or ^{131}I) scans are not helpful for assessing whether a thyroid nodule is benign or malignant. Hyperfunctioning (hot) nodules are ordinarily benign (but may rarely be malignant). RAI uptake and scanning is helpful mainly for assessing the etiology of hyperthyroidism (eg, hyperfunctioning nodule).

D. Incidentally Discovered Thyroid Nodules

Thyroid nodules are frequently discovered as an incidental finding, with an incidence that depends on the imaging modality: Ultrasound, about 30% (20% are larger than 1 cm in diameter); MRI, 50%; CT, 13%; and ^{18}FDG-PET, 2%. When MRI, CT, and ^{18}FDG-PET detect a thyroid nodule, an ultrasound is performed to better determine the nodule’s risk for malignancy and the need for FNA cytology, and to establish a baseline for ultrasound follow-up. The malignancy risk is about 13–17% for nodules discovered incidentally on CT, MRI, or ultrasound and 25–50% for nodules discovered incidentally by ^{18}FDG-PET. However, most such malignancies are very low grade. For incidentally discovered thyroid nodules of borderline concern, follow-up thyroid ultrasound in 3–6 months may be helpful; growing lesions should be assessed with FNA cytology or resected.

E. Fine-Needle Aspiration of Thyroid Nodules

FNA is the best method to assess a thyroid nodule for malignancy. FNA can be done while patients continue taking anticoagulants or aspirin. For multinodular goiters, the four largest nodules (1 cm or larger in diameter) are usually biopsied to minimize the risk of missing a malignancy.

Thyroid nodules are classified for malignancy risk according to their appearance on ultrasound. High-risk nodules (80% malignancy risk) have microcalcifications, irregular margins, extrathyroidal extension, extrusion of soft tissue into a calcified rim, or are taller than wide; such nodules require FNA if they are 1 cm or larger in diameter. Intermediate-risk nodules (15% malignancy risk) are hypoechoic and solid; they also usually require FNA if they are 1 cm or larger in diameter. Low-risk nodules (7% malignancy risk) are partially cystic with eccentric solid areas; they require biopsy if they are 1.5 cm or larger in diameter. Very low-risk nodules (below 3% malignancy risk) are those that are spongiform or simple cysts; FNA is optional if they are 2 cm or larger in diameter. Using ultrasound guidance for FNA biopsy improves the diagnostic accuracy for both palpable and nonpalpable thyroid nodules. FNA cytology is typically reported using The Bethesda System for Reporting Thyroid Cytopathology (TBSRTC), which divides results into six categories:

1. **Nondiagnostic or unsatisfactory:** The malignancy risk is 1–4%. The usual management is a repeat FNA under ultrasound guidance.
2. **Benign:** The malignancy risk is about 2.5%. The usual management is clinical follow-up with palpation or ultrasound at 6- to 18-month intervals.
3. **Atypia of undetermined significance (AUS):** The malignancy risk is about 14%, higher with sonographic features of malignancy. The usual management is clinical correlation and a repeat FNA.
4. **Suspicious for follicular neoplasm (SFN) or follicular neoplasm (FN):** The malignancy risk is about 25%, higher when Hürthle cells are present and in patients over age 50. The usual management is usually direct surgical lobectomy.
5. **Suspicious for malignancy (SFM):** The malignancy risk is about 70%. The usual management is usually direct thyroid lobectomy or near-total thyroidectomy.
6. **Malignant:** The malignancy risk is about 99%. The usual management is a near-total thyroidectomy.

Treatment

All thyroid nodules, including those that are benign, need to be monitored by regular periodic palpation and ultrasound about every 6 months initially. After several years of stability, yearly examinations are sufficient. Thyroid nodules should be rebiopsied if growth occurs. A toxic multinodular goiter and hyperthyroidism may develop in patients who have had exposure to large amounts of iodine, either orally (eg, amiodarone) or intravenously (eg, radiographic contrast). Therefore, excessive iodine intake should be minimized. Patients found to have hyperthyroidism may have a RAI uptake and scan, especially if ^{131}I is a therapeutic consideration.

Managing thyroid nodules and multinodular goiter is the treatment of hyperthyroidism, if present, with thioureas, propranolol, surgery, or RAI (see Hyperthyroidism treatment of toxic nodular goiter, above).

A. Levothyroxine Suppression Therapy

Patients with nodules larger than 2 cm and elevated or normal TSH levels may be considered for TSH suppression with levothyroxine (starting doses of 50 mcg orally daily). Levothyroxine suppression therapy is not recommended for small benign thyroid nodules if the serum TSH level is normal. Levothyroxine suppression therapy is more successful in iodine-deficient areas of the world. Long-term levothyroxine suppression of TSH tends to keep nodules from enlarging but only 20% shrink more than 50%. Thyroid nodule size increased in 29% of patients treated with levothyroxine versus 56% of patients not receiving levothyroxine. Levothyroxine suppression also reduces the emergence of new nodules: 8% with levothyroxine and 29% without levothyroxine. Levothyroxine suppression therapy is not usually given to patients with ischemic heart disease, since it increases the risk for angina and atrial fibrillation. Levothyroxine suppression causes a small loss of bone density, particularly in postmenopausal women if the serum TSH is suppressed to less than 0.05 milli-international units/L. Such patients are advised to have bone density testing every 3–5 years. For patients with a low baseline TSH level, levothyroxine should not be administered, since that is an indication of autonomous thyroid secretion; levothyroxine will be ineffective and could cause thyrotoxicosis.

Levothyroxine suppression needs to be carefully monitored, since it carries a 17% risk of inducing hyperthyroidism. All patients receiving levothyroxine suppression therapy should have serum TSH levels monitored at least annually, with the levothyroxine dose adjusted to keep the serum TSH mildly suppressed (between 0.1 milli-international units/L and 0.8 milli-international units/L).

B. Surgery

Total thyroidectomy is required for thyroid nodules that are malignant on FNA biopsy. More limited thyroid surgery is indicated for benign nodules with indeterminate or suspicious cytologic test results, compression symptoms, discomfort, or cosmetic embarrassment. Surgery may also be used to remove hyperfunctioning “hot” thyroid adenomas or toxic multinodular goiter causing hyperthyroidism.

C. Percutaneous Ethanol Injection

Percutaneous ethanol injection can shrink pure cysts; the success rate is 80%, although it must often be repeated. Percutaneous ethanol injection can also be used to shrink biopsy-proven benign nodules. While complications occur in about 9%, serious or permanent complications are rare. Thyroid cysts can be aspirated, but cystic fluid recurs in 75% of patients.

D. Radioiodine (^{131}I) Therapy

Radioactive ^{131}I is a treatment option for hyperthyroid patients with toxic thyroid adenomas, multinodular goiter, or Graves disease. See **Precautions** for RAI use, above. Therapy with ^{131}I shrinks benign nontoxic thyroid nodules by an average of 40% by 1 year and 59% by 2 years after ^{131}I therapy. Nodules that shrink after ^{131}I therapy generally remain palpable and become firmer; they may develop unusual cytologic characteristics on FNA biopsy. ^{131}I therapy may be used to shrink large multinodular goiters but may rarely induce Graves disease. Hypothyroidism may occur years after ^{131}I therapy, so it is advisable to assess thyroid function every 3 months for the first year, every 6 months thereafter, and immediately for symptoms of hypothyroidism or hyperthyroidism.

Prognosis

Benign thyroid nodules may involute but usually persist or grow slowly. About 90% of thyroid nodules will increase their volume by 15% or more over 5 years; about 11% of nodules increase their volume by more than 50% on follow-up. Growth is more common with multinodular goiter and larger nodules and in men; nodules are less likely to grow when they are solitary or cystic and when patients are over age 60. Multinodular goiters tend to persist or grow slowly. Cytologically benign nodules that grow are unlikely to be malignant; in one series, only 1 of 78 rebiopsied nodules was found to be malignant. The risk of a given thyroid nodule being malignant decreases with age. Iodine supplementation in iodine-deficient areas does not usually shrink established goiters. Patients with very small (less than 1 cm diameter), incidentally discovered, nonpalpable thyroid nodules that have a benign ultrasound appearance require no FNA cytology and only yearly palpation and clinical follow-up, whereas such small nodules that have a slightly suspicious ultrasound appearance may require FNA cytology or thyroid ultrasound every 1–2 years.

THYROID CANCER

ESSENTIALS OF DIAGNOSIS

- Painless swelling in region of thyroid.
- Thyroid function tests usually normal.
- Possible history of childhood irradiation to head and neck region.
- Positive thyroid FNA cytology.

General Considerations

The incidence of differentiated (papillary and follicular) thyroid carcinomas increases with age (Table 26–6). The overall female:male ratio is 3:1. The yearly incidence of thyroid cancer has been increasing in the United States, with the number of cases diagnosed annually reaching 52,000, probably as a result of the wider use of ultrasound, CT, MRI, and PET that incidentally find small thyroid malignancies. Thyroid cancer mortality has been stable, accounting for about 2000 deaths in the United States annually. Clearly, the increasing incidence of thyroid cancer has been mainly due to incidentally found tumors; however, some true increase in cancer incidence is possible. In routine autopsy series, thyroid papillary microcarcinoma (10 mm diameter or smaller) is found with the surprising frequency of 11.5%. Most thyroid cancers remain microscopic and indolent. However, larger thyroid cancers (palpable or greater than or equal to 1 cm in diameter) are more malignant and require treatment.

Table 26–6. Some characteristics of thyroid cancer.

	Papillary	Follicular	Medullary	Anaplastic
Incidence	Most common	Common	Uncommon	Uncommon
Average age	42	50	50	57
Females	70%	72%	56%	56%
Invasion				
Juxtanodal	+++++	+	++++++	+++
Blood vessels	+	+++	+++	+++++
Distant sites	+	+++	++	++++
^{123}I uptake	+	++++	0	0
10-year disease-specific survival	97%	92%	78%	7.3%

Pure papillary (and mixed papillary-follicular) carcinoma comprises about 80% of all thyroid cancers. It usually presents as a single thyroid nodule, but it can arise out of a multinodular goiter. Papillary thyroid carcinoma is commonly multifocal within the gland, with other foci usually arising de novo rather than representing intraglandular metastases. The tumor involves both lobes in 30% of patients.

Papillary thyroid carcinoma is generally the least aggressive thyroid malignancy. It tends to grow slowly and often remains confined to the thyroid and regional lymph nodes for years. In about 80% of patients, there are microscopic metastases to cervical lymph nodes. However, the malignancy may become more aggressive, especially in patients over age 45 years, and most particularly in older adults. The cancer may invade the trachea and local muscles and may spread to the lungs.

Exposure to head and neck radiation therapy poses a particular threat to children who then have an increased lifetime risk of developing thyroid cancer, including papillary carcinoma. These cancers may emerge between 10 and 40 years after exposure, with a peak occurrence 20–25 years later.

Papillary thyroid carcinoma can occur in familial syndromes as an autosomal dominant trait, caused by loss of various tumor suppressor genes.

Microscopic “micropapillary” carcinoma (1 mm or smaller and invisible on thyroid ultrasound) is a variant of normal, being found in 24% of thyroidectomies performed for benign thyroid disease when 2-mm sections were carefully examined. Thus, the overwhelming majority of these microscopic foci never become clinically significant. The surgical pathology report of such a tiny papillary carcinoma does not justify aggressive measures. All that may be required is yearly follow-up with palpation of the neck and mild TSH suppression by thyroxine.

Follicular thyroid carcinoma and its variants (eg, Hürthle cell carcinoma) account for about 14% of thyroid malignancies; follicular carcinomas are generally more aggressive than papillary carcinomas. Most follicular thyroid carcinomas avidly absorb iodine, making possible diagnostic scanning and treatment with ^{131}I after total thyroidectomy. The follicular histopathologic features that are associated with a high risk of metastasis and recurrence are poorly differentiated and Hürthle cell (oncocytic) variants. The latter variants do not take up RAI.

Medullary thyroid carcinoma represents 2–3% of thyroid cancers. About one-third of cases are sporadic, one-third are familial, and one-third are associated with MEN type 2A or 2B. Medullary thyroid carcinoma is often caused by an activating mutation of the ret protooncogene on chromosome 10. Mutation analysis of the ret protooncogene exons 10, 11, 13, 14, and 16 detects most mutations causing MEN 2A and MEN 2B and the mutations causing familial medullary thyroid carcinoma. These germline mutations can be detected by DNA analysis of peripheral WBCs. Therefore, discovery of a medullary thyroid carcinoma makes genetic analysis mandatory. If a gene defect is discovered, related family members must have genetic screening for that specific gene defect. When a family member with MEN 2 or 3 or familial medullary thyroid carcinoma does not have an identifiable ret protooncogene mutation, gene carriers may still be identified using family linkage analysis. Even when no gene defect is detectable, family members should have thyroid surveillance every 6 months. Medullary thyroid carcinoma arises from thyroid parafollicular cells that can secrete calcitonin, prostaglandins, serotonin, ACTH, corticotropin-releasing hormone (CRH), and other peptides. These peptides can cause symptoms and can be used as tumor markers.

Anaplastic thyroid carcinoma represents about 2% of thyroid cancers. It usually presents in an older patient as a rapidly enlarging mass in a multinodular goiter. It is the most aggressive thyroid carcinoma and metastasizes early to surrounding nodes and distant sites. This tumor does not concentrate iodine.

Other thyroid malignancies together represent about 3% of thyroid cancers. Primary thyroid lymphomas are most commonly diffuse large B-cell lymphomas (50%), mucosa-associated lymphoid tissue lymphoma (23%), or mixed type; other types include follicular, small lymphocytic, and Burkitt lymphoma and Hodgkin disease. Thyroidectomy is rarely required. Other cancers may sometimes metastasize to the thyroid, particularly bronchogenic, breast, and renal carcinomas and malignant melanoma.

Clinical Findings

A. Symptoms and Signs

Thyroid carcinoma usually presents as a palpable, firm, nontender nodule in the thyroid. Most thyroid carcinomas are asymptomatic, but large thyroid cancers can cause neck discomfort, dysphagia, or hoarseness (due to pressure on the recurrent laryngeal nerve).

Papillary thyroid cancer presents with palpable lymph node involvement in 10%; it may invade the trachea and local muscles. Occult metastases to the lung occur in 10–15%. **Follicular thyroid carcinoma** commonly metastasizes to neck nodes, bones, and lung, but nearly every organ can be involved. Metastatic functioning differentiated thyroid carcinoma can sometimes secrete enough thyroid hormone to produce thyrotoxicosis.

Medullary thyroid carcinoma typically metastases to local nodes and adjacent muscle and trachea as well as mediastinal lymph nodes. Eventually, metastases may appear in the bones, lungs, adrenals, or liver. Medullary thyroid carcinoma frequently causes flushing and persistent diarrhea (30%), which may be the initial clinical feature. Patients with metastases often experience fatigue as well as other symptoms. Cushing syndrome develops in about 5% of patients from secretion of ACTH or CRH.

Anaplastic thyroid carcinoma is more apt to be advanced at the time of diagnosis, presenting with signs of pressure or invasion of surrounding tissue, resulting in dysphagia, hoarseness, or recurrent laryngeal nerve palsy. Patients may also have dyspnea with metastases to the lungs. **Lymphoma** usually presents as a rapidly enlarging, painful mass arising out of a multinodular or diffuse goiter due to autoimmune thyroiditis, with which it may be confused microscopically. About 20% of cases have concomitant hypothyroidism.

B. Laboratory Findings

FNA biopsy is discussed in Thyroid Nodules, above. Thyroid function tests are generally normal unless there is concomitant thyroiditis. Follicular carcinoma may secrete enough T_4 to suppress TSH and cause clinical hyperthyroidism.

Serum thyroglobulin is high in most metastatic papillary and follicular tumors, making this a useful marker for recurrent or metastatic disease. Caution must be exercised for the following reasons: (1) Circulating antithyroglobulin antibodies can cause erroneous thyroglobulin determinations. However, declining levels of antithyroglobulin antibodies are a good prognostic sign after treatment. (2) Thyroglobulin levels may be misleadingly elevated in thyroiditis, which often coexists with carcinoma. (3) Certain thyroglobulin assays falsely report the continued presence of thyroglobulin after total thyroidectomy and tumor resection, causing undue concern about possible metastases. Therefore, unexpected detectable thyroglobulin levels post-thyroidectomy should prompt a repeat assay in another reference laboratory.

Serum calcitonin levels are usually elevated in medullary thyroid carcinoma, making this a marker for metastatic disease. However, serum calcitonin may be elevated in many other conditions, such as thyroiditis; pregnancy; kidney disease; hypergastrinemia; hypercalcemia; and other malignancies, particularly neuroendocrine tumors (including pheochromocytomas, carcinoid tumors) and carcinomas of the lung, pancreas, breast, and colon. Serum calcitonin and carcinoembryonic antigen (CEA) determinations should be obtained before surgery, then regularly in postoperative follow-up: every 4 months for 5 years, then every 6 months for life. In patients with extensive metastases, serum calcitonin should be measured in the laboratory with serial dilutions. Calcitonin levels remain elevated in patients with persistent tumor but also in some patients with apparent cure or indolent disease. Therefore, serum calcitonin levels greater than 250 ng/L (73 pmol/L) or rising levels of calcitonin are the best indication for recurrence or metastatic disease. Serum CEA levels are also usually elevated with medullary thyroid carcinoma, making this a useful second marker; however, it is not specific for this cancer.

C. Imaging

1. Ultrasound of the neck—Ultrasound of the neck should be performed on all patients with thyroid cancer for the initial diagnosis and for follow-up. Ultrasound is useful in determining the size and location of the malignancy as well as the location of any neck metastases.

2. Radioactive iodine scanning—RAI (^{131}I or ^{123}I) thyroid and whole-body scanning is used after thyroidectomy for differentiated thyroid cancer utilizing the protocol described later. (See Radioactive Iodine (^{131}I) Therapy for Differentiated Thyroid Cancer, later.) Medullary thyroid cancer does not avidly uptake RAI.

3. CT and MRI scanning—CT scanning may demonstrate metastases and is particularly useful for localizing and monitoring lung metastases but is less sensitive than ultrasound for detecting metastases within the neck. Medullary carcinoma in the thyroid, nodes, and liver may calcify, but lung metastases rarely do so. MRI is particularly useful for imaging bone metastases.

4. PET scanning—PET scanning is especially helpful for detecting thyroid cancer metastases that do not have sufficient iodine uptake to be visible on RAI scans. Metastases are best detected using ^{18}FDG-PET whole-body scanning. The sensitivity of ^{18}FDG-PET scanning for differentiated thyroid cancer is enhanced if the patient is hypothyroid or receiving thyrotropin, which increases the metabolic activity of differentiated thyroid cancer. Patients with medullary thyroid cancer are monitored with MRI and ^{18}FDG PET/CT scanning. ^{68}Ga PET is usually inferior to ^{18}FDG PET and other imaging for locating medullary thyroid cancer.

Differential Diagnosis

RAI uptake occurs in many different tissues and can be mistaken for metastatic differentiated thyroid carcinoma. Head-neck RAI uptake is seen in normal thyroid, salivary glands, nasal mucosa, thyroglossal duct remnants, and sinusitis.

Negative RAI scans are common in early metastatic differentiated thyroid carcinoma. Unfortunately, negative RAI scans also occur frequently with more advanced metastatic thyroid carcinoma, making it more difficult to detect and to distinguish from nonthyroidal neoplasms. An elevated serum thyroglobulin in patients with a clear RAI scan should arouse suspicion for metastases that are not avid for radioiodine. Medullary thyroid carcinoma does not concentrate iodine.

Complications

Hyperthyroidism can develop in patients with a heavy tumor burden. One-third of medullary thyroid carcinomas secrete serotonin and prostaglandins, producing flushing and diarrhea. The management of patients with medullary carcinomas may be complicated by the coexistence of pheochromocytomas or hyperparathyroidism.

Treatment of Differentiated Thyroid Carcinoma

A. Surgical Treatment

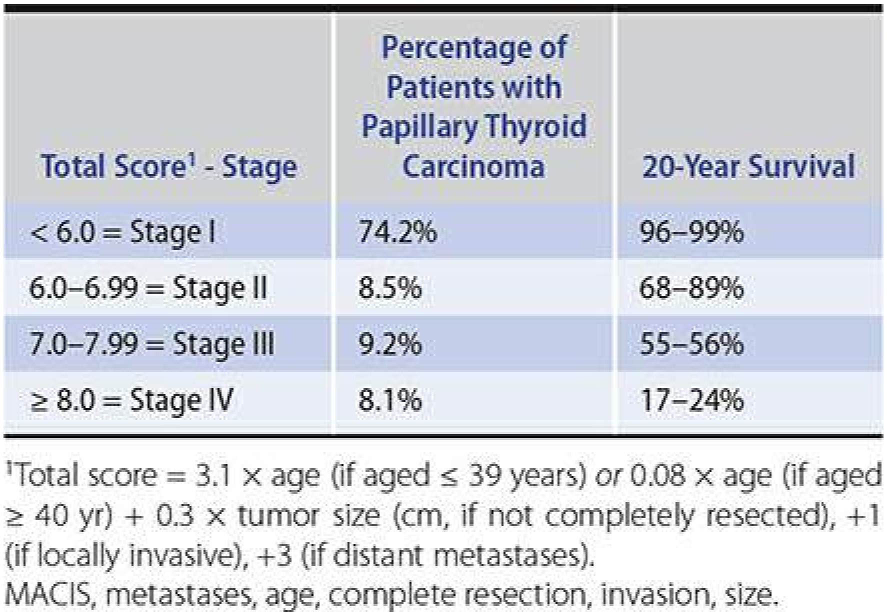
Surgical removal is the treatment of choice for thyroid carcinomas. Neck ultrasound is obtained preoperatively, since suspicious cervical lymphadenopathy is detected in about 25%.

For differentiated papillary and follicular carcinoma larger than 1 cm diameter, total thyroidectomy is performed with limited removal of cervical lymph nodes. Surgery consists of a thyroid lobectomy for an indeterminate “follicular lesion” that is 4 cm diameter or smaller. If malignancy is diagnosed on pathology intraoperatively, a completion thyroidectomy is performed. For indeterminate follicular lesions larger than 4 cm diameter that are at higher risk for being malignant, a bilateral thyroidectomy is performed as the initial surgery. Higher-risk lesions include those with an FNA biopsy that shows marked atypia or that are suspicious for papillary carcinoma and those that occur in patients with a history of radiation exposure or a family history of thyroid carcinoma.

For biopsies that are diagnostic of malignancy, surgery involves lobectomy alone for papillary thyroid carcinomas smaller than 1 cm in diameter in patients under age 45 years who have no history of head and neck irradiation and no evidence of lymph node metastasis on ultrasonography. Other patients should have a total or near total thyroidectomy. The advantage of near-total thyroidectomy for differentiated thyroid carcinoma is that multicentric foci of carcinoma are more apt to be resected. Also, there is less normal thyroid tissue to compete with cancer for ^{131}I administered later for scans or treatment. A central neck lymph node dissection is performed at the time of thyroidectomy for patients with nodal metastases that are clinically evident. A lateral neck dissection is performed for patients with biopsy-proven lateral cervical lymphadenopathy. Metastases to the brain are best treated surgically, since treatment with radiation or RAI is ineffective. Levothyroxine is prescribed in doses of 0.05–0.1 mg orally daily immediately postoperatively. About 2–4 months after surgery, patients require reevaluation and often ^{131}I therapy.

Permanent injury to one recurrent laryngeal nerve occurs in between 1–2% and 7% of patients, depending on the experience of the surgeon. Temporary recurrent laryngeal nerve palsies occur in another 5% but often resolve within 6 months. After total thyroidectomy, temporary hypoparathyroidism occurs in 20% and becomes permanent in about 2%. The incidence of hypoparathyroidism may be reduced if accidentally resected parathyroids are immediately autotransplanted into the neck muscles. Thyroidectomy requires at least an overnight hospital admission, since late bleeding, airway problems, and tetany can occur. Ambulatory thyroidectomy is potentially dangerous and should not be done. Following surgery, staging (Table 26–7) should be done to help determine prognosis and to plan therapy and follow-up.

Table 26–7. Staging and prognosis for patients with papillary thyroid carcinoma using MACIS scoring.



Total Score[1] - Stage	Percentage of Patients with Papillary Thyroid Carcinoma	20-Year Survival
< 6.0 = Stage I	74.2%	96–99%
6.0–6.99 = Stage II	8.5%	68–89%
7.0–7.99 = Stage III	9.2%	55–56%
≥ 8.0 = Stage IV	8.1%	17–24%

[1] Total score = 3.1 × age (if aged ≤ 39 years) *or* 0.08 × age (if aged ≥ 40 yr) + 0.3 × tumor size (cm, if not completely resected), +1 (if locally invasive), +3 (if distant metastases).

MACIS, metastases, age, complete resection, invasion, size.

In pregnant women with thyroid cancer, surgery is usually delayed until after delivery, except for fast-growing tumors that may be resected after 24 weeks gestation; there has been no difference in survival or tumor recurrence rates in women who underwent surgery during or after their pregnancy. Differentiated thyroid carcinoma does not behave more aggressively during pregnancy. However, compared to nonpregnant women, there is a higher risk of complications in pregnant women undergoing thyroid surgery.

B. Active Surveillance for Papillary Thyroid Microcarcinoma

Most papillary thyroid microcarcinomas that are less than 1 cm in diameter are indolent with an excellent prognosis. Therefore, for microcarcinomas, an ongoing active surveillance protocol used in some medical centers is to perform a clinical examination and neck ultrasound every 6 months. Such conservative management may be particularly warranted for patients who have a limited life expectancy, a high surgical risk, or very low-risk tumors.

C. Levothyroxine Suppression for Differentiated Thyroid Cancer

Patients who have had a thyroidectomy for differentiated thyroid cancer must take levothyroxine replacement for life. Oral levothyroxine should be given in doses that suppress serum TSH without causing clinical thyrotoxicosis. Serum TSH should be suppressed below 0.1 milli-international units/L for patients with stage II disease and below 0.05 milli-international units/L for patients with stage 3–4 disease. (See Table 26–7.) Although patients receiving levothyroxine suppression therapy (TSH less than 0.05 milli-international units/L) are at risk for a lower bone density than age-matched controls, the adverse effect upon bone density and fracture risk is relatively minor for patients who remain clinically euthyroid. Nevertheless, patients receiving levothyroxine suppression therapy should have periodic bone densitometry.

D. Radioactive Iodine (^{131}I) Therapy for Differentiated Thyroid Cancer

There are two reasons to treat patients with ^{131}I after thyroidectomy: (1) thyroid remnant ablation for patients at high risk for recurrence and (2) treatment of metastatic thyroid cancer. ^{131}I is usually administered 2–4 months after surgery. However, the indications and optimal activity (dose) for ^{131}I therapy for differentiated thyroid cancer remain controversial since there is an overwhelmingly good prognosis for most patients with differentiated thyroid cancer.

Before receiving ^{131}I therapy, patients should follow a low-iodine diet for at least 2 weeks. Patients must not be given amiodarone or intravenous radiologic contrast dyes containing iodine. Despite restriction of dietary iodine, differentiated thyroid cancer frequently lacks sufficient radioiodine avidity to allow RAI therapy.

1. RAI thyroid remnant ablation—A low activity[1] of 30 mCi (1.1 GBq) ^{131}I is given for “remnant ablation” of residual normal thyroid tissues after surgery for differentiated thyroid cancer. This small amount of ^{131}I is given to patients with no known lymph node involvement who are at low risk for metastases. However, ^{131}I remnant ablation is not required for patients with low-risk stage I papillary thyroid carcinomas or carcinomas that are smaller than 1 cm in diameter (whether unifocal or multifocal), except for patients with unfavorable histopathology (tall-cell, columnar cell, insular cell, Hūrthle cell, or diffuse sclerosing subtypes).

2. RAI treatment of metastases—Therapy with ^{131}I improves survival and reduces recurrence rates for patients with stage III–IV cancer and those with stage II cancer having gross extrathyroidal extension. RAI therapy is also given to patients with stage II cancer who have distant metastases, a primary tumor larger than 4 cm in diameter, or primary tumors 1–4 cm diameter with lymph node metastases or other high-risk features. Brain metastases do not usually respond to ^{131}I and are best resected or treated with gamma knife radiosurgery. A post-therapy whole-body scan is performed 2–10 days after ^{131}I therapy. About 70% of small lung metastases resolve following ^{131}I therapy; however, larger pulmonary metastases have only a 10% remission rate.

Staging with RAI scanning or ^{18}FDG-PET/CT scanning assists with determining the activity of ^{131}I to be administered. Treatment protocols vary among institutions. Generally, patients with higher-risk stage I cancer or stage II cancer are treated with ^{131}I activities of 50–100 mCi (1.8–3.7 GBq). Patients with stage III–IV cancers typically receive ^{131}I activities of 100–150 mCi (3.7–5.5 GBq). Repeated treatments may be required for persistent radioiodine-avid metastatic disease. Patients with differentiated thyroid carcinoma who have little or no uptake of RAI into metastases (about 35% of cases) should not be treated with ^{131}I. Patients with asymptomatic, stable, radioiodine-resistant metastases should receive levothyroxine to suppress serum TSH and should be carefully monitored for tumor progression.

Some patients have elevated serum thyroglobulin levels but a negative whole-body radioiodine scan and a negative neck ultrasound. In such patients, an ^{18}F-FDG PET/CT scan is obtained. If all scans are negative, the patient has a good prognosis and empiric therapy with ^{131}I is not useful.

Activities of ^{131}I over 100 mCi (3.7 GBq) can cause gastritis, temporary oligospermia, sialadenitis, and xerostomia. Therapy with ^{131}I can cause neurologic decompensation in patients with brain metastases; such patients are treated with prednisone 30–40 mg orally daily for several days before and after ^{131}I therapy. Cumulative doses of ^{131}I over 500 mCi (18.5 GBq) can cause infertility, pancytopenia (4%), and leukemia (0.3%). Pulmonary fibrosis can occur in patients with diffuse lung metastases after receiving cumulative ^{131}I activities over 600 mCi (22 GBq). The kidneys excrete RAI, so patients receiving dialysis require only 20% of the usual ^{131}I activity.

3. Recombinant human TSH (rhTSH)-stimulated ^{131}I therapy—Recombinant human thyroid-stimulating hormone (rhTSH, Thyrogen) is given to increase the sensitivity of serum thyroglobulin for residual cancer and to increase the uptake of ^{131}I into residual thyroid tissue (thyroid remnant "ablation") or cancer. Thyrogen must be kept refrigerated and is administered according to the following protocol: Levothyroxine replacement is held for 2 days before rhTSH and for 3 days afterward. For 2 consecutive days, rhTSH (0.9 mg/day, reconstituted with 0.2 mL sterile saline) should be administered intragluteally (not intravenously). On the third day, blood is drawn: serum TSH is assayed to confirm that it is greater than 30 milli-units/L; serum hCG is measured in reproductive-age women to exclude pregnancy; and serum thyroglobulin is measured as a tumor marker. RAI is then administered at the prescribed activity (see above).

Thyrogen should not be administered to patients with an intact thyroid gland because it can cause severe thyroid swelling and hyperthyroidism. Hyperthyroidism can also occur in patients with significant metastases or residual normal thyroid. Other side effects include nausea (11%) and headache (7%). Thyrotropin has caused neurologic deterioration in 7% of patients with CNS metastases.

4. Thyroid-withdrawal stimulated ^{131}I therapy—Thyroid withdrawal is sometimes used because of its lower cost, despite the discomforts of becoming hypothyroid. Levothyroxine is withdrawn for 14 days and the patient is allowed to become hypothyroid; high levels of endogenous TSH stimulate the uptake of RAI and production of thyroglobulin by thyroid cancer or residual thyroid. Just prior to ^{131}I therapy, the following blood tests are obtained: serum TSH to confirm it is greater than 30 milli-units/L, serum hCG in reproductive-age women to screen for pregnancy, and serum thyroglobulin as a tumor marker. Three days after ^{131}I therapy, levothyroxine therapy may be resumed at full replacement dose.

5. Side effects and contraindications to ^{131}I therapy—National Cancer Institute surveillance data for thousands of patients with thyroid cancer indicate that patients with differentiated thyroid cancer, treated with only surgery, have a 5% increased risk of developing a second non-thyroid malignancy. Patients with thyroid cancer who received ^{131}I therapy have a slightly increased risk of developing a second non-thyroid malignancy (especially leukemia and lymphoma). The risk of second cancers peaks about 5 years following ^{131}I therapy.

Sialadenitis and xerostomia are potential side effects, particularly in women, older-age patients, patients with a prior history of sialadenitis, and patients with autoimmune diseases associated with Sjögren syndrome. See **Precautions** about RAI use, above.

E. Other Therapies for Differentiated Thyroid Cancer

Patients with osteolytic metastases to bone from differentiated thyroid cancer may be treated with one of two anti-bone resorptive drugs: (1) zoledronic acid, 4 mg intravenously; or (2) denosumab, 120 mg subcutaneously. The frequency and duration of therapy are individualized according to each patient's symptoms and response. These drugs must be used judiciously; there is an increased risk of atypical femur fractures and osteonecrosis of the jaw with prolonged therapy with either drug.

Patients with aggressive differentiated thyroid cancers may have metastases that are refractory to RAI therapy. Recurrence in the neck may be treated with surgical debulking and external beam radiation therapy. Patients with RAI-refractory differentiated thyroid cancer metastases that are advanced and rapidly progressive may be treated with certain tyrosine kinase inhibitors. Vandetanib and sunitinib induce partial responses in about 40%, while lenvatinib induces partial responses in about 65%; however, median progression-free survival has been only about 18 months and all tyrosine kinase inhibitors can cause serious adverse reactions, so the patient and clinician must decide whether this chemotherapy is worthwhile.

Treatment of Other Thyroid Malignancies

Anaplastic thyroid carcinoma is treated with local resection and radiation. Lovastatin has been demonstrated to cause differentiation and apoptosis of anaplastic thyroid carcinoma cells in vitro, but clinical studies are lacking. Anaplastic thyroid carcinoma does not respond to ^{131}I therapy and is resistant to most chemotherapy. Anaplastic thyroid cancers with mTOR mutations may be inhibited by everolimus.

Medullary thyroid carcinoma is best treated with surgery for the primary tumor and metastases. Patients with a ret protooncogene mutation should have a prophylactic total thyroidectomy, ideally by age 6 years (MEN 2A) or at age 6 months (MEN 2B). Medullary thyroid carcinoma does not respond to ^{131}I therapy and is relatively resistant to chemotherapy. Patients should be monitored closely, with serum calcitonin levels checked about every 3 months. Since medullary thyroid carcinoma can be indolent, patients should be considered for chemotherapy only if they have rapidly progressive metastases, as evidenced by a doubling time of serum calcitonin or CEA doubling time is within 2 years. Scanning with ^{18}FDG-PET is also useful for identifying rapidly progressive metastases. Vandetanib and cabozantinib are approved for use against rapidly progressive metastatic medullary thyroid carcinoma; both require close observation to avoid toxicity. Vandetanib should usually not be administered to patients with cardiac disease or a prolonged QT interval. Cabozantinib should usually not be administered to patients with small bowel or large bowel disease or prior radiation to the neck or mediastinum, since it increases the risk for gastrointestinal perforation and tracheoesophageal fistula. Patients with medullary thyroid carcinoma and diabetes should not receive diabetic therapy with glucagon-like peptide-1 (GLP-1) agonists because they may stimulate the growth of medullary thyroid carcinoma.

Thyroid mucosa-associated lymphoid tissue lymphomas have a low risk of recurrence after simple thyroidectomy. Patients with other thyroid lymphomas are best treated with external radiation therapy; chemotherapy is added for extensive lymphoma (Table 39–2).

External beam radiation therapy may be delivered to bone metastases, especially those that are without radioiodine uptake or are RAI-refractory. Local neck radiation therapy may also be given to patients with anaplastic thyroid carcinoma. Brain metastases can be treated with gamma knife radiosurgery.

Follow-Up

Most differentiated thyroid carcinoma recurs within the first 5–10 years after thyroidectomy. While lifetime monitoring is recommended, the follow-up protocol can be tailored to the staging and aggressiveness of the malignancy. All patients require at least a yearly thyroid ultrasound and serum thyroglobulin level (while taking levothyroxine). Patients at higher risk usually require at least two annual consecutively negative stimulated serum thyroglobulin determinations less than 1 ng/mL and normal RAI scans (if done) and neck ultrasound scans before they are considered to be in remission. The first surveillance occurs with stimulated postoperative serum thyroglobulin, ^{131}I therapy, and post-therapy scanning about 2–4 months after surgery. At 9–12 months postoperatively, patients may receive another stimulated serum thyroglobulin and RAI scan. Patients need not have repeated ^{131}I therapies if persistent RAI uptake is confined to the thyroid bed and if neck ultrasounds appear normal and stimulated serum thyroglobulin levels remain less than 2 ng/mL. Patients with differentiated thyroid carcinoma must be monitored long term for recurrent or metastatic disease. Further radioiodine or other scans may be required for patients with more aggressive differentiated thyroid cancer, prior metastases, rising serum thyroglobulin levels, or other evidence of metastases.

1. Serum TSH suppression—Patients with differentiated thyroid cancer are treated with levothyroxine doses that are sufficient to suppress the serum TSH below the normal range. For intermediate- or high-risk patients, the serum TSH should be suppressed below 0.1 milli-international units/L, while the target TSH for low-risk patients is 0.1–0.5 milli-international units/mL. Patients who are considered cured should nevertheless be treated with sufficient levothyroxine to keep the serum TSH less than 2 milli-international units/L. Follow-up must include physical examinations and laboratory testing to ensure that patients remain clinically euthyroid with serum TSH levels in the target range. To achieve suppression of serum TSH, the required dose of levothyroxine may be such that serum FT_4 levels may be slightly elevated; in that case, measurement of serum T_3 or free T_3 can be useful to ensure the patient is not frankly hyperthyroid. Thyrotoxicosis can be caused by over-replacement with levothyroxine or by the growth of functioning metastases.

2. Serum thyroglobulin—Thyroglobulin is produced by normal thyroid tissue and by most differentiated thyroid carcinomas. It is only after a total or near-total thyroidectomy and ^{131}I remnant ablation that thyroglobulin becomes a useful tumor marker for patients with differentiated papillary or follicular thyroid cancer, particularly for patients who do not have serum antithyroglobulin antibodies.

Detectable thyroglobulin levels do not necessarily indicate the presence of residual or metastatic thyroid cancer. Conversely, baseline serum thyroglobulin levels are insensitive markers for disease recurrence. However, baseline or stimulated serum thyroglobulin levels 2 ng/mL or higher indicate the need for a repeat neck ultrasound and further scanning with RAI or ^{18}FDG-PET. If serum thyroglobulin levels remain 2 ng/mL or higher in the presence of normal scanning, it is prudent to repeat the serum thyroglobulin in a national reference laboratory. In one series of patients with differentiated thyroid cancer following thyroidectomy, there was a 21% incidence of metastases in patients with serum thyroglobulin less than 1 ng/mL (while receiving levothyroxine for TSH suppression). Therefore, baseline serum thyroglobulin levels are inadequately sensitive and stimulated serum thyroglobulin measurements should be used and always with neck ultrasound. The usefulness of routinely doing a radioiodine scan in low-risk patients is controversial but continues to be done in many centers during stimulation following either rhTSH or thyroid hormone withdrawal.

3. Neck ultrasound—Neck ultrasound should be used in all patients with thyroid carcinoma to supplement neck palpation; it should be performed preoperatively, 3 months postoperatively, and regularly thereafter. Ultrasound is more sensitive for lymph node metastases than either CT or MRI scanning. Small inflammatory nodes may be detected postoperatively and do not necessarily indicate metastatic disease, but follow-up is necessary. Ultrasound-guided FNA biopsy should be performed on suspicious lesions.

4. Radioactive iodine (RAI: ^{131}I or ^{123}I) neck and whole-body scanning—Despite its limitations, RAI scanning has traditionally been used to detect metastatic differentiated thyroid cancer and to determine whether the cancer is amenable to treatment with ^{131}I. RAI scanning is particularly useful for high-risk patients and those with persistent antithyroglobulin antibodies that make serum thyroglobulin determinations unreliable.

The ^{131}I radioisotope may be used in scanning activities provided it is given less than 2 weeks before scheduled ^{131}I treatment to avoid "stunning" metastases such that they take up less of the RAI therapy activity. Alternatively, the ^{123}I radioisotope may also be used and does not stun tumors; it allows single-photon emission computed tomography (SPECT) to better localize metastases. Initial RAI scanning is typically performed about 2–4 months following surgery for differentiated thyroid carcinoma.

About 65% of metastases are detectable by RAI scanning but only after optimal preparation. Patients should ideally have a total or near-total thyroidectomy, since any residual normal thyroid competes for RAI with metastases, which are less avid for iodine. It is reasonable to perform a rhTSH-stimulated scan and thyroglobulin level 2–3 months after the initial neck surgery; if the scan is negative and the serum thyroglobulin is less than 2 ng/mL, low-risk patients may not require further scanning but should continue to be monitored with neck ultrasound and serum thyroglobulin levels every 6–12 months. For higher-risk patients, the rhTSH-stimulated thyroglobulin and RAI scan may be repeated about 1 year after surgery and then again if warranted. Serum thyroglobulin and radioiodine scanning are stimulated by either rhTSH or thyroid hormone withdrawal according to the protocols described above for ^{131}I treatment.

The combination of rhTSH-stimulated scanning and thyroglobulin levels detects a thyroid remnant or cancer with a sensitivity of 84%. However, the presence of antithyroglobulin antibodies renders the serum thyroglobulin determination uninterpretable. In about 21% of low-risk patients, rhTSH stimulates serum thyroglobulin to above 2 ng/mL; such patients have a 23% risk of local neck metastases and a 13% risk of distant metastases. The rhTSH-stimulated radioiodine neck and whole-body scan detects only about half of these metastases because they are small or not avid for iodine. Some patients have persistent radioiodine uptake in the neck on diagnostic scanning but have no visible tumor on neck ultrasound; such patients do not require additional radioiodine therapy, especially if the serum thyroglobulin level is very low.

5. Positron emission tomography scanning—^{18}FDG-PET scanning is particularly useful for detecting thyroid cancer metastases in patients with a detectable serum thyroglobulin (especially serum thyroglobulin levels greater than 10 ng/mL and rising) who have a normal whole-body RAI scan and an unrevealing neck ultrasound. It is also sensitive for detecting metastases from medullary thyroid carcinoma. Diabetic patients with serum glucose less than 200 mg/dL (11.2 mmol/L) may be scanned, since the tracer acts like glucose in the body. ^{18}FDG-PET scanning can be combined with a CT scan; the resultant ^{18}FDG-PET/CT fusion scan is 60% sensitive for detecting metastases that are not visible by other methods. This scan is less sensitive for small brain metastases. ^{18}FDG-PET scanning detects the metabolic activity of tumor tissue; for differentiated thyroid carcinoma, this scan is more sensitive when the patient's thyroid cancer is stimulated with rhTSH (Thyrogen). One problem with ^{18}FDG-PET scanning is its lack of specificity. False-positives can occur with benign hepatic tumors, sarcoidosis, radiation therapy, suture granulomas, reactive lymph nodes, or inflammation at surgical sites that can persist for months.

6. Other scanning—Thallium-201 (^{201}Tl) scans may be useful for detecting metastatic differentiated thyroid carcinoma when the ^{131}I scan is normal but serum thyroglobulin is elevated. MRI scanning is particularly useful for imaging metastases in the brain, mediastinum, or bones. CT scanning is useful for imaging and monitoring pulmonary metastases.

Prognosis

Papillary thyroid carcinoma has an overall mortality rate of 3%. It is best staged using the MACIS (metastasis, age, completeness of resection, invasion, size) scoring system (Table 26–7). ^{18}FDG-PET scanning independently predicts survival, with patients having few PET-avid metastases and low SUV_{max} (highest image-pixel standardized uptake value) having a generally good prognosis, particularly for adults under age 45 years. Unlike other forms of cancer, patients with papillary thyroid carcinoma who have palpable lymph node metastases do not have a particularly increased mortality rate; however, their risk of local recurrence is increased. The following characteristics imply a worse prognosis: age over 45 years, male sex, bone or brain metastases, macronodular (greater than 1 cm) pulmonary metastases, and lack of ^{131}I uptake into metastases. Younger patients with pulmonary metastases tend to respond better to ^{131}I therapy than do older adults. Certain papillary histologic types are associated with a higher risk of recurrence and reduced survival: tall cell, columnar cell, and diffuse sclerosing types tend to be more aggressive than classic papillary thyroid cancer; the best prognosis has been with the follicular variant of papillary thyroid cancer. Brain metastases are detected in 1%; they reduce median survival to 12 months, but the patient's prognosis is improved by surgical resection.

Patients with **follicular thyroid carcinoma** have a cancer mortality rate that is 3.4 times higher than patients with papillary carcinoma. The Hürthle cell variant of follicular carcinoma is even more aggressive. Both follicular carcinoma and its Hürthle cell variant tend to present at a more advanced stage than papillary carcinoma. However, at a given stage, the different types of differentiated thyroid carcinoma have a similar prognosis. Patients with primary tumors larger than 1 cm in diameter who undergo limited thyroid surgery (subtotal thyroidectomy or lobectomy) have a 2.2-fold increased mortality over those having total or near-total thyroidectomies. Patients who have not received ^{131}I ablation have mortality rates that are increased twofold by 10 years and threefold by 25 years (over those who have received ablation). The risk of cancer recurrence is twofold higher in men than in women and 1.7-fold higher in multifocal than in unifocal tumors.

Patients with a normal ^{18}FDG-PET scan have a 98% 5-year survival, while those having more than 10 metastases have a 20% 5-year survival. Those with a SUV_{max} of 0.1-4.6 have a 5-year survival of 85%, while those with a SUV_{max} greater than 13.3 have a 5-year survival of 20%. Patients with only local metastases have a 5-year survival of 95%, while those with regional (supraclavicular, mediastinal) metastases have a 5-year survival of 70%, and those with distant metastases have a 5-year survival of 35%.

Medullary thyroid carcinoma is more aggressive than differentiated thyroid cancer but is typically fairly indolent. However, medullary thyroid carcinoma with a somatic RET codon M918T mutation is the most aggressive medullary thyroid carcinoma and has a poorer prognosis. The overall 10-year survival rate is 90% when the tumor is confined to the thyroid, 70% for those with metastases to cervical lymph nodes, and 20% for those with distant metastases. When postoperative serum calcitonin levels are below 150 pg/mL (44 pmol/L), residual disease is likely confined to the neck, whereas when postoperative serum calcitonin levels are above 500 pg/mL (146 pmol/L), distant metastases are likely. Patients with sporadic disease usually have lymph node involvement noted at the time of diagnosis, whereas distal metastases may not be noted for years. For patients who have metastases to lymph nodes, modified radical neck dissection is recommended. Familial cases and those associated with MEN 2A tend to be less aggressive; the 10-year survival rate is higher, in part due to earlier detection. Patients with metastatic medullary thyroid carcinoma whose serum calcitonin doubling time is over 2 years also have a relatively good prognosis.

Medullary thyroid carcinoma that is seen in MEN 2B (MEN 3) is more aggressive, arises earlier in life, and carries a worse overall prognosis, especially when associated with a germline M918T mutation. Older adults tend to have more aggressive medullary thyroid carcinomas. Women with medullary thyroid carcinoma who are under age 40 years have a better prognosis. A better prognosis is also obtained in patients undergoing total thyroidectomy and neck dissection; radiation therapy reduces recurrence in patients with metastases to neck nodes. The mortality rate is increased 4.5-fold when primary or metastatic tumor tissue stains heavily for myelomonocytic antigen M-1. Conversely, tumors with heavy immunoperoxidase staining for calcitonin are associated with prolonged survival even in the presence of significant metastases.

Anaplastic thyroid carcinoma carries a 1-year survival rate of about 10% and a 5-year survival rate of about 5%. Patients with fully localized tumors on MRI have a better prognosis.

Localized thyroid lymphoma carries a 5-year survival of nearly 100%. Those with disease outside the thyroid have a 63% 5-year survival. However, the prognosis is better for those with mucosa-associated lymphoid tissue lymphoma compared to diffuse large B-cell lymphoma. Patients presenting with stridor, pain, laryngeal nerve palsy, or mediastinal extension tend to fare worse.

IODINE DEFICIENCY DISORDER & ENDEMIC GOITER

ESSENTIALS OF DIAGNOSIS

- Common in regions with low-iodine diets.
- High rate of congenital hypothyroidism and cretinism.
- Goiters may become multinodular and enlarge.

- Most adults with endemic goiter are euthyroid; however, some are hypothyroid or hyperthyroid.

General Considerations

The daily minimum dietary requirement for iodine is 150 mcg/day in nonpregnant adults and 250 mcg/day for pregnant or lactating women. Mild-to-moderate and sometimes severe iodine deficiency exists in 30 countries. An estimated 1.9 billion people have insufficient iodine intake. Severe iodine deficiency increases the risk of miscarriage and stillbirth. Cretinism occurs in about 0.5% of live births in iodine-deficient areas. Moderate iodine deficiency during gestation and infancy can cause manifestations of hypothyroidism, deafness, short stature, and lowers a child's intelligence quotient by 10–15 points. Even mild-to-moderate iodine deficiency appears to impair a child's perceptual reasoning and global cognitive index.

Although iodine deficiency is the most common cause of endemic goiter, there are other natural goitrogens, including certain foods (eg, sorghum, millet, maize, cassava), mineral deficiencies (selenium, iron, zinc), and water pollutants, which can themselves cause goiter or aggravate a goiter proclivity caused by iodine deficiency. In iodine-deficient patients, smoking can induce goiter growth. Pregnancy aggravates iodine deficiency and can increase the size of thyroid nodules and cause new nodules. Some individuals are particularly susceptible to goiter owing to congenital partial defects in thyroid enzyme activity.

Clinical Findings

A. Symptoms and Signs

Endemic goiters may become multinodular and very large. Growth often occurs during pregnancy and may cause compressive symptoms.

Substernal goiters are usually asymptomatic but can cause tracheal compression, respiratory distress and failure, dysphagia, superior vena cava syndrome, gastrointestinal bleeding from esophageal varices, palsies of the phrenic or recurrent laryngeal nerves, or Horner syndrome. Cerebral ischemia and stroke can result from arterial compression or thyrocervical steal syndrome. Substernal goiters can rarely cause pleural or pericardial effusions. The incidence of significant malignancy is less than 1%.

Some patients with endemic goiter may become hypothyroid. Others may become thyrotoxic as the goiter grows and becomes more autonomous, especially if iodine is added to the diet.

B. Laboratory Findings

The serum T_4 and TSH are generally normal. TSH falls in the presence of hyperthyroidism if a multinodular goiter has become autonomous in the presence of sufficient amounts of iodine for thyroid hormone synthesis. TSH rises with hypothyroidism. Thyroid RAI uptake is usually elevated, but it may be normal if iodine intake has improved. Serum levels of antithyroid antibodies are usually either undetectable or in low titers. Serum thyroglobulin is often elevated above 13 mcg/L. Urine iodine concentrations are low.

Differential Diagnosis

Endemic goiter must be distinguished from all other forms of nodular goiter that may coexist in an endemic region.

Prevention

The minimum dietary requirement for iodine is about 50 mcg daily, with optimal iodine intake being 150–300 mcg daily. Iodized salt contains iodine at about 20 mg per kg salt. Other sources of iodine include commercial bread, milk, and seafood. Initiating iodine supplementation in an iodine-deficient area greatly reduces the emergence of new goiters but causes an increased frequency of hyperthyroidism during the first year. One iodine-depleted area was Pescopagano, Italy, where 46% of adults had goiters. Salt was iodized (30 mg of potassium iodate per kg salt) and made available in 1985. After 15 years, the incidence of goiter declined to 23%. However, the prevalence of Hashimoto thyroiditis rose from 3.5% to 14.5% after 15 years of iodine supplementation.

Treatment

Iodine supplementation has not proven effective for treating adults with large multinodular goiter due to iodine deficiency and actually increases their risk of developing thyrotoxicosis. Thyroidectomy may be required for cosmesis, compressive symptoms, or thyrotoxicosis. There is a high goiter recurrence rate in iodine-deficient geographic areas, so near-total thyroidectomy is preferred when surgery is indicated. Certain patients may be treated with ^{131}I for large compressive goiters.

Complications

Dietary iodine supplementation increases the risk of autoimmune thyroid dysfunction, which may cause hypothyroidism or hyperthyroidism. Excessive iodine supplementation increases the risk of goiter. Suppression of TSH by administering levothyroxine carries the risk of inducing hyperthyroidism, particularly in patients with autonomous multinodular goiters; therefore, levothyroxine suppression should not be started in patients with a low TSH level. Treating patients with ^{131}I for large multinodular goiter may shrink the gland; however, Graves disease develops in some patients 3–10 months following therapy.

DISEASES OF THE PARATHYROIDS

Parathyroid hormone (PTH) increases osteoclastic activity in bone, increases the renal tubular reabsorption of calcium, and stimulates the synthesis of 1,25-dihydroxycholecalciferol by the kidney. Meanwhile, PTH inhibits the reabsorption of phosphate and bicarbonate by the renal tubule. All of these effects cause a net increase in serum calcium.

HYPOPARATHYROIDISM & PSEUDOHYPOPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Tetany, carpopedal spasms, tingling of lips and hands, cramps, irritability.
- Chvostek sign and Trousseau phenomenon.
- Hypocalcemia with low serum PTH; serum phosphate high; alkaline phosphatase normal; urine calcium excretion reduced.
- Serum magnesium may be low.

General Considerations

Acquired hypoparathyroidism is most commonly caused by anterior neck surgery, occurring after total thyroidectomy in about 25% of patients transiently, and in about 4% of patients permanently. The risk of permanent postoperative hypoparathyroidism can be reduced during thyroid surgery by taking parathyroid glands with suspected vascular damage and autotransplanting them into the sternocleidomastoid muscle. Permanent hypoparathyroidism may occur after the resection of multiple parathyroid adenomas. It also occurs transiently after the surgical removal of a single parathyroid adenoma for primary hyperparathyroidism due to suppression of the remaining normal parathyroids and accelerated remineralization of the skeleton. This is known as "hungry bone syndrome." In such cases, hypocalcemia can be quite severe, particularly in patients with preoperative hyperparathyroid bone disease and vitamin D or magnesium deficiency. All patients undergoing thyroidectomy or parathyroidectomy must be observed closely overnight. Neck irradiation is a rare cause of hypoparathyroidism.

Autoimmune hypoparathyroidism may be isolated or combined with other endocrine deficiencies. Autoimmune polyendocrine syndrome type I (APS-I) is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED). In APS-I, mucocutaneous candidiasis appears in the newborn period. Hypoparathyroidism is the most frequent and often the only endocrine deficiency. Addison disease is the next most common autoimmune endocrinopathy and may present anytime from childhood to young adulthood. Hypothyroidism, type 1 diabetes, or pituitary deficiency as well as cataracts, uveitis, alopecia, or vitiligo can also develop. Autoimmune gastrointestinal manifestations are also common. Fat malabsorption occurs in 20% of patients with APS-I; treatment of hypocalcemia can be challenging in patients with APS-I, since vitamin D_3 is fat-soluble. Hypoparathyroidism can also occur in SLE caused by antiparathyroid antibodies.

Parathyroid deficiency may also be the result of damage from heavy metals such as copper (Wilson disease) or iron (hemochromatosis, transfusion hemosiderosis), granulomas, Riedel thyroiditis, tumors, or infection.

Magnesium deficiency causes functional hypoparathyroidism. Hypomagnesemia is most commonly caused by alcoholism, diuretics, intestinal malabsorption, and proton pump inhibitors. Hypomagnesemia can also be caused by aminoglycosides, amphotericin, pentamidine, and epithelial growth factor inhibitors (panitumumab, cetuximab). Although mild hypomagnesemia stimulates PTH secretion, more severe hypomagnesemia (below 1.2 mg/dL) inhibits PTH secretion. Hypomagnesemia also causes resistance to PTH in bone and renal tubules. Correction of hypomagnesemia results in rapid disappearance of the condition.

Hypermagnesemia also suppresses PTH secretion. Hypermagnesemia occurs most commonly in patients with kidney dysfunction who take magnesium-containing antacids, laxatives, or dietary supplements.

Symptomatic hypoparathyroidism may be precipitated by a proton pump inhibitor, since absorption of calcium decreases with reduced stomach acidity.

Congenital hypoparathyroidism causes hypocalcemia beginning in infancy. However, it may not be diagnosed for many years. Since hypoparathyroidism can be familial, screening is suggested for family members of any patient with idiopathic hypoparathyroidism.

Clinical Findings

A. Symptoms and Signs

Manifestations of hypocalcemia vary from subtle to life-threatening. Patients have a reduced quality of life, with fatigue; irritability; depression; anxiety; cognitive impairment or “brain fog”; lethargy; and paresthesias in the circumoral area, hands, and feet. More severe manifestations include muscle weakness or cramps, carpopedal spasm, convulsions, tetany, laryngospasm and stridor. Chronic hypocalcemia with hyperphosphatemia can cause calcifications in soft tissues, such as joints, skin, and arteries. Brain calcifications in the basal ganglia and cerebral cortex can cause parkinsonian symptoms or choreoathetosis. However, some patients with chronic hypocalcemia are asymptomatic, even with very low levels of serum calcium.

Chvostek sign (facial muscle contraction on tapping the facial nerve in front of the ear) is positive, and Trousseau phenomenon (carpal spasm after application of a sphygmomanometer cuff) is present. Cataracts may occur; the nails may be thin and brittle; the skin is dry and scaly, at times with fungus infection (candidiasis), and there may be loss of eyebrows; and deep tendon reflexes may be hyperactive. Pseudotumor cerebri with papilledema and elevated CSF pressure is occasionally seen. Teeth may be defective if the onset of the disease occurs in childhood.

B. Laboratory Findings

Serum calcium is low, serum phosphate high, urinary calcium low, and alkaline phosphatase normal. Serum calcium is largely bound to albumin. In patients with hypoalbuminemia, the serum ionized calcium may be determined; it should be 4.6–5.3 mg/dL (1.15–1.32 mmol/L). Alternatively, the serum calcium level can be corrected for serum albumin level as follows:

$$\text{“Corrected” serum } Ca^{2+} = \text{Serum } Ca^{2+} \text{mg/dL} + (0.8 \times [4.0 - \text{Albumin g/dL}])$$

Serum PTH levels are usually low or not elevated in the presence of hypocalcemia. Serum magnesium levels should always be measured. Serum calcium should not be determined within 24 hours following intravenous gadolinium, since gadolinium interferes with the colorimetric calcium assay, thereby causing artefactual hypocalcemia.

C. Imaging

Radiographs or CT scans of the skull may show basal ganglia calcifications. The bones may appear denser than normal and the bone mineral density is usually increased. Cutaneous calcification may occur.

D. Other Examinations

Slit-lamp examination may show early posterior lenticular cataract formation. The electrocardiogram (ECG) may show heart block, have a prolonged QTc interval, and there may be T wave abnormalities in the presence of hypocalcemia. Patients with chronic hypoparathyroidism tend to have increased bone mineral density, particularly in the lumbar spine.

Complications

Acute tetany with stridor, especially if associated with vocal cord palsy, may lead to respiratory obstruction requiring tracheostomy. There may be associated autoimmunity causing celiac disease, pernicious anemia, or Addison disease. Ossification of the paravertebral ligaments may occur with nerve root compression; surgical decompression may be required. Seizures are common in untreated patients. Overtreatment with vitamin D and calcium may produce nephrocalcinosis and impairment of kidney function. Hypocalcemia can also cause heart failure and dysrhythmias.

Differential Diagnosis

Paresthesias, muscle cramps, or tetany due to respiratory alkalosis, in which the serum calcium is normal, can be confused with hypocalcemia. In fact, hyperventilation tends to accentuate hypocalcemic symptoms.

Hypocalcemia may be caused by certain drugs: loop diuretics, plicamycin, phenytoin, foscarnet, denosumab, and bisphosphonates. In addition, hypocalcemia may be seen in cases of rapid intravascular volume expansion or due to chelation from transfusions of large volumes of citrated blood. Hypocalcemia may also be due to malabsorption of calcium, magnesium, or vitamin D; patients do not always have diarrhea. It is also observed in patients with acute pancreatitis. Hypocalcemia may develop in some patients with certain osteoblastic metastatic carcinomas (especially breast, prostate) instead of the expected hypercalcemia. Hypocalcemia with hyperphosphatemia (simulating hypoparathyroidism) is seen in azotemia, but may also be caused by large doses of intravenous, oral, or rectal phosphate preparations and by chemotherapy of responsive lymphomas or leukemias.

Hypocalcemia with hypercalciuria may be due to a familial syndrome involving a mutation in the calcium-sensing receptor; such patients have serum PTH levels that are in the normal range, distinguishing it from hypoparathyroidism. It is transmitted as an autosomal dominant disorder. Such patients are hypercalciuric; treatment with calcium and vitamin D may cause nephrocalcinosis.

Congenital pseudohypoparathyroidism is a group of disorders characterized by hypocalcemia due to resistance to PTH. Subtypes are caused by different mutations involving the renal PTH receptor, the receptor's G protein, or adenylyl cyclase.

Treatment

A. Prophylaxis Against Severe Postoperative Hypocalcemia

Post-thyroidectomy hypocalcemia can be detected early by closely monitoring serum PTH and calcium. If the serum calcium falls below 8.0 mg/dL (2.0 mmol/L) with a serum PTH below 10–15 pg/mL (1.0–1.5 pmol/L) after thyroid or parathyroid surgery, the patient is at high risk for hypocalcemia and can be prophylactically treated with calcitriol and oral calcium. Calcitriol is typically given orally in doses of 0.25–1 mcg twice daily. Prophylactic elemental calcium is given orally as calcium carbonate (with meals) 500–1000 mg twice daily.

B. Emergency Treatment for Acute Hypocalcemia (Hypoparathyroid Tetany)

1. Airway—Be sure an adequate airway is present.

2. Intravenous calcium gluconate—Calcium gluconate, 10–20 mL of 10% solution intravenously, may be given slowly until tetany ceases. Ten to 50 mL of 10% calcium gluconate may be added to 1 L of 5% glucose in water or saline and administered by slow intravenous drip. The rate should be adjusted so that the serum calcium is maintained in the range of 8–9 mg/dL (2–2.25 mmol/L).

3. Oral calcium—Calcium salts should be given orally as soon as possible to supply 1–2 g of calcium daily. Liquid calcium carbonate, 500 mg/5 mL, contains 40% calcium and may be especially useful. The dosage is 1–3 g calcium orally daily; it should be given with meals.

4. Vitamin D preparations—(Table 26–8.) Therapy should be started as soon as oral calcium is begun. The active metabolite of vitamin D, 1,25-dihydroxycholecalciferol (calcitriol), has a very rapid onset of action and is not long-lasting if hypercalcemia occurs. It is of great use in the treatment of acute hypocalcemia. Therapy is commenced at a dosage of 0.25 mcg orally each morning with upward dosage titration to near normocalcemia. Ultimately, doses of 0.5–2 mcg/day are usually required.

Table 26–8. Vitamin D preparations used in the treatment of hypoparathyroidism.

	Available Preparations	Daily Dose	Duration of Action
Ergocalciferol, ergosterol (vitamin D_2, calciferol)	50,000 international units capsules; 8000 international units/mL oral solution	2000–200,000 units	1–2 weeks
Cholecalciferol (vitamin D_3)	50,000 international units capsules, not available commercially in United States; may be compounded	10,000–50,000 units	4–8 weeks
Calcitriol (Rocaltrol)	0.25 and 0.5 mcg capsules; 1 mcg/mL oral solution; 1 mcg/mL for injection	0.25–4 mcg	½–2 weeks

5. Magnesium—If hypomagnesemia (serum magnesium less than 1.8 mg/dL or less than 0.8 mmol/L) is present, it must be corrected to treat the resulting hypocalcemia. For critical hypomagnesemia (serum magnesium less than 1.0 mg/dL or less than 0.45 mmol/L), 50% magnesium sulfate solution (5 g/10 mL) is diluted in 250 mL 0.9% saline or 5% dextrose in water and given by an intravenous infusion of 5 g over 3 hours, with further dosing based on serum magnesium levels. Long-term oral magnesium replacement may be given as magnesium oxide 500 mg (60% elemental magnesium) tablets, one to three times daily.

C. Maintenance Treatment of Hypoparathyroidism

Patients with mild hypoparathyroidism may require no therapy but need close monitoring for manifestations of hypocalcemia. Therapy is ordinarily required for patients with symptomatic hypocalcemia or serum calcium levels below 8.0 mg/dL (2 mmol/L).

Vitamin D, calcium, and magnesium therapy: Patients with hypoparathyroidism have a reduced renal tubular reabsorption of calcium and are thus prone to hypercalciuria and kidney stones if the serum calcium is normalized with calcium and vitamin D therapy. Therefore, the goal is to maintain the serum calcium in a slightly low but asymptomatic range of 8–8.6 mg/dL (2–2.15 mmol/L). It is prudent to monitor urine calcium with “spot” urine determinations and keep the level below 30 mg/dL (7.5

mmol/L), if possible. Hypercalciuria may respond to oral hydrochlorothiazide, 25 mg daily, usually given with a potassium supplement. Serum magnesium should be monitored and kept in the normal range with supplemental magnesium, if required. Serum phosphate should also be monitored and the serum calcium × phosphate product kept below 55 mg^2/dL^2 (4.4 $mmol^2/L^2$).

Calcium supplements can be given in doses of 800–1000 mg orally daily. Calcium carbonate 1 g contains 400 mg of elemental calcium and should be given with meals; calcium citrate 1 g contains 211 mg of elemental calcium, but can be given any time and causes less gastrointestinal intolerance. Calcium lactate (13% elemental calcium) and calcium gluconate (9% elemental calcium) are other options for calcium supplementation.

Vitamin D is generally required for patients with chronic hypoparathyroidism (Table 26–8). Monitoring of serum calcium at regular intervals (at least every 3–4 months) is recommended. Calcitriol, a short-acting preparation, is given in doses that range from 0.25 mcg/day to 2.0 mcg orally daily. Ergocalciferol (vitamin D_2) is derived from plants; the usual dose ranges from 25,000 to 150,000 units/day. It is stored in fat, giving it a long duration of action. If toxicity develops, hypercalcemia—treatable with hydration and prednisone—may persist for weeks after it is discontinued. Despite this risk, ergocalciferol usually produces a more stable serum calcium level than do the shorter-acting preparations.

PTH is effective for treating patients with hypoparathyroidism but is restricted to patients whose hypocalcemia cannot be adequately treated with calcium and vitamin D analogs (see above). Recombinant human parathyroid hormone (rhPTH) is an 84-amino acid polypeptide that is identical to native PTH (1–84). It is FDA approved and marketed as NATPARA as an adjunct to calcium and vitamin D analogs to control symptomatic hypocalcemia in patients with hypoparathyroidism. It must be given by subcutaneous injection every 1–2 days. Although rhPTH can normalize serum calcium levels in patients with severe hypocalcemia, there have been no controlled studies indicating that rhPTH is superior to conventional therapy in reversing the fatigue and muscle weakness often reported by these patients. Side effects of rhPTH include nausea, vomiting, diarrhea, arthralgias, and paresthesias. Also, osteosarcoma has occurred in rats receiving very high-dose PTH. The FDA requires that prescribers be certified before prescribing the drug and that patients and prescribers formally acknowledge the risk of osteosarcoma. rhPTH is expensive, which limits its use.

Transplantation of cryopreserved parathyroid tissue, removed during prior surgery, restores normocalcemia in about 23% of cases.

Hypoparathyroidism in pregnancy presents special challenges. Maternal hypocalcemia can adversely affect the skeletal development of the fetus and cause compensatory hyperparathyroidism in the newborn. Maternal hypercalcemia can suppress fetal parathyroid development, resulting in neonatal hypocalcemia. This requires very close clinical and biochemical monitoring during pregnancy.

Caution: Phenothiazine drugs should be administered with caution, since they may precipitate extrapyramidal symptoms in hypocalcemic patients. Furosemide should be avoided, since it may worsen hypocalcemia.

Prognosis

Patients with mild hypoparathyroidism generally do well. Periodic serum calcium levels are required, since changes may call for modification of the treatment schedule. Hypercalcemia that develops in patients with seemingly stable, treated hypoparathyroidism may be a presenting sign of Addison disease.

Despite optimal therapy, patients with moderate-to-severe hypoparathyroidism have been reported to have an overall reduced quality of life. Chronically affected patients frequently develop calcifications in their kidneys and basal ganglia. They have an increased risk of calcium kidney stones and kidney dysfunction as well as seizures, mood and psychiatric disorders, and a reduced overall sense of well-being. Therapy with rhPTH may prevent or improve these manifestations.

HYPERPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Often found incidentally by routine blood testing.
- Renal calculi, polyuria, hypertension, constipation, fatigue, mental changes.
- Bone pain; rarely, cystic lesions and pathologic fractures.
- Elevated PTH, serum and urine calcium, and urine phosphate; serum phosphate low to normal; alkaline phosphatase normal to elevated.

General Considerations

Primary hyperparathyroidism is the most common cause of hypercalcemia, with a prevalence of 1000 to 4000 cases per 1 million persons. It occurs at all ages but most commonly in the seventh decade and in women (74%). Before age 45, the prevalence is similar in men and women. It is more prevalent in blacks, followed by whites, then other races.

Parathyroid glands vary in number and location and ectopic parathyroid glands have been found within the thyroid gland, high in the neck or carotid sheath, in the retroesophageal space, and within the thymus or mediastinum. Hyperparathyroidism is caused by hypersecretion of PTH, usually by a single parathyroid adenoma (80%), and less commonly by hyperplasia of two or more parathyroid glands (20%), or carcinoma (less than 1%). However, when hyperparathyroidism presents before age 30 years, there is a higher incidence of multiglandular disease (36%) and parathyroid carcinoma (5%). The size of the parathyroid adenoma correlates with the serum PTH level.

Hyperparathyroidism is familial in about 10% of cases; hyperparathyroidism presenting before age 45 has a higher chance of being familial. Parathyroid hyperplasia may arise in MEN types 1, 2 (2A), and 4. (See Table 26–12.) In MEN 1, multiglandular hyperparathyroidism is usually the initial manifestation and ultimately occurs in 90% of affected individuals. Hyperparathyroidism in MEN 2 (2A) is less frequent than in MEN 1 and is usually milder.

Hyperparathyroidism results in the excessive excretion of calcium and phosphate by the kidneys. PTH stimulates renal tubular reabsorption of calcium; however, hyperparathyroidism causes hypercalcemia and an increase in calcium in the glomerular filtrate that overwhelms tubular reabsorption capacity, resulting in hypercalciuria. At least 5% of renal calculi are associated with this disease. Diffuse parenchymal calcification (nephrocalcinosis) is seen less commonly. Hyperparathyroidism causes demineralization of cortical bone and a gain of trabecular bone. Severe, chronic hyperparathyroidism can cause pathologic fractures, and cystic bone lesions throughout the skeleton, a condition known as osteitis fibrosa cystic.

Parathyroid carcinoma is a rare cause of hyperparathyroidism, accounting for less than 1% of hyperparathyroidism. There is typically a palpable neck mass (75%). However, some cases present with smaller tumors, less severe hypercalcemia, and benign-appearing histologic features. Local recurrence is the rule if surgical margins are positive. Distant metastases arise most commonly in the lungs but also in bones, liver, brain, and mediastinum. Although parathyroid carcinoma is typically indolent, an increasing tumor burden is associated with critically severe hypercalcemia and death.

Secondary and tertiary hyperparathyroidism usually occurs in patients with chronic kidney disease, in which hyperphosphatemia and decreased renal production of 1,25-dihydroxycholecalciferol (1,25$[OH]_2D_3$) initially produce a decrease in ionized calcium. The parathyroid glands are stimulated (secondary hyperparathyroidism) and may enlarge, becoming autonomous (tertiary hyperparathyroidism). The bone disease seen in this setting is known as renal osteodystrophy (see Disorders of Mineral Metabolism, Chapter 22). Hypercalcemia often occurs after kidney transplant. Secondary hyperparathyroidism predictably develops in patients with a deficiency in vitamin D. Serum calcium levels are typically in the normal range, but may rise to become borderline elevated with time, with tertiary hyperparathyroidism due to parathyroid glandular hyperplasia.

Clinical Findings

A. Symptoms and Signs

In the developed world, hypercalcemia is typically discovered incidentally by routine chemistry panels. Many patients are asymptomatic or have mild symptoms that may be elicited only upon questioning. Parathyroid adenomas are usually so small and deeply located in the neck that they are almost never palpable; when a mass is palpated, it usually turns out to be an incidental thyroid nodule.

Symptomatic patients are said to have problems with “bones, stones, abdominal groans, psychic moans, with fatigue overtones.”

1. Skeletal manifestations—Low bone density is typically most prominent at the distal one-third of the radius, a site of mostly cortical bone. Lumbar (trabecular) spine bone density is often spared and is higher compared to the distal radius. Hip bones are a mixture of trabecular and cortical bone, and femur bone density tends to be midway between the lumbar spine and distal radius. Postmenopausal women are prone to asymptomatic vertebral fractures. Although significant bone demineralization is uncommon in mild hyperparathyroidism, osteitis fibrosa cystica may present as pathologic fractures or as “brown tumors” or cysts of the jaw. More commonly, patients experience arthralgias and bone pain, particularly involving the legs.

2. Hypercalcemia manifestations—Mild hypercalcemia may be asymptomatic. However, hypercalcemia of hyperparathyroidism usually causes a variety of manifestations whose severity is not entirely predictable by the level of serum calcium or PTH. In fact, patients with only mild hypercalcemia can have significant symptoms, particularly depression, constipation, and bone and joint pain. **Neuromuscular** manifestations include paresthesias, muscle cramps and weakness, and diminished deep tendon reflexes. **Central nervous system** manifestations include malaise, headache, fatigue, intellectual weariness, insomnia, irritability, and depression. Patients may have cognitive impairment that can vary from intellectual weariness to more severe disorientation, psychosis, or stupor. **Cardiovascular** symptoms include hypertension, palpitations, prolonged P-R interval, shortened Q-T interval, bradyarrhythmias, heart block, asystole, and sensitivity to digitalis. **Kidney** manifestations include polyuria and polydipsia, caused by hypercalcemia-induced nephrogenic diabetes insipidus. Among all patients with newly discovered hyperparathyroidism, calcium-containing renal calculi have occurred or are detectable in about 18%. Patients with asymptomatic hyperparathyroidism have a 7% incidence of asymptomatic calcium nephrolithiasis, compared to 1.6% incidence in age-matched controls. **Gastrointestinal** symptoms include anorexia, nausea, heartburn, vomiting, abdominal pain, weight loss, constipation, and obstipation. Pancreatitis occurs in 3%. Pruritus may be present. Calcium may precipitate in the corneas (“band keratopathy”), in extravascular tissues (calcinosis), and in small arteries, causing small vessel thrombosis and skin necrosis (calciphylaxis).

3. Normocalcemic primary hyperparathyroidism—Patients with normocalcemic primary hyperparathyroidism generally have few symptoms. However, on average, such patients have a slightly more atherogenic lipid panel and higher blood pressures (systolic blood pressure 10 mm Hg higher and diastolic blood pressure 7 mm Hg higher) than controls. Also, affected patients can have very subtle symptoms, such as mild fatigue, that may not be appreciated as abnormal.

4. Hyperparathyroidism during pregnancy—Pregnant women having mild hyperparathyroidism with a serum calcium below 11.0 mg/dL (less than 2.75 mmol/L) generally tolerate pregnancy well with normal outcomes. However, the majority of women with more severe hypercalcemia during pregnancy experience complications such as nephrolithiasis, hyperemesis, pancreatitis, muscle weakness, and cognitive changes. Hypercalcemic crisis may occur, especially postpartum. About 80% of fetuses experience complications of maternal hyperparathyroidism, including fetal demise, preterm delivery, and low birth weight. Newborns have hypoparathyroidism that can be permanent. Hypocalcemia in the infant can present with tetany even 2–3 months after delivery.

5. Parathyroid carcinoma—Hyperparathyroidism with a large neck mass, or vocal fold paralysis from recurrent laryngeal nerve palsy, raises concern for parathyroid carcinoma. FNA biopsy is not recommended because it may seed the biopsy tract with tumor and cytologic distinction between benign and malignant tumors is problematic. Parathyroid carcinoma is more frequent in patients with hyperparathyroidism–jaw tumor (HP-JT) syndrome as well as patients with MEN 1 and MEN 2A. Therefore, patients should have genetic testing.

B. Laboratory Findings

The hallmark of primary hyperparathyroidism is hypercalcemia, with the serum adjusted total calcium greater than 10.5 mg/dL (2.6 mmol/L). The adjusted total calcium = measured serum calcium in mg/dL + [0.8 × (4.0 – patient's serum albumin in g/dL)]. Serum ionized calcium levels are elevated (above 1.36 mmol/L).

To confirm the diagnosis of hyperparathyroidism, an assessment of urinary calcium excretion is recommended, particularly for patients with mild hyperthyroidism. In primary hyperparathyroidism the urine calcium excretion may be high or normal: 100–300 mg/day (25–75 mmol/day). However, low urine calcium excretions (below 100 mg/day [25 mmol/day]) in the absence of thiazide diuretics, occurs in only 4% of cases of primary hyperthyroidism and raises the differential diagnosis of familial hypocalciuric hypercalcemia.

The serum phosphate is often less than 2.5 mg/dL (0.8 mmol/L). In primary hyperparathyroidism, there is an excessive loss of phosphate in the urine in the presence of hypophosphatemia (25% of cases). A serum calcium:phosphate (Ca/P) ratio above 2.5 (mg/dL) or above 2.17 (mmol/L) helps confirm the diagnosis of primary hyperparathyroidism. The alkaline phosphatase is elevated only if bone disease is present. The plasma chloride and uric acid levels may be elevated. Vitamin D deficiency is common in patients with hyperparathyroidism, and it is prudent to screen for vitamin D deficiency with a serum 25-OH vitamin D determination. Serum 25-OH vitamin D levels below 20 mcg/L (50 nmol/L) can aggravate hyperparathyroidism and its bone manifestations.

Elevated serum levels of intact PTH confirm the diagnosis of hyperparathyroidism. Parathyroid carcinoma must always be suspected in patients with a serum calcium of 14.0 mcg/dL (3.5 mmol/L) or more and a serum PTH 5 or more times the upper limit of normal.

Patients with low bone density who have an elevated serum PTH but a normal serum calcium must be evaluated for causes of secondary hyperparathyroidism (eg, vitamin D or calcium deficiency, hyperphosphatemia, chronic kidney disease). In the absence of secondary hyperparathyroidism, patients with an elevated serum PTH but normal serum calcium are determined to have normocalcemic hyperparathyroidism.

Such individuals require monitoring, since hypercalcemia develops in about 19% of patients over 3 years of follow-up.

Genetic testing is recommended for patients with documented primary hyperparathyroidism who are younger than age 40 or who have multiglandular disease or a family history of hyperparathyroidism.

C. Imaging

Parathyroid imaging is not necessary for the diagnosis of hyperparathyroidism. Imaging is performed for most patients prior to parathyroid surgery and is particularly important for patients who have had prior neck surgery. The visualization of an apparent parathyroid adenoma helps secure the diagnosis when there is occasional diagnostic difficulty and often allows for minimally invasive surgery.

Ultrasound of the neck should scan the neck from the mandible to the superior mediastinum in an effort to locate ectopic parathyroid adenomas. Ultrasound has a sensitivity of 79% for single adenomas but only 35% for multiglandular disease.

Sestamibi scintigraphy with ^{99m}Tc-sestamibi and single-photon emission computed tomography (SPECT) is most useful for localizing parathyroid adenomas. However, false-positive scans are common, caused by thyroid nodules, thyroiditis, or cervical lymphadenopathy. Sestamibi-SPECT imaging improves sensitivity for single parathyroid adenomas. Small benign thyroid nodules are discovered incidentally in nearly 50% of patients with hyperparathyroidism who have imaging with ultrasound or MRI.

^{18}F-flurocholine PET/MRI is a useful scan for patients with primary hyperparathyroidism and negative or discordant localization imaging on neck ultrasound and sestamibi scanning. In a small study, the sensitivity of this scan was 90%, with a 100% positive predictive value.

Conventional CT and MRI imaging are not usually required prior to a first neck surgery for hyperparathyroidism. However, a four-dimensional CT (4D-CT), with the fourth dimension referring to time, captures the rapid uptake and washout of contrast from parathyroid adenomas; it is particularly useful for preoperative imaging when ultrasonography and sestamibi scans are negative. It can also be helpful for patients who have had prior neck surgery and for those with ectopic glands. In such patients, 4D-CT has a sensitivity of 88%, versus 54% for sestamibi SPECT and 21% for ultrasound. However, 4D-CT delivers more radiation to the thyroid and so is used mostly for older patients. MRI may also be useful for repeat neck operations and when ectopic parathyroid glands are suspected. MRI shows better soft tissue contrast than CT.

Noncontrast-enhanced CT scanning of the kidneys should be considered in all patients with hyperparathyroidism to determine whether calcium-containing stones are present. For patients with apparently asymptomatic hyperparathyroidism, the presence or absence of calcium nephrolithiasis can be a deciding factor about whether to have parathyroidectomy surgery.

Bone density measurements by dual energy x-ray absorptiometry (DXA) are helpful in determining the amount of bone loss in patients with hyperparathyroidism. Bone loss occurs mostly in long bones, and DXA should ideally include three areas: lumbar spine, hip, and distal radius.

Bone radiographs are usually normal and are not required to make the diagnosis of hyperparathyroidism.

Complications

Pathologic long bone fractures are a complication of hyperparathyroidism. Urinary tract infection due to stone and obstruction may lead to kidney disease and uremia. If the serum calcium level rises rapidly, clouding of sensorium, kidney disease, and rapid precipitation of calcium throughout the soft tissues may occur. Peptic ulcer and pancreatitis may be intractable before surgery. Insulinomas or gastrinomas may be associated, as well as pituitary tumors (MEN type 1). Pseudogout may complicate hyperparathyroidism both before and after surgical removal of tumors. Hypercalcemia during gestation produces neonatal hypocalcemia.

In tertiary hyperparathyroidism due to chronic kidney disease, high serum calcium and phosphate levels may cause disseminated calcification in the skin, soft tissues, and arteries (calciphylaxis); this can result in painful ischemic necrosis of skin and gangrene, cardiac arrhythmias, and respiratory failure. The actual serum levels of calcium and phosphate have not correlated well with calciphylaxis, but a calcium (mg/dL) × phosphate (mg/dL) product over 70 is usually present.

Differential Diagnosis

Artefactual hypercalcemia is common, so a confirmatory serum calcium level should be drawn after an overnight fast along with a serum protein, albumin, and triglyceride while ensuring that the patient is well-hydrated. Hypercalcemia may be due to high serum protein concentrations; in the presence of very high or low serum albumin concentrations, an adjusted serum calcium or a serum ionized calcium is more dependable than the total serum calcium concentration. Hypercalcemia may also be seen with dehydration.

Hypercalcemia of malignancy occurs most frequently with breast, lung, pancreatic, uterine, and renal cell carcinoma, and paraganglioma. Most of these tumors secrete PTH-related protein (PTHrP) that has tertiary structural homologies to PTH and causes bone resorption and hypercalcemia similar to those caused by PTH. Serum PTH levels are low or low-normal while serum PTHrP levels are elevated; phosphate is often low. Other tumors can secrete excessive 1,25 $(OH)_2$ vitamin D_3, particularly lymphoproliferative and ovarian malignancies. The clinical features of malignant hypercalcemia can closely simulate hyperparathyroidism.

Pseudohyperparathyroidism of pregnancy presents with hypercalcemia during pregnancy. It is caused by hypersensitivity of the breasts to PRL. The breasts become abnormally enlarged and secrete excessive amounts of PTHrP that causes hypercalcemia. Treatment with dopamine agonists reverses the hypercalcemia.

Plasma cell myeloma causes hypercalcemia in older individuals. Many other hematologic cancers, such as monocytic leukemia, T cell leukemia and lymphoma, and Burkitt lymphoma, have also been associated with hypercalcemia.

Sarcoidosis and other granulomatous disorders, such as tuberculosis, berylliosis, histoplasmosis, coccidioidomycosis, leprosy, and foreign-body granuloma, can cause hypercalcemia. Sarcoid granulomas can secrete PTHrP, but granulomas secrete $1,25(OH)_2D_3$ and serum levels of $1,25(OH)_2D_3$ are usually elevated in the presence of hypercalcemia. However, in hypercalcemia with disseminated coccidiomycosis, serum $1,25(OH)_2D_3$ levels may not be elevated. Serum PTH levels are usually low.

Excessive calcium or vitamin D ingestion can cause hypercalcemia, especially in patients who concurrently take thiazide diuretics, which reduce urinary calcium loss. Hypercalcemia is reversible following withdrawal of calcium and vitamin D supplements. If hypercalcemia persists, the possibility of associated hyperparathyroidism should be considered. In vitamin D intoxication, hypercalcemia may persist for several weeks. Serum levels of 25-hydroxycholecalciferol $(25[OH]D_3)$ are helpful to confirm the diagnosis. A brief course of corticosteroid therapy may be necessary if hypercalcemia is severe.

Familial hypocalciuric hypercalcemia (FHH) is an uncommon autosomal dominant inherited disorder. Three different loss-of-function germline mutations have been recognized as causative. Reduced function of the calcium-sensing receptor (CaSR) causes the parathyroid glands to falsely “sense” hypocalcemia and inappropriately release excessive amounts of PTH. The renal tubule CaSRs are also affected, causing hypocalciuria.

FHH was previously termed “benign FHH” and thought to be asymptomatic. However, FHH can sometimes present with neonatal severe primary hyperparathyroidism with serum calcium levels as high as 12 mg/dL and hyperparathyroidism and rickets-like bone disease with rib fractures in the newborn period. In adulthood, patients with hypercalcemia due to FHH are either asymptomatic or have nonspecific complaints such as fatigue, weakness, or cognitive issues. Recurrent pancreatitis can occur.

FHH is characterized by a mildly elevated serum calcium that is usually below 11.0

mg/dL (2.75 mmol/L) and a low urine calcium excretion that is usually less than 50 mg/24 h (13 mmol/24 h). Serum PTH levels are usually normal or minimally elevated. Serum phosphate levels are normal. About 4% of patients with true hyperparathyroidism can have a low urine calcium (below 100 mg/day). Therefore, FHH is most reliably confirmed with genetic testing for FHH gene mutations. These patients do not normalize their hypercalcemia after subtotal parathyroid removal and should not be subjected to surgery. Cinacalcet, a calcimimetic, has provided successful therapy for several reported patients.

Prolonged immobilization at bed rest commonly causes hypercalcemia, particularly in adolescents, critically ill patients, and patients with extensive Paget disease of bone. Hypercalcemia develops in about one-third of acutely ill patients being treated in intensive care units, particularly patients with acute kidney injury. Serum calcium elevations are typically mild but may reach 15 mg/dL (3.75 mmol/L). Serum PTH levels are usually slightly elevated, consistent with mild hyperparathyroidism but may be suppressed or normal.

Rare causes of hypercalcemia include untreated adrenal insufficiency. Modest hypercalcemia is occasionally seen in patients taking thiazide diuretics or lithium; such patients may have an inappropriately nonsuppressed PTH level with hypercalcemia. Hyperthyroidism causes increased turnover of bone and occasional hypercalcemia. Bisphosphonates can increase serum calcium in 20% and serum PTH becomes high in 10%, mimicking hyperparathyroidism. Hypercalcemia may also occur following liver transplantation. Other causes of hypercalcemia are shown in Table 21–8.

Treatment

A. “Asymptomatic” Primary Hyperparathyroidism

Patients with mild hyperparathyroidism should be considered “asymptomatic” only after very close questioning. Many patients may not realize they have manifestations, such as cognitive slowing, having become accustomed to such symptoms over years. It is important to assess blood pressure, kidney function with a serum BUN and creatinine, and to determine the presence of nephrolithiasis or nephrocalcinosis by radiography, ultrasonography, or CT scan of the kidneys. Truly asymptomatic patients may be closely monitored and advised to keep active, avoid immobilization, and drink adequate fluids. For postmenopausal women with hyperparathyroidism, estrogen replacement therapy reduces serum calcium by an average of 0.75 mg/dL (0.19 mmol/L) and slightly improves bone density. For patients with hypercalciuria (more than 400 mg daily) or calcium nephrolithiasis, hydrochlorthiazide may be used in doses of 12.5–25 mg daily to reduce calciuria; however, serum calcium must be monitored carefully.

Affected patients should avoid large doses of thiazide diuretics, vitamin A, and calcium-containing antacids or supplements. Serum calcium and albumin are checked at least twice yearly, kidney function and urine calcium once yearly, and three-site bone density (distal radius, hip, and spine) every 2 years. Rising serum calcium should prompt further evaluation and determination of serum PTH levels.

If it is not clear whether a patient with primary hyperparathyroid is symptomatic, it is reasonable to consider a trial of medical therapy with cinacalcet.

B. Medical Measures

1. Fluids—Hypercalcemia is treated with a large fluid intake unless contraindicated. Severe hypercalcemia requires hospitalization and intensive hydration with intravenous saline.

2. CaSR activators—Cinacalcet hydrochloride is a calcimimetic agent that binds to sites of the parathyroid glands' extracellular CaSRs to increase the glands' affinity for extracellular calcium, thereby decreasing PTH secretion. Cinacalcet may be used as the initial therapy for patients with hyperparathyroidism or for failed surgical parathyroidectomy. For mild hypercalcemia, an initial dose of 15 mg (one-half of a 30-mg tablet) is advisable with weekly monitoring of serum calcium and an increased dose every 2 weeks if hypercalcemia persists until the patient becomes normocalcemic, which is successful in 73% of patients. Patients with parathyroid carcinoma and severe hypercalcemia are treated with cinacalcet in addition to zoledronic acid. For parathyroid cancer, cinacalcet is administered in doses of 30 mg orally twice daily, increased progressively to 60 mg twice daily, then 90 mg twice daily to a maximum of 90 mg every 6–8 hours. Cinacalcet is usually well tolerated but may cause nausea and vomiting, which are usually transient. Hypocalcemia has occurred, even at 30 mg/day. About 50% of azotemic patients with secondary or tertiary hyperparathyroidism have hypercalcemia that is resistant to vitamin D analogs; cinacalcet is given orally in starting doses of 30 mg daily to a maximum of 250 mg daily, with dosage adjustments to keep the serum PTH in the range of 150–300 pg/mL (15.8–31.6 pmol/L). Etelcalcetide also activates the parathyroid glands' CaSR and reduces hypercalcemia in dialysis patients; it is given intravenously at the end of hemodialysis sessions, thereby avoiding the gastrointestinal side effects of cinacalcet.

3. Bisphosphonates—Intravenous bisphosphonates are potent inhibitors of bone resorption and can temporarily treat the hypercalcemia of hyperparathyroidism. Pamidronate in doses of 30–90 mg (in 0.9% saline) is administered intravenously over 2–4 hours. Zoledronic acid 5 mg is administered intravenously over 15–20 minutes. These drugs cause a gradual decline in serum calcium over several days that may last for weeks to months. Such intravenous bisphosphonates are used generally for patients with severe hyperparathyroidism in preparation for surgery. Oral bisphosphonates, such as alendronate, are not effective for treating the hypercalcemia or hypercalciuria of hyperparathyroidism. However, oral alendronate has been shown to improve bone mineral density in the lumbar spine and hip (not distal radius) and may be used for asymptomatic patients with hyperparathyroidism who have a low bone mineral density. It may also be combined with cinacalcet for the medical treatment of osteoporosis in patients with persistent hyperparathyroidism.

4. Denosumab—For patients with severe hypercalcemia due to parathyroid carcinoma, denosumab 120 mcg subcutaneously monthly may be effective. However, high-dose denosumab increases the risk of jaw osteonecrosis and serious infections.

5. Vitamin D and vitamin D analogs—

A. PRIMARY HYPERPARATHYROIDISM—For patients with vitamin D deficiency, vitamin D replacement may be beneficial to patients with hyperparathyroidism. Aggravation of hypercalcemia does not ordinarily occur. Serum PTH levels may fall with vitamin D replacement in doses of 800–2000 international units daily or more to achieve serum 25-OH vitamin D levels 30 ng/mL or more (50 nmol/L or more).

B. SECONDARY AND TERTIARY HYPERPARATHYROIDISM ASSOCIATED WITH AZOTEMIA—Calcitriol, given orally or intravenously after dialysis, suppresses parathyroid hyperplasia of kidney disease. For patients with normal serum calcium levels, it is given orally in starting doses of 0.25 mcg on alternate days or daily. Calcitriol often causes hypercalcemia, so that serum levels of calcium and phosphate must be monitored to ensure that the serum $Ca^{2+} \times PO_4^{3}$ product remains no greater than 70. If the product exceeds 70, the dose of calcitriol is decreased or the patient is switched to therapy with vitamin D analogs or cinacalcet.

The vitamin D analogs paricalcitol and doxercalciferol suppress PTH secretion and cause less hypercalcemia than calcitriol. The doses are adjusted to keep serum PTH levels in the range of 150–300 pg/mL (15.9–31.8 pmol/L). Paricalcitol is administered intravenously during dialysis three times weekly in starting doses of 0.04–0.1 mcg/kg to a maximum dose of 0.24 mcg/kg three times weekly. Alternatively, paricalcitol may be administered orally at doses of 1–2 mcg daily for serum PTH levels 100–500 pg/mL (10.5–53.7 pmol/L) or 2–4 mcg daily for serum PTH levels greater than 500 pg/mL (53.7 pmol/L). Dialysis patients receiving paricalcitol have improved survival compared with patients receiving calcitriol. Doxercalciferol is administered intravenously three times weekly during hemodialysis to patients with azotemic secondary hyperparathyroidism in starting doses of 4 mcg three times weekly to a maximum dose of 18 mcg three times weekly. Alternatively, doxercalciferol may be administered orally three times weekly at dialysis, starting with 10 mcg three times weekly at dialysis to a maximum of 60 mcg/wk.

6. Other measures—Estrogen replacement reduces hypercalcemia slightly in postmenopausal women with hyperparathyroidism. Similarly, oral raloxifene (60 mg/day) may be given to postmenopausal women with hyperparathyroidism; it reduces serum calcium an average of 0.4 mg/dL (0.1 mmol/L), while having an anti-estrogenic effect on breast tissue. Beta-blockers, such as propranolol, may also be useful for preventing the adverse cardiac effects of hypercalcemia. Parathyroid carcinoma metastases may be treated with radiofrequency ablation or arterial embolization.

C. Surgical Parathyroidectomy

Parathyroidectomy is recommended for patients with hyperparathyroidism who are symptomatic or who have nephrolithiasis or bone disease. During pregnancy, parathyroidectomy is performed in the second trimester for women who are symptomatic or have a serum calcium above 11 mg/dL (2.75 mmol/L).

Some patients with seemingly asymptomatic hyperparathyroidism may be surgical candidates for other reasons such as (1) serum calcium 1 mg/dL (0.25 mmol/L) above the upper limit of normal with urine calcium excretion greater than 50 mg/24 h (off thiazide diuretics), (2) urine calcium excretion greater than 400 mg/day (10 mmol/day), (3) creatinine clearance less than 60 mL/min, (4) nephrolithiasis or nephrocalcinosis, (5) cortical bone density (wrist, hip, or distal radius) indicating osteoporosis (T score below –2.5) or previous fragility bone fracture, (6) relative youth (under age 50 years), (7) difficulty ensuring medical follow-up, or (8) pregnancy.

Surgery for patients with “asymptomatic” hyperparathyroidism may improve bone mineral density and confer modest benefits in social and emotional well-being and overall quality of life in comparison to similar patients being monitored without surgery. Cognitive function may benefit with improvements in nonverbal abstraction and memory.

Preoperative parathyroid imaging has been used in an attempt to allow unilateral minimally invasive neck surgery (see Imaging, above). The reported success rates vary considerably. Even in patients with concordant sestamibi and ultrasound scans, and an intraoperative PTH drop of more than 50%, hyperparathyroidism may persist postoperatively in up to 15% of patients.

Without preoperative localization studies, bilateral neck exploration is usually advisable for the following: (1) patients with a family history of hyperparathyroidism, (2) patients with a personal or family history of MEN, and (3) patients wanting an optimal chance of success with a single surgery. Patients undergoing unilateral neck exploration can have the incision widened for bilateral neck exploration if two abnormal glands are found or if the serum quick PTH level falls by less than 63% within 10 minutes of the parathyroid resection. Parathyroid glands are often supernumerary (five or more) or ectopic (eg, intrathyroidal, carotid sheath, mediastinum). The optimal surgical management for patients with MEN type 1 is subtotal parathyroidectomy that usually results in a cure, although recurrent hyperparathyroidism develops in 18% and the rate of postoperative hypoparathyroidism is high.

Intraoperative quick serum PTH monitoring is helpful. Serum PTH levels that fall greater than 63% within 10 minutes of a parathyroid adenoma resection indicates a high likelihood that the surgery will be curative.

Intraoperative near-infrared autofluorescence spectroscopy imaging may improve intraoperative localization of parathyroid glands in primary hyperparathyroidism, particularly when preoperative localization studies have been negative or discrepant.

Parathyroid hyperplasia is commonly seen with secondary or tertiary hyperparathyroidism associated with uremia. Cinacalcet is an alternative to surgery. When surgery is performed, a subtotal parathyroidectomy is optimal; three and one-half glands are usually removed, and a metal clip is left to mark the location of residual parathyroid tissue.

Parathyroid carcinoma surgery consists of en bloc resection of the tumor and ipsilateral thyroid lobe with care to avoid rupturing the tumor capsule. If the surgical margins are not clear of tumor, postoperative neck radiation therapy may be given. Local and distant metastases may be debulked or irradiated. Preoperative MRI scanning is required to delineate the tumor. Zoledronic acid or denosumab is given preoperatively. Severe hypercalcemia requires multiple medical measures, including hydration, furosemide, cinacalcet, zoledronic acid, or denosumab. Patients with refractory metastases may receive combined chemotherapy with dacarbazine-based chemotherapy that has produced short-term remissions but with adverse effects.

Complications—Serum PTH levels fall below normal in 70% of patients within hours after successful surgery, commonly causing hypocalcemic paresthesias or even tetany. Hypocalcemia tends to occur the evening after surgery or on the next day. Therefore, frequent postoperative monitoring of serum calcium (or serum calcium plus albumin) is advisable beginning the evening after surgery. Once hypercalcemia has resolved, liquid or chewable calcium carbonate is given orally to reduce the likelihood of hypocalcemia. Symptomatic hypocalcemia is treated with larger doses of calcium; calcitriol (0.25–1 mcg daily orally) may be added, with the dosage depending on symptom severity. Magnesium salts are sometimes required postoperatively, since adequate magnesium is required for functional recovery of the remaining suppressed parathyroid glands.

In about 12% of patients having successful parathyroid surgery, PTH levels rise above normal (while serum calcium is normal or low) by 1 week postoperatively. This secondary hyperparathyroidism is probably due to “hungry bones” and is treated with calcium and vitamin D preparations. Such therapy is usually needed only for 3–6 months but is required long term by some patients.

Hyperthyroidism commonly occurs immediately following parathyroid surgery. It is caused by release of stored thyroid hormone during surgical manipulation of the thyroid. In symptomatic patients, short-term treatment with propranolol may be required for several days.

Prognosis

Patients with symptomatic hyperparathyroidism usually experience worsening disease (eg, nephrolithiasis) unless they have treatment. Conversely, the majority of completely asymptomatic patients with a serum calcium below 11.0 mg/dL (2.75 mmol/L) remain stable with follow-up. However, worsening hypercalcemia, hypercalciuria, and reductions in cortical bone mineral density develop in about one-third of asymptomatic patients. Therefore, asymptomatic patients must be monitored carefully and treated with oral hydration and mobilization.

Surgical removal of apparently single sporadic parathyroid adenomas is successful in 94%. Patients with MEN 1 undergoing subtotal parathyroidectomy may experience long remissions, but hyperparathyroidism frequently recurs. Despite treatment for hyperparathyroidism, patients remain at increased risk for all-cause mortality, cardiovascular disease, renal calculi, and kidney dysfunction. These increased risks are likely the residuals of pretreatment hypertension and nephrolithiasis.

Spontaneous cure due to necrosis of the tumor has been reported but is exceedingly rare. The bones, in spite of severe cyst formation, deformity, and fracture, will heal if hyperparathyroidism is successfully treated. The presence of pancreatitis increases the mortality rate. Acute pancreatitis usually resolves with correction of hypercalcemia, whereas subacute or chronic pancreatitis tends to persist. Significant kidney damage may progress even after removal of a parathyroid adenoma.

Parathyroid carcinoma is associated with 5- and 10-year survival rates of 78% and 49%, respectively. A better prognosis is associated with clear surgical margins and no detectable metastases postoperatively. Conversely, positive surgical margins or metastases predict a very poor 5-year survival. The prognosis is also poorer for nonfunctioning parathyroid carcinoma and those tumors that carry a CDC73 mutation, loss of fibromin, or loss of CaSR expression. Repeat surgical debulking procedures may improve survival. Aggressive medical management can also prolong life. Metastases are relatively radiation-resistant, but additional therapies such as radiofrequency ablation or arterial embolization may be palliative.

When to Refer

Refer to parathyroid surgeon for parathyroidectomy.

When to Admit

Patients with severe hypercalcemia for intravenous hydration.

METABOLIC BONE DISEASE

The term “metabolic bone disease” denotes those conditions producing diffusely decreased bone density and diminished bone strength. It is categorized by histologic appearance: osteoporosis (bone matrix and mineral both decreased) and osteomalacia (bone matrix intact, mineral decreased). Osteoporosis and osteomalacia often coexist in the same patient.

OSTEOPOROSIS

ESSENTIALS OF DIAGNOSIS

- Fracture propensity of spine, hip, pelvis, and wrist from depletion of bone matrix with subsequent demineralization.
- Asymptomatic until a fracture has occurred.
- Serum PTH, calcium, phosphorus, and alkaline phosphatase usually normal.
- Serum 25-hydroxyvitamin D levels often low as a comorbid condition.

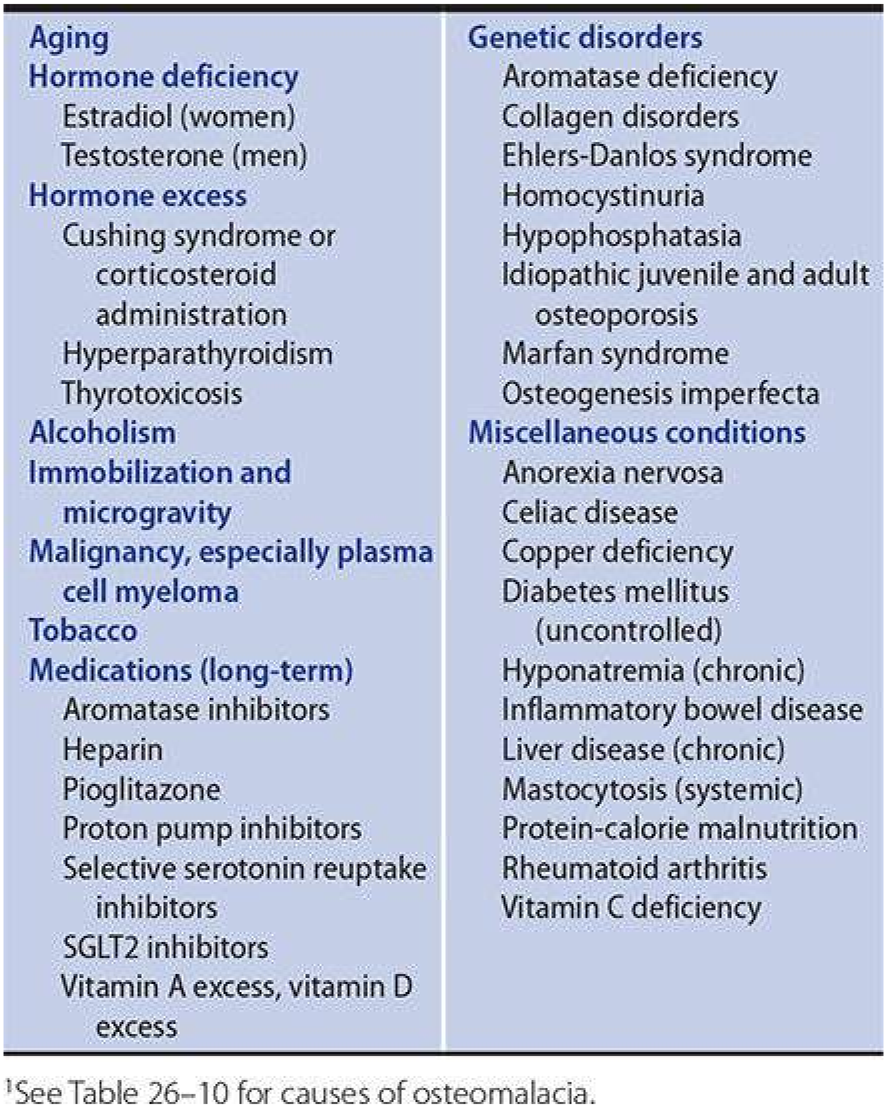
General Considerations

Osteoporosis is a skeletal disorder characterized by a loss of bone osteoid that reduces bone integrity and bone strength, predisposing to an increased risk of fracture. In the United States, osteoporosis causes over 1.5 million fractures annually, most commonly vertebral fractures, followed by hip fractures (300,000 annually) and pelvic fractures. In the United States, at least 20% of men and women over age 50 years have one or more fractured vertebrae. White women age 50 years and older (who do not receive estrogen replacement) have a 46% risk of sustaining an osteoporotic fracture during the remainder of their lives. Vertebral fractures are the most common fracture; they are associated with increased mortality, pain, and spinal kyphosis, although they are usually diagnosed incidentally on radiographs or CT scanning. Hip fractures are also associated with increased mortality, pain, reduced independence, and diminished quality of life.

The frequency of fragility fractures varies with ethnicity, sex, and age. The lifetime risk of hip fracture in the United States is 15.8% in white women and 6.0% in white men, 8.5% in Hispanic women and 3.8% in Hispanic men, and 2.4% in Chinese women and 1.9% in Chinese men. Blacks also have a lower risk for fracture due to higher bone mineral density and hip morphology that is less fracture-prone. There is much less ethnic variability for vertebral fractures. The prevalence of vertebral fractures in women older than 65 years is 70% for white women, 68% for Japanese women, 55% for Mexican women, and 50% in African American women.

Osteoporosis can be caused by a variety of factors (Table 26–9). The most common causes include aging, sex hormone deficiency, alcoholism, smoking, long-term proton pump inhibitor therapy, and high-dose corticosteroid administration. Hypogonadal men frequently develop osteoporosis. Anti-androgen therapy for prostate cancer can cause osteoporosis, and such men should be monitored with bone densitometry.

Table 26–9. Causes of osteoporosis.[1]



- **Aging**
- **Hormone deficiency**
  - Estradiol (women)
  - Testosterone (men)
- **Hormone excess**
  - Cushing syndrome or corticosteroid administration
  - Hyperparathyroidism
  - Thyrotoxicosis
- **Alcoholism**
- **Immobilization and microgravity**
- **Malignancy, especially plasma cell myeloma**
- **Tobacco**
- **Medications (long-term)**
  - Aromatase inhibitors
  - Heparin
  - Pioglitazone
  - Proton pump inhibitors
  - Selective serotonin reuptake inhibitors
  - SGLT2 inhibitors
  - Vitamin A excess, vitamin D excess
- **Genetic disorders**
  - Aromatase deficiency
  - Collagen disorders
  - Ehlers-Danlos syndrome
  - Homocystinuria
  - Hypophosphatasia
  - Idiopathic juvenile and adult osteoporosis
  - Marfan syndrome
  - Osteogenesis imperfecta
- **Miscellaneous conditions**
  - Anorexia nervosa
  - Celiac disease
  - Copper deficiency
  - Diabetes mellitus (uncontrolled)
  - Hyponatremia (chronic)
  - Inflammatory bowel disease
  - Liver disease (chronic)
  - Mastocytosis (systemic)
  - Protein-calorie malnutrition
  - Rheumatoid arthritis
  - Vitamin C deficiency

[1] See Table 26–10 for causes of osteomalacia.

Clinical Findings

A. Symptoms and Signs

Osteoporosis is usually asymptomatic until fractures occur. It may present as backache of varying degrees of severity or as a spontaneous fracture or collapse of a vertebra. Loss of height is common. Once osteoporosis is identified, a directed history and physical examination must be performed to determine its cause (Table 26–9).

B. Laboratory Findings

The objective for laboratory testing is to screen for secondary causes of osteoporosis or concomitant osteomalacia. For primary osteoporosis, the BUN, creatinine, albumin, serum calcium, phosphate, and PTH are normal. The alkaline phosphatase is usually normal but may be slightly elevated, especially following a fracture. A low serum alkaline phosphatase (below 40 units/L in adults) may indicate hypophosphatasia. A complete blood count is obtained and is usually normal; for patients with anemia, further screening is required, including a serum protein electrophoresis to screen for myeloma and intestinal malabsorption screening, where indicated. Vitamin D deficiency is very common and serum determination of 25-hydroxyvitamin D should be obtained for every individual with low bone density. Serum 25-hydroxyvitamin D levels below 20 ng/mL (50 nmol/L) are considered frank vitamin D deficiency. Lesser degrees of vitamin D insufficiency (serum 25-hydroxyvitamin D levels in the range of 20–30 ng/mL [50–75 nmol/L]) may also slightly increase the risk for hip fracture. Testing for thyrotoxicosis and hypogonadism may be required. If intestinal malabsorption is suspected, appropriate screening should be performed. Celiac disease may be screened for with serum tissue transglutaminase antibody determinations.

C. Bone Densitometry

Dual-energy x-ray absorptiometry (DXA) is used to determine the bone density of the lumbar spine, hip, and distal radius. Bone densitometry should be performed on all patients who are at risk for osteoporosis or osteomalacia, including all postmenopausal women aged 65 years and older and all men aged 70 years and older. DXA screening should also be considered for younger postmenopausal women with elevated risk, especially women with early menopause and those with a family history of osteoporosis. It should also be performed in younger patients who have had pathologic fractures or radiographic evidence of diminished bone density. DXA delivers negligible radiation, and the measurements are quite accurate. However, DXA cannot distinguish osteoporosis from osteomalacia; in fact, both are often present. Also, the bone mineral density does not directly measure bone quality and is only fairly successful at predicting fractures. Vertebral bone mineral density may be misleadingly high in compressed vertebrae and in patients with extensive arthritis. DXA also overestimates the bone mineral density of taller persons and underestimates the bone mineral density of smaller persons.

Bone mineral density is typically expressed in g/cm^2, for which there are different normal ranges for each bone and for each type of DXA-measuring machine. The “T score” is a simplified way of reporting bone density in which the patient’s bone mineral density is compared to the young normal mean and expressed as a standard deviation score. The World Health Organization has established criteria for defining osteoporosis based upon the T score:

T score ≥ –1.0: Normal.
T score –1.0 to –2.5: Osteopenia (“low bone density”).
T score < –2.5: Osteoporosis.
T score < –2.5 with a fracture: Severe osteoporosis.

It is prudent to obtain DXA bone density measurements at two or three sites, including total lumbar spine and total hip. DXA bone density of the non-dominant distal radius is helpful for patients with hyperparathyroidism, for men receiving androgen deprivation therapy, and for patients with conditions causing other DXA measurement artifacts. Such artifacts can be caused by hip arthroplasties, spinal orthopedic hardware, severe spinal arthritis, or lumbar vertebral compression fractures; in such patients, only noncompressed vertebrae are relevant. Any bone density classification is somewhat arbitrary and there really is no bone mineral density fracture threshold; instead, the fracture risk increases about twofold for each standard deviation drop in bone mineral density. Surveillance DXA bone densitometry is recommended for postmenopausal women and elderly men with a frequency according to their T scores: obtain DXA every 5 years for T scores –1.0 to –1.5, every 3–5 years for scores –1.5 to –2.0, and every 1–2 years for scores under –2.0.

The “Z score” is used to express bone density in premenopausal women and young adult men. The Z score is a statistical term expressing an individual’s bone density as standard deviation from age-matched, race-matched, and sex-matched means.

Pharmacologic treatment is recommended for patients with a spontaneous hip or vertebral fracture or a T score in any location less than or equal to –2.5.

Fracture Risk Assessment Tool (FRAX) was developed by the World Health Organization to better predict an individual’s 10-year risk of hip or other major osteoporotic fracture. It is particularly useful for treatment decisions in patients with osteopenia and takes into consideration age, sex, ethnicity, bone mineral density, and other risk factors. Treatment is recommended for individuals with osteopenia (T score between –1.0 and –2.5) with a computed 10-year hip fracture risk of at least 3% or a 10-year risk of any major fracture of at least 20%. However, the FRAX model has limitations, only considering femoral neck bone mineral density and not considering vertebral bone mineral density. Also, FRAX does not consider the dose of exposure to corticosteroids, alcohol, smoking, or an individual’s proclivity to falls; treatment decisions must always be individualized. FRAX is available for use online at http://www.shef.ac.uk/FRAX/.

Differential Diagnosis

Osteopenia and fractures can be caused by osteomalacia and bone marrow neoplasia such as myeloma or metastatic bone disease. These conditions coexist in many patients and cannot be distinguished with bone densitometry.

Prevention & Treatment

A. Nonpharmacologic Measures

For prevention and treatment of osteoporosis, the diet should be adequate in protein, total calories, calcium, and vitamin D. Pharmacologic corticosteroid (oral, parenteral, or inhaled) should be reduced or discontinued if possible. Cigarette smoking cessation is strongly urged. Excessive alcohol intake must be avoided. Exercise is strongly recommended to increase both bone density and strength, thereby reducing the risk of fractures due to frailty falls. Walking increases the bone density at both the spine and hip. Resistance exercise increases spine density. The patient must choose an enjoyable exercise regimen to facilitate long-term compliance. Other fall prevention measures include adequate home lighting, handrails on stairs, handholds in bathrooms, and physical therapy training in fall prevention and balance exercises. Patients who have weakness or balance problems must use a cane or a walker; rolling walkers should have a brake mechanism. Medications that cause orthostasis, dizziness, or confusion should be avoided.

B. Pharmacologic Measures

Generally, treatment is indicated for all patients with osteoporosis (DXA T scores below –2.5), women with previous fragility fractures of the hip or vertebra, or a DXA T score between –2.5 and –1.0 with FRAX-determined (see above) 10-year hip fracture risk greater than 3% or major osteoporotic fracture risk greater than 20%.

1. Vitamin D and calcium—Deficiency of vitamin D or calcium causes osteomalacia, rather than osteoporosis, but they often coexist and cannot be distinguished by DXA bone densitometry; it is crucial to ensure sufficient vitamin D and calcium intake. Recommended daily vitamin D intake of 600–800 units/day is difficult to achieve by diet (unless high in fish) and sun exposure, particularly during winter months and for patients with intestinal malabsorption or during prolonged hospitalization or nursing home care. Oral vitamin D_3 (cholecalciferol) is given either as a universal supplement of 800–2000 units/day or in doses titrated to achieve 25-hydroxvitamin D (25-OHD) serum levels greater than or equal to 20 ng/mL (50 nmol/L) for most of the population. However, the 25-OHD serum levels should be maintained at 30 ng/mL (75 nmol/L) or higher for those “at risk”: pregnant women, older adults, and those with osteoporosis or fragility fractures. There are early observational data of adverse outcomes (increased heart disease and all-cause mortality) at 25-OHD serum levels greater than 50 ng/mL (125 nmol/L), so the optimal therapeutic range for 25-OHD serum levels appears to about 30–50 ng/mL (75–125 nmol/L).

A total elemental calcium intake at least 1000 mg/day is recommended for all adults and 1200 mg/day for postmenopausal women and men older than 70 years. Most healthy individuals do not require calcium supplementation, and 74% of cohort studies showed no association between dietary calcium intake and fracture risk. Other studies have reported that associated calcium supplementation (1 g/day or more) showed no reduced risk for hip or forearm fractures and a mere 14% reduction in vertebral fractures. Calcium supplements are generally reserved for patients with intestinal malabsorption or calcium-deficient diets that do not include dairy products, dark leafy greens, sardines, tofu, or fortified foods. Calcium citrate does not require acid for absorption and is preferred for patients receiving acid blockers. Calcium carbonate should be taken with food to enhance calcium absorption. Calcium supplements are usually taken along with vitamin D_3, and many commercial supplements contain the combination.

Some reports have indicated that calcium supplements increase the risk of myocardial infarction. However, the Women's Health Initiative found that 7 years of vitamin D and calcium supplementation did not increase cardiovascular disease but did increase the risk of nephrolithiasis by 13%. Taking calcium supplements with meals can reduce the risk of nephrolithiasis. Although calcium supplements are usually tolerated, some patients experience intestinal bloating and constipation.

2. Sex hormones—Sex hormone replacement can prevent osteoporosis in hypogonadal women and men but is not an effective therapy for established osteoporosis. Low-dose transdermal systemic estrogen prevents osteoporosis in women with hypogonadism (see Hormone Replacement Therapy). Testosterone replacement therapy prevents osteoporosis in men with severe testosterone deficiency (see Male Hypogonadism).

3. Bisphosphonates—Bisphosphonate therapy is indicated for patients with a pathologic spine fracture or a low-impact hip fracture, and for patients with osteoporosis, defined as a DXA T score of –2.5 or less in the spine, total hip, or femoral neck. They are also indicated for patients with osteopenia (DXA T score between –2.5 and –1.5) and a FRAX-determined (see above) 10-year hip fracture risk greater than 3% or major osteoporotic fracture risk greater than 20%. Bisphosphonates all work similarly, inhibiting osteoclast-induced bone resorption. They increase bone density significantly and all reduce the incidence of vertebral fractures; all but ibandronate have been demonstrated to also reduce the risk of nonvertebral fractures. Bisphosphonates have also been effective in preventing corticosteroid-induced osteoporosis. To ensure intestinal absorption, oral bisphosphonates must be taken in the morning with at least 8 oz of plain water at least 40 minutes before consumption of anything else. The patient must remain upright after taking bisphosphonates to reduce the risk of esophagitis. No dosage adjustments are required for patients with creatinine clearances above 35 mL/min. There has been little experience giving bisphosphonates to patients with severe kidney disease; if given, the dose would need to be greatly reduced and serum phosphate levels monitored. Bone density falls in 18% of patients during their first year of treatment with bisphosphonates, but 80% of such patients gain bone density with continued bisphosphonate treatment. The half-life of bisphosphonates in bone is about 10 years. Therefore, after 3 years, a DXA bone densitometry may be obtained. If the patient's T score has risen above –2.5 and the patient has a relatively low fracture risk, the bisphosphonate may be discontinued. However, for patients with continued osteoporosis and a high fracture risk, the bisphosphonate may be continued another 2 years. The usual treatment course with bisphosphonates is 3–5 years due to the increasing risk of atypical femoral fractures after that time.

Alendronate is administered orally once weekly as either a 70-mg standard tablet (Fosamax) or a 70-mg effervescent tablet (Binosto). The effervescent tablet must be dissolved in 4 oz plain water over at least 5 minutes and stirred 10 seconds before drinking; it is easier to swallow for some patients and may reduce esophageal injury, but there have been no studies comparing it to standard alendronate tablets. **Risedronate** (Actonel) may be given once monthly as a 150-mg tablet. Risedronate is favored for women of childbearing age, since it has a shorter half-life and less bone retention than other bisphosphonates. Both medications reduce the risk of vertebral and nonvertebral fractures, but alendronate appears to be superior to risedronate in preventing nonvertebral fractures. **Ibandronate sodium** (Boniva) is taken once monthly in a dose of 150 mg orally. It reduces the risk of vertebral fractures but not nonvertebral fractures; its effectiveness has not been directly compared with other bisphosphonates. Oral bisphosphonates can cause nausea, chest pain, and hoarseness. Erosive esophagus can occur, particularly in patients with hiatal hernia and gastroesophageal reflux. Although no increased risk of esophageal cancer has been conclusively demonstrated, the FDA recommends that oral bisphosphonates not be used by patients with Barrett esophagus.

For patients who cannot take oral bisphosphonates, intravenous bisphosphonates are available. **Zoledronic acid** (Reclast) is a third-generation bisphosphonate and a potent osteoclast inhibitor. It can be given every 12 months in doses of 5 mg intravenously over at least 15–30 minutes. **Pamidronate** (Aredia) can be given in doses of 30–60 mg by slow intravenous infusion in normal saline solution every 3–6 months.

Bisphosphonate therapy can cause side effects that are collectively known as the acute-phase response. Such a response occurs in 42% of patients following the first infusion of zoledronic acid and usually starts within the first few days following the infusion. Among patients receiving their first infusion of zoledronic acid, these adverse side effects have included fever, chills, or flushing (20%); musculoskeletal pain (20%); nausea, vomiting, or diarrhea (8%); nonspecific symptoms, such as fatigue, dyspnea, edema, headache, or dizziness (22%); and ocular inflammation (0.6%). Intravenous zoledronic acid has caused seizures that may be idiosyncratic or due to hypocalcemia. The acute-phase response tends to diminish with time. Symptoms are transient, lasting several days and usually resolving spontaneously but typically recurring with subsequent doses. Symptoms may be treated with acetaminophen or NSAIDs.

Loratadine may reduce musculoskeletal pain. For patients experiencing a severe acute-phase response with zoledronic acid, intravenous pamidronate can be substituted for subsequent treatment. In addition, patients who experience an especially severe acute-phase response can be given prophylactic corticosteroids and ondansetron prior to subsequent bisphosphonate infusions.

Osteonecrosis of the jaw is a rare complication of bisphosphonate therapy for osteoporosis. A painful, necrotic, nonhealing lesion of the jaw occurs, particularly after tooth extraction. It occurs twice as frequently in the mandible compared to the maxilla. The risk is increased with older age, in women, and in patients concomitantly receiving chemotherapy or corticosteroid therapy. About 95% of jaw osteonecrosis cases have occurred with intravenous high-dose therapy with zoledronic acid or pamidronate for patients with osteolytic metastases. Only about 5% of cases have occurred in patients receiving oral bisphosphonates or once-yearly bisphosphonate infusions for osteoporosis. The incidence of osteonecrosis is estimated to be about 1:100,000 patients treated for osteoporosis with oral bisphosphonates and 1:100 patients being treated for cancer with intravenous bisphosphonates. The risk for osteonecrosis of the jaw with dental surgery can be approximated with a serum level of C-telopeptide, a fragment of collagen released during bone remodeling. Bisphosphonates reduce C-telopeptide levels. Serum C-telopeptide levels greater than or equal to 150 pg/mL are associated with a minimal risk of osteonecrosis, whereas C-telopeptide levels 100–149 pg/mL are associated with a moderate risk, and C-telopeptide levels less than 100 pg/mL are associated with a high risk for osteonecrosis. Patients receiving bisphosphonates must receive regular dental care and try to avoid dental extraction. Ideally, elective dental surgery should be completed before starting bisphosphonates. If dental surgery is required, bisphosphonate therapy is ordinarily stopped 3 months before the surgery and may be resumed about 1 month afterward if the bone has healed.

Atypical low-impact “chalkstick” fractures of the femoral shaft are a rare complication of bisphosphonate therapy. In more than 52,000 postmenopausal women taking bisphosphonates for 5 years or longer, a subtrochanteric fracture occurred in 0.22% during the subsequent 2 years; 27% of such fractures were bilateral. About 70% of affected patients have had prodromal thigh pain prior to the fracture. The risk for atypical femoral fractures is particularly increased among Asian women and among patients taking high-dose corticosteroids and those receiving bisphosphonate treatment for more than 5 years. Teriparatide may be helpful to promote healing of such fractures. Despite this rare complication, the overall risk of hip fracture is reduced among patients taking bisphosphonates for up to 5 years.

In patients taking bisphosphonates, hypercalcemia is seen in 20% and serum PTH levels increase above normal in 10%, mimicking primary hyperparathyroidism. Hypocalcemia occurs frequently, resulting in secondary hyperparathyroidism; such patients may be treated with oral calcium salt supplements (500–1000 mg/day) and with oral vitamin D_3 (starting at 1000 units/day).

4. Denosumab—Denosumab (Prolia) is a monoclonal antibody that inhibits the proliferation and maturation of preosteoclasts into mature osteoclast bone-resorbing cells. It does this by binding to the osteoclast receptor activator of nuclear factor-kappa B ligand (RANKL). It is indicated for treatment of osteoporosis, major fragility fractures, or osteopenia with a high FRAX score in both men and women. It is also used for patients with high fracture risk who are receiving sex hormone suppression therapy for breast cancer or prostate cancer. Treatment reduces vertebral fractures by 68% and reduces hip fractures by 40%. Denosumab is administered in doses of 60 mg subcutaneously every 6 months. Unlike bisphosphonates, denosumab can be given to patients with severe kidney disease. It has been relatively well tolerated, with an 8% incidence of flu-like symptoms. It can decrease serum calcium and should not be administered to patients with hypocalcemia. Other side effects include hypercholesterolemia, eczema and dermatitis, new malignancies, and pancreatitis. Denosumab may also increase the risk of serious infections, so it is not recommended for patients receiving high-dose corticosteroid therapy, whose risk of infection is already high. In women with childbearing potential, denosumab should be used with great caution and with birth control, since denosumab has caused fetal teratogenicity in animal studies. With prolonged use, denosumab predisposes to atypical femoral fractures and osteonecrosis of the jaw and is additive to bisphosphonates in that regard. As with bisphosphonates, denosumab is usually administered for a 3- to 5-year course.

Compared to oral bisphosphonates, denosumab appears to be slightly superior at improving bone mineral density of the spine, total femur, and femoral neck and at reducing fracture risk after 2 years of therapy. Compared to intravenous zoledronic acid, denosumab has been somewhat superior at increasing bone mineral density at the total femur and femoral neck, but the two have similar efficacy at improving spine bone mineral density.

5. PTH analogs—Teriparatide (Forteo) and **abaloparatide** (Tymlos) are analogs of PTH and PTHrP, respectively. These analogs are anabolic agents that stimulate the production of new collagenous bone matrix, particularly in vertebral trabecular bone that must be mineralized. Patients receiving teriparatide or abaloparatide must have sufficient intake of vitamin D and calcium. When given in a sequence with an antiresorptive agent, the preferred sequence is to first give a course of PTH/PTHrP analog therapy followed by a bisphosphonate or denosumab.

Teriparatide is administered subcutaneously in doses of 20 mg daily, whereas abaloparatide is given subcutaneously in doses of 80 mg daily. When administered to patients with osteoporosis for 2 years, these drugs dramatically improve bone density in most bones except the distal radius. They may also be used to promote healing of atypical femoral chalkstick fractures associated with bisphosphonate therapy. The recommended dose should not be exceeded, since both drugs have caused osteosarcoma in rats when administered long-term in very high doses. Due to the potential risk for osteosarcoma, patients are excluded from receiving teriparatide or abaloparatide if they have an increased risk of osteosarcoma due to the following: Paget disease of bone, unexplained elevations in serum alkaline phosphatase, prior radiation therapy to bones, open epiphyses, or a past history of osteosarcoma or chondrosarcoma. Side effects may include injection site reactions, orthostatic hypotension, arthralgia, muscle cramps, depression, or pneumonia. Hypercalcemia can occur and manifest as nausea, constipation, asthenia, or muscle weakness. These drugs are approved for only a 2-year course of treatment.

Teriparatide and abaloparatide should not be used for patients with hypercalcemia. Similarly, they should be used with caution in patients if they are also taking corticosteroids and thiazide diuretics along with oral calcium supplementation because hypercalcemia may develop.

Following a 2-year course of teriparatide or abaloparatide, bisphosphonates should be considered in order to retain the improved bone density. Alternatively, for very severe osteoporosis, these drugs may be administered along with denosumab; combined treatment for 2 years is more effective than any other single therapy.

6. Selective estrogen receptor modulators (SERMs)—SERMs can prevent osteoporosis but are not effective therapy for established osteoporosis. **Raloxifene** 60 mg/day orally may be taken by postmenopausal women in place of estrogen for prevention of osteoporosis. Bone density increases about 1% over 2 years in postmenopausal women versus 2% increases with estrogen replacement. It reduces the risk of vertebral fractures by about 40% but does not appear to reduce the risk of nonvertebral fractures. Raloxifene produces a reduction in LDL cholesterol, but not the rise in high-density lipoprotein (HDL) cholesterol seen with estrogen. It has no direct effect on coronary plaque. Unlike estrogen, raloxifene does not reduce hot flushes; in fact, it often intensifies them. It does not relieve vaginal dryness. Unlike estrogen, however, raloxifene does not cause endometrial hyperplasia, uterine bleeding, or cancer, nor does it cause breast soreness. The risk of breast cancer is reduced 76% in women taking raloxifene for 3 years. Since it is a potential teratogen, it is relatively contraindicated in women capable of pregnancy. Raloxifene increases the risk for thromboembolism and should not be used by women with such a history. Leg cramps can also occur. **Tamoxifen** is another SERM that is commonly administered to women for up to 5 years after resection of breast cancer that is estrogen receptor positive. **Bazedoxifene** is a SERM that is available as a fixed-dose combination medication with conjugated estrogens (dose: 0.45 mg/20 mg [Duavee]). It is FDA approved for the prevention of osteoporosis in postmenopausal women with an intact uterus. However, unlike raloxifene, it has not been shown to reduce the risk of breast cancer. Women taking this combination medication long-term experience an increased risk of thromboembolic events.

7. Calcitonin—Nasal salmon calcitonin is used primarily for its analgesic effect for the pain of acute osteoporotic vertebral compression fractures. It is ineffective for chronic pain. Its analgesic effect may be seen within 2–4 weeks. If it appears to be effective for analgesia, it is continued for up to 3 months. A nasal spray of calcitonin-salmon (Miacalcin) is available that contains 2200 units/mL in 2-mL metered-dose bottles. The usual dose is one puff (0.09 mL, 200 international units) once daily, alternating nostrils. Nasal symptoms such as rhinitis and epistaxis occur commonly; other less common adverse reactions include flu-like symptoms, allergy, arthralgias, back pain, headache, and hypocalcemia. Salmon calcitonin is available in an injectable form that can be used when the nasal formulation is not tolerated due to local reactions; it is used for up to 3 months for vertebral fracture pain in doses of 100 international units subcutaneously or intramuscularly every 1–2 days. Salmon calcitonin is no longer used long-term as an anti-osteoporosis therapy, since other available therapies are much more effective. Also, while long-term calcitonin therapy reduces the risk of breast cancer, it increases the risk of liver cancer.

8. Orthopedic surgery—Percutaneous vertebroplasty or kyphoplasty may be considered for patients with vertebral compression fractures who fail conservative pain management. However, no prospective randomized study has adequately compared the effectiveness of these orthopedic procedures compared to conservative therapy.

Prognosis

Osteoporosis should ideally be prevented, since it can be only partially reversed. Measures noted above are reasonably effective in preventing and treating osteoporosis and reducing fracture risk.

RICKETS & OSTEOMALACIA

ESSENTIALS OF DIAGNOSIS

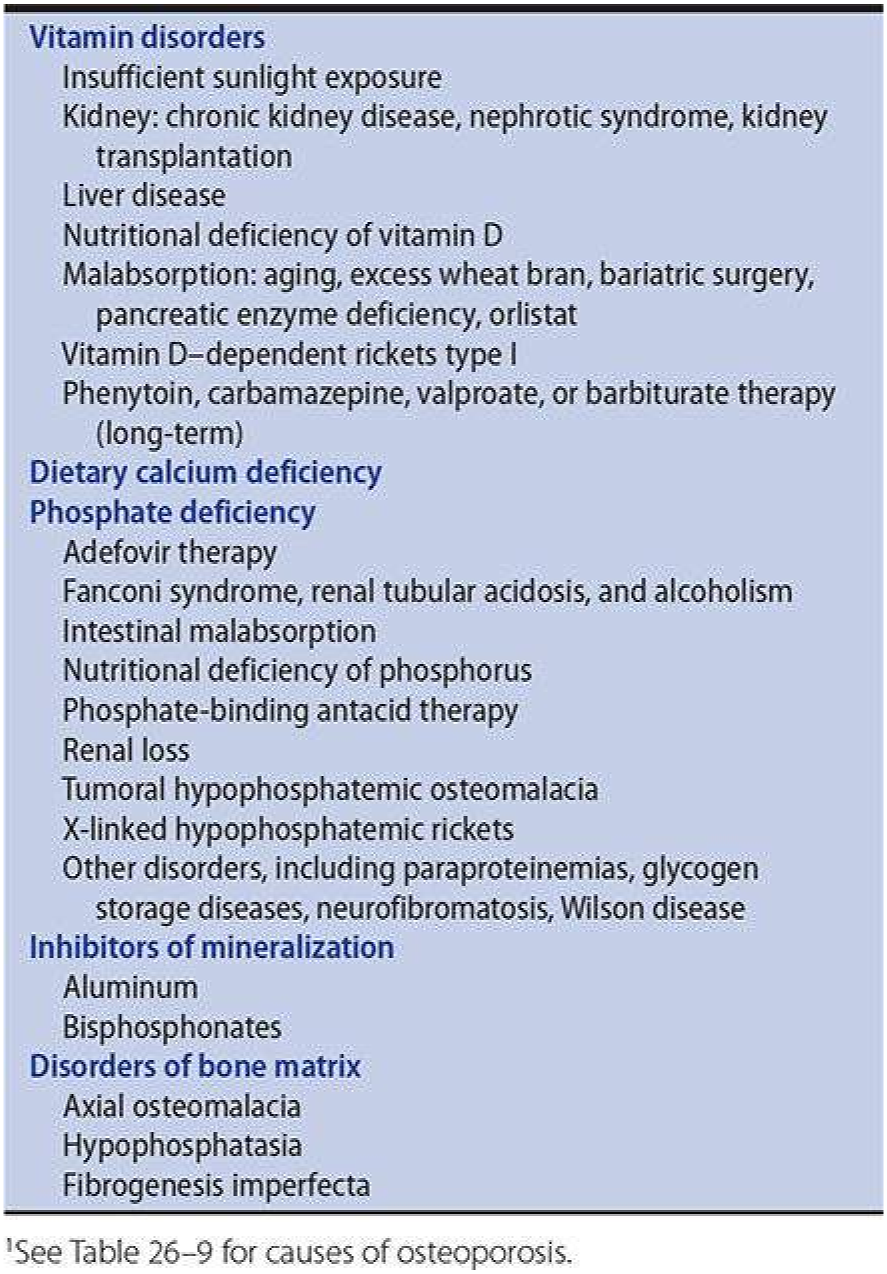
- Low bone density from defective mineralization.
- Caused by deficiency in calcium, phosphorus, or low alkaline phosphatase.
- **Rickets**: defective bone mineralization in childhood or adolescence before epiphyseal fusion.
- **Osteomalacia:** defective bone mineralization in adults with fused epiphyses.
- Painful proximal muscle weakness (especially pelvic girdle); bone pain.
- Low 25-hydroxy-vitamin D (25-OHD), hypocalcemia, hypocalciuria, hypophosphatemia, secondary hyperparathyroidism.
- Classic radiologic features may be present.

General Considerations

Defective mineralization of the growing skeleton in childhood causes permanent bone deformities (rickets). Defective skeletal mineralization in adults is known as osteomalacia. It is caused by any condition that results in inadequate calcium or phosphate mineralization of bone osteoid.

Etiology (Table 26–10)

Table 26–10. Causes of osteomalacia.[1]



- **Vitamin disorders**
  - Insufficient sunlight exposure
  - Kidney: chronic kidney disease, nephrotic syndrome, kidney transplantation
  - Liver disease
  - Nutritional deficiency of vitamin D
  - Malabsorption: aging, excess wheat bran, bariatric surgery, pancreatic enzyme deficiency, orlistat
  - Vitamin D–dependent rickets type I
  - Phenytoin, carbamazepine, valproate, or barbiturate therapy (long-term)
- **Dietary calcium deficiency**
- **Phosphate deficiency**
  - Adefovir therapy
  - Fanconi syndrome, renal tubular acidosis, and alcoholism
  - Intestinal malabsorption
  - Nutritional deficiency of phosphorus
  - Phosphate-binding antacid therapy
  - Renal loss
  - Tumoral hypophosphatemic osteomalacia
  - X-linked hypophosphatemic rickets
  - Other disorders, including paraproteinemias, glycogen storage diseases, neurofibromatosis, Wilson disease
- **Inhibitors of mineralization**
  - Aluminum
  - Bisphosphonates
- **Disorders of bone matrix**
  - Axial osteomalacia
  - Hypophosphatasia
  - Fibrogenesis imperfecta

[1] See Table 26–9 for causes of osteoporosis.

A. Vitamin D Deficiency and Resistance

Vitamin D deficiency is the most common cause of osteomalacia; its incidence is increasing throughout the world as a result of diminished exposure to sunlight caused by urbanization, automobile and public transportation, modest clothing, and sunscreen use. About 36% of adults in the United States are deficient in vitamin D.

Vitamin D deficiency is most commonly caused by insufficient sunlight exposure from living at high latitudes, winter season, institutionalization, wearing sun protection, or very modest dressing. Other risk factors for vitamin D deficiency include the following: pregnant women, infants breastfed exclusively, age over 65 years, obesity, dark skin, malnutrition, and intestinal malabsorption. Orlistat causes fat and vitamin D malabsorption. Cholestyramine binds bile acids necessary for vitamin D absorption. Patients with severe nephrotic syndrome lose large amounts of vitamin D–binding protein in the urine.

Anticonvulsants (eg, phenytoin, carbamazepine, valproate, phenobarbital) inhibit the hepatic production of 25-OHD and sometimes cause osteomalacia. Phenytoin can also directly inhibit bone mineralization.

Vitamin D–dependent rickets type I is caused by a rare autosomal recessive disorder with a defect in the renal enzyme 1-alpha-hydroxylase leading to defective synthesis of 1,25$(OH)_2$D. It presents in childhood with rickets and alopecia; osteomalacia develops in adults with this condition unless treated with oral calcitriol in doses of 0.5–1 mcg daily.

Vitamin D–dependent rickets type II (better known as hereditary 1,25$[OH]_2$D-resistant rickets) is caused by a genetic defect in the 1,25$(OH)_2$D receptor. Patients have hypocalcemia with childhood rickets and adult osteomalacia. Alopecia is common. These patients respond variably to oral calcitriol in very large doses (2–6 mcg daily).

B. Deficient Calcium Intake

The total daily consumption of calcium should be at least 1000 mg daily. Patients who have deficient calcium intake develop rickets (childhood) or osteomalacia (adulthood) despite sufficient vitamin D. A nutritional deficiency of calcium can occur in any severely malnourished patient. Some degree of calcium deficiency is common in older adults, since intestinal calcium absorption declines with age. Ingestion of excessive wheat bran also causes calcium malabsorption.

C. Phosphate Deficiency

Osteomalacia develops in patients with hypophosphatemia due to lack of sufficient phosphate to mineralize bone osteoid. Such patients typically have musculoskeletal pain, muscle weakness, and are prone to fractures.

1. Genetic disorders—Fibroblast growth factor-23 (FGF23) is a phosphaturic factor (phosphatonin) that is secreted by bone osteoblasts in response to elevated serum phosphate levels. Families with autosomal dominant hypophosphatemic rickets have a gain-of-function mutation in the gene encoding FGF23, which makes it resistant to proteolytic cleavage. In X-linked hypophosphatemic rickets, there is a mutation in the gene encoding PHEX endopeptidase, which fails to cleave FGF23. An autosomal recessive form of hypophosphatemic rickets is caused by mutations in DMP1, a transcription factor that regulates FGF23 production in bone. All three conditions have high serum FGF23 levels causing hypophosphatemia and bone mineral depletion.

2. Tumor-induced osteomalacia—A variety of mesenchymal tumors (87% benign) secrete FGF23 and cause marked hypophosphatemia due to renal phosphate wasting. Such tumors are usually phosphaturic mesenchymal tumors (70%); other tumors include hemangiopericytomas, osteosarcomas, and giant cell tumors. The condition is characterized by hypophosphatemia, excessive phosphaturia, reduced or normal serum $1,25(OH)_2D$ concentrations, and osteomalacia. Serum levels of FGF23 are elevated. Such tumors are often small and difficult to find, frequently lying in extremities.

3. Other causes of hypophosphatemia—Osteomalacia from hypophosphatemia can be caused by severe intestinal malabsorption or poor nutrition. Tenofovir therapy (tenofovir disoproxil fumarate more so than tenofovir alafamide) can cause renal phosphate wasting and hypophosphatemia. Severe hypophosphatemia can occur with refeeding after starvation. Hypophosphatemia can also be caused by chelation of phosphate in the gut by aluminum hydroxide antacids, calcium acetate (Phos-Lo), or sevelamer hydrochloride (Renagel). Excessive renal phosphate losses are also seen in proximal renal tubular acidosis and Fanconi syndrome.

D. Aluminum Toxicity

Bone mineralization is inhibited by aluminum. Osteomalacia may occur in patients receiving long-term renal hemodialysis with tap water dialysate or from aluminum-containing antacids used to reduce phosphate levels.

E. Hypophosphatasia

Hypophosphatasia must not be confused with hypophosphatemia. Hypophosphatasia refers to a severe deficiency of bone alkaline phosphatase. It is a rare genetic cause of osteomalacia that is commonly misdiagnosed as osteoporosis.

F. Fibrogenesis Imperfecta Ossium

This rare condition sporadically affects middle-aged patients, who present with progressive bone pain and pathologic fractures. Bones have a dense “fishnet” appearance on radiographs. Serum alkaline phosphatase levels are elevated. Some patients have a monoclonal gammopathy, indicating a possible plasma cell dyscrasia causing an impairment in osteoblast function and collagen disarray. Remission has been reported after repeated courses of melphalan, corticosteroids, and vitamin D analog over 3 years.

Clinical Findings

The clinical manifestations of osteomalacia depend on the underlying cause, severity, and the age at onset.

Neonates and young children with hypocalcemia may have spasms and convulsions. Older children and adolescents can have bone pain and muscle weakness and may develop the skeletal deformities of classic rickets, such as delayed longitudinal growth, deformities at epiphyses leading to thickened wrists and ankles, and bowing of the legs as well as bowed legs or knock-knees (adolescents). Kyphoscoliosis or lumbar lordosis is common. Thickening at the costochondral joints can cause widening of the chest and deformities known as a “rachitic rosary.”

In adults, osteomalacia is initially asymptomatic. Then, nonspecific complaints that include fatigue, reduced endurance and muscle strength, and pain in the bones involving their shoulders ribs, low back, and thighs develop. Pathologic fractures can occur with little or no trauma.

Hypocalcemia causes a reduced quality of life, with fatigue, irritability, depression, anxiety, cognitive impairment, lethargy, and paresthesias in the circumoral area, hands, and feet. More severe manifestations include muscle weakness or cramps, carpopedal spasm, convulsions, tetany, laryngospasm, and stridor. Hypophosphatemia can cause severe major muscle weakness, reduced endurance, dysphagia, diplopia, cardiomyopathy, and respiratory muscle weakness. Patients may also have impaired cognition.

Diagnostic Tests

Serum is obtained for calcium, albumin, phosphate, alkaline phosphatase, PTH, and 25-OHD determinations. Vitamin D deficiency is defined as a serum 25-OHD less than 20 ng/mL (50 nmol/L). Vitamin D insufficiency is defined as a serum 25-OHD between 20 ng/mL and 30 ng/mL (50–75 nmol/L). Patients in whom clinically severe osteomalacia develops typically have had chronic severe vitamin D deficiency (serum 25-OHD under 10 ng/mL or 25 nmol/L).

1,25$(OH)_2D_3$ may be low even when 25$(OH)D_2$ levels are normal. In one series of biopsy-proved osteomalacia, alkaline phosphatase was elevated in 94% of patients; the calcium or phosphorus was low in 47% of patients; 25$(OH)D_3$ was low in 29% of patients; and urinary calcium was low in 18% of patients. Pseudofractures were seen in 18% of patients. Radiographs may show diagnostic features. Bone densitometry helps document the degree of osteopenia.

Genetic testing can confirm the diagnosis of autosomal dominant hypophosphatemic rickets (FGF23), X-linked hypophosphatemic rickets (PHEX), and autosomal recessive hypophosphatemic rickets (DMP1).

Patients with apparent tumor-induced osteomalacia with hypophosphatemia require localization studies. Whole-body scanning with somatostatin analogs ^{68}Ga-DOTATOC PET/CT is the preferred imaging technique in this condition, detecting about 90% of tumors in small series.

Patients with hypophosphatasia have low serum levels of alkaline phosphatase (below 40 units/L in adults and below 20 units/L in severe cases). To confirm the diagnosis of hypophosphatasia in patients with a low serum alkaline phosphatase, a 24-hour urine is assayed for phosphoethanolamine, a substrate for tissue-nonspecific alkaline phosphatase whose excretion is always elevated in patients with hypophosphatasia. The diagnosis is further confirmed with genetic testing for mutations in the ALPL gene.

Differential Diagnosis

Osteomalacia often coexists with osteoporosis. The relative contribution of the two entities to diminished bone density may not be apparent until treatment, since a dramatic rise in bone density is often seen with therapy for osteomalacia. Phosphate deficiency must be distinguished from hypophosphatemia seen in hyperparathyroidism.

Prevention & Treatment

Humans naturally receive about 90% of their vitamin D from sunlight. To obtain adequate sunshine vitamin D, the face, arms, hands, or back must have sun exposure without sunscreen for 15 minutes at least twice weekly. In sunlight-deprived individuals (eg, veiled women, confined patients, or residents of higher latitudes during winter), vitamin D_3, 1000 international units daily, should be given prophylactically. Patients receiving long-term phenytoin therapy should also receive vitamin D_3 supplementation. The main natural food source of vitamin D is fish, particularly salmon, mackerel, cod liver oil, and sardines or tuna canned in oil. Most commercial cow's milk is fortified with vitamin D at about 400 international units (10 mcg) per quart; however, yogurt and cottage cheese may contain little to no vitamin D_3.

Many vitamin supplements contain plant-derived vitamin D_2, which has variable biologic availability. Over-the-counter multivitamin/mineral supplements contain variable amounts of vitamin D, and vitamin D toxicity has occurred from two different multivitamins sold in the United States. Therefore, it is prudent to recommend that patients take a dedicated vitamin D_3 supplement from a reliable manufacturer.

Frank vitamin D deficiency can be treated with ergocalciferol (D_2), 50,000 international units orally once weekly for 8 weeks. Some patients require long-term supplementation with D_2 of up to 50,000 international units weekly. The danger of high-dose D_2 therapy is that some patients may mistakenly take it daily. The alternative is to treat vitamin D–deficient patients with daily cholecalciferol D_3 at doses of at least 2000 international units daily. The recommended maximum daily dose of vitamin D_3 is 4000 international units/day for children and 10,000 international units/day for adults, with such high daily doses sometimes being required for patients with obesity, intestinal malabsorption, or following gastric bypass surgery. Some patients with severe malabsorption may require oral doses of 25,000–100,000 international units of vitamin D_3 daily. Some patients with steatorrhea respond better to oral $25(OH)D_3$ (calcifediol), 50–100 mcg/day. Serum levels of 25-OHD should be monitored, and the dosage of vitamin D adjusted to maintain serum 25-OHD levels above 30 ng/mL. The Endocrine Society has recommended a preferred target range of serum 25-OHD of 40–60 ng/mL.

Beyond increasing the intestinal absorption of calcium, vitamin D supplementation may improve muscle strength and reduce fall risk, factors that reduce the risk of bone fracture.

The addition of calcium supplements to vitamin D is probably not necessary for the prevention of osteomalacia in the majority of otherwise well-nourished patients. However, patients with malabsorption or poor nutrition should receive calcium supplementation: calcium citrate (eg, Citracal), 0.4–0.6 g elemental calcium per day, or calcium carbonate (eg, OsCal, Tums), 1–1.5 g elemental calcium per day. Calcium supplements are best administered with meals.

In hypophosphatemic rickets or osteomalacia, nutritional deficiencies are corrected, aluminum-containing antacids are discontinued, and patients with renal tubular acidosis are given bicarbonate therapy. In patients with sporadic adult-onset hypophosphatemia, hyperphosphaturia, and low serum $1,25(OH)_2D$ levels, a search is conducted for occult tumors; whole-body MRI scanning may be required.

For those with X-linked or idiopathic hypophosphatemia and hyperphosphaturia, oral phosphate supplements must be given long term. Calcitriol, 0.25–0.5 mcg/day, is given also to improve the impaired calcium absorption caused by the oral phosphate. Oral phosphate causes diarrhea at higher doses, and many patients do not achieve normal serum phosphate levels. If necessary, recombinant human growth hormone (rhGH) may be added to the above regimen to reduce phosphaturia. The hypophosphatemia of autosomal dominant hypophosphatemic rickets has been reported to resolve with high-dose dietary iron supplementation.

Patients with hypophosphatasia may be treated with asfotase alfa (Strensiq), which is administered subcutaneously in doses of 2 mg/kg three times weekly; adverse effects include injection site reactions, lipodystrophy ectopic calcifications, and hypersensitivity reactions. Patients have also been treated with teriparatide with improvement in bone pain and fracture healing.

PAGET DISEASE OF BONE (Osteitis Deformans)

ESSENTIALS OF DIAGNOSIS

- Often asymptomatic.
- Bone pain may be the first symptom.
- Kyphosis, bowed tibias, large head, deafness, and frequent fractures.
- Serum calcium and phosphate normal; elevated alkaline phosphatase and urinary hydroxyproline.
- Dense, expanded bones on radiographs.

General Considerations

Paget disease of bone is manifested by one or more bony lesions having high bone turnover and disorganized osteoid formation. The involved bone first has increased osteoclast activity, causing lytic lesions in bone that may progress at about 1 cm/year. Increased osteoblastic activity follows, producing a high rate of disorganized bone formation. Involved bones become vascular, weak, and deformed. Eventually, there appears to be a final burned-out phase with markedly reduced bone cell activity and abnormal bones that may be enlarged with skeletal deformity.

The prevalence of Paget disease has declined by about 36% over the past 20 years, yet it is the second most common bone disease after osteoporosis. In the United States, Paget disease affects 3% of whites over age 55 years, with its prevalence increasing with age. It is uncommon in Africa, Asia, and Scandinavia. Usually diagnosed in patients over age 40 years, its prevalence doubles with each decade thereafter, reaching an incidence of about 10% after age 80. About 20% of cases are symptomatic, but most cases are discovered incidentally during radiology imaging or because of incidentally discovered elevations in serum alkaline phosphatase.

The cause of Paget disease is unknown. About 20% of cases are familial and transmitted as an autosomal dominant trait with incomplete penetrance. Mutations in the SQSTM1 gene have been discovered in about 35% of patients with familial Paget disease and in 7% of patients with apparently sporadic Paget disease.

Clinical Findings

A. Symptoms and Signs

Paget disease is often mild and asymptomatic. Only 27% of affected individuals are symptomatic at the time of diagnosis. Paget disease involves multiple bones (polyostotic) in 72% and only a single bone (monostotic) in 28%. It occurs most commonly in the pelvis, vertebrae, femur, humerus, and skull. The affected bones are typically involved simultaneously, and the disease tends not to involve additional bones during its course. Pain, often described as aching and deep and often worse at night, is the usual first symptom. It may occur in the involved bone or in an adjacent joint, which can be involved with degenerative arthritis. Paget disease typically first affects long bones proximally and then advances distally, with bone pain at the osteolytic front being aggravated by weight bearing. Joint surfaces (such as the knee) can be involved and cause arthritic pain. The bones can become soft, leading to bowed tibias, kyphosis, and frequent “chalkstick” fractures with slight trauma. If the skull is involved, the patient may report headaches and an increased hat size; the finding of dilated scalp veins, present in half such patients, is known as the “scalp vein sign.” Involvement of the petrous temporal bone frequently damages the cochlea and causes hearing loss (mixed sensorineural and conductive) and occasionally tinnitus or vertigo. Increased vascularity over the involved bones causes increased warmth and can cause vascular “steal” syndromes.

B. Laboratory Findings

Serum alkaline phosphatase is usually markedly elevated. However, some patients with monostotic involvement may have normal serum alkaline phosphatase levels. A serum bone-specific alkaline phosphatase is usually high and is useful for patients with a normal serum alkaline phosphatase and to distinguish the source of an elevated alkaline phosphatase as being from bone (rather than liver). However, bone alkaline phosphatase is less useful for following the effectiveness of therapy. Other useful measures for bone turnover are serum N-terminal propeptide of type 1 collagen (NTx) and serum beta C-terminal propeptide of type 1 collagen (betaCTx). However, such bone turnover markers may overestimate or underestimate the response to treatment. Serum calcium may be elevated, particularly if the patient is at bed rest. A serum 25-OH vitamin D determination should be obtained to screen for vitamin D deficiency, which can also present with an increased serum alkaline phosphatase and bone pain.

C. Imaging

On radiographs, the initial lesions are typically osteolytic, with focal radiolucencies (“osteoporosis circumscripta”) in the skull or advancing flame-shaped lytic lesions in long bones. Bone lesions may subsequently become sclerotic and have a mixed lytic and sclerotic appearance. The affected bones eventually become thickened and deformed. Technetium-99m pyrophosphate bone scans are helpful in delineating activity of bone lesions even before any radiologic changes are apparent.

Differential Diagnosis

Certain rare familial types of sclerosing bone dysplasias share phenotypic homologies with Paget disease of bone. The differential diagnosis also includes myelofibrosis, intramedullary osteosclerosis, Erdheim-Chester disease, Langerhans cell histiocytosis, and sickle cell disease.

Paget disease must be differentiated from primary bone lesions such as osteogenic sarcoma, plasma cell myeloma, and fibrous dysplasia and from secondary bone lesions such as osteitis fibrosa cystica and metastatic carcinoma to bone. Fibrogenesis imperfecta ossium is a rare symmetric disorder that can mimic the features of Paget disease; serum alkaline phosphatase is likewise elevated. This condition may be associated with paraproteinemias.

Complications

If immobilization occurs, hypercalcemia and renal calculi may develop. With severe polyostotic disease, the increased vascularity may give rise to high-output heart failure. Arthritis frequently develops in joints adjacent to involved bone.

Extensive skull involvement may cause cranial nerve palsies from impingement of the neural foramina. Skull involvement can also cause a vascular steal syndrome with somnolence or ischemic neurologic events; the optic nerve may be affected, resulting in loss of vision. Jaw involvement can cause the teeth to spread intraorally and become misaligned. Vertebral collapse can cause compression of spinal cord or spinal nerves, resulting in radiculopathy or paralysis. Vertebral involvement can also cause a vascular steal syndrome with paralysis. Surgery for fractured long bones is often complicated by excessive blood loss from these vascular lytic lesions.

A sarcoma or giant cell tumor may develop in long-standing lesions but is rare (less than 1%). Sarcomatous change is suggested by a marked increase in bone pain, sudden rise in alkaline phosphatase, and appearance of a new lytic lesion.

Treatment

Asymptomatic patients may require only clinical surveillance and no treatment. However, treatment should be considered for asymptomatic patients who have significant involvement of the skull, long bones, or vertebrae. Patients must be monitored carefully before, during, and after treatment with clinical examinations and serial serum alkaline phosphatase determinations.

Bisphosphonates are used to treat patients with Paget disease. Zoledronic acid is the treatment of choice. Administered intravenously as a single 5-mg dose, it normalizes the serum alkaline phosphatase in 89% of patients by 6 months and in 98% by 2 years.

Zoledronic acid should be administered prior to total arthroplasty for a Paget-involved joint in order to reduce the risk of intraoperative hemorrhaging and loosening of the prosthesis postoperatively. Zoledronic acid should also be administered before osteotomy for severe bowing of a lower extremity caused by Paget disease. For patients with paraplegia due to vertebral involvement, intravenous zoledronic acid should be given while neurosurgical consultation is obtained.

Patients frequently experience a paradoxical increase in pain at sites of disease soon after commencing bisphosphonate therapy; this is the “first dose effect” and the pain usually subsides with further treatment. Following intravenous zoledronic acid, patients frequently experience fever, fatigue, myalgia, bone pain, and ocular problems. Serious side effects are rare but include seizures, uveitis, and acute kidney disease. Asthma may occur in aspirin-sensitive patients. Hypocalcemia is common and may be severe, especially if intravenous bisphosphonates are given along with loop diuretics. Therefore, it is advisable to administer calcium and vitamin D supplements, especially during the first 2 weeks following treatment. Any vitamin D deficiency should be corrected before prescribing a bisphosphonate.

Oral bisphosphonate regimens are inferior to intravenous zoledronic acid for therapy of Paget disease. However, if they are given, to prevent esophageal complications, oral bisphosphonates should be taken with 8 oz of plain water only; they are relatively contraindicated in patients with a history of esophagitis, esophageal stricture, dysphagia, hiatal hernia, or achalasia.

Prognosis

The prognosis is good, but relapse can occur after an initial successful treatment with bisphosphonate. By 6.5 years after initial therapy, the recurrence rate is 12.5% after treatment with zoledronic acid and 62% after risedronate. Therefore, patients must be monitored long term, measuring serum alkaline phosphatase at least yearly. In general, the prognosis is worse the earlier in life the disease starts. Fractures usually heal well. In the severe forms, marked deformity, intractable pain, and high-output heart failure occur if not treated with bisphosphonates. Osteosarcoma that arises at sites of Paget disease results in a 2-year survival of only 25%.

DISEASES OF THE ADRENAL CORTEX

PRIMARY ADRENAL INSUFFICIENCY (Addison Disease)

ESSENTIALS OF DIAGNOSIS

- Weakness, vomiting, diarrhea; abdominal pain, arthralgias; amenorrhea.
- Sparse axillary hair; increased skin pigmentation, especially of creases, pressure areas, and nipples.
- Hypotension, small heart.
- Hyponatremia; potassium, calcium, and BUN elevated; mild anemia and relative neutropenia, lymphocytosis, and eosinophilia.
- Plasma ACTH level elevated; cosyntropin unable to stimulate serum cortisol to 20 mcg/dL (550 nmol/L) or more.

- **Acute adrenal crisis:** above manifestations become critical, with fever, shock, confusion, coma, death.

General Considerations

Primary adrenal insufficiency (Addison disease) is caused by dysfunction or absence of the adrenal cortices. It is distinct from secondary adrenal insufficiency caused by deficient secretion of ACTH.

Addison disease is an uncommon disorder with a prevalence of about 140 per million and an annual incidence of about 5 cases per million in the United States. Addison disease is characterized by a chronic deficiency of cortisol. Serum ACTH and alpha-MSH levels are consequently elevated, causing pigmentation that ranges from none to strikingly dark. Patients with destruction of the adrenal cortices or with classic 21-hydroxylase deficiency also have mineralocorticoid deficiency, typically with hyponatremia, volume depletion, and hyperkalemia. In contrast, mineralocorticoid deficiency is not present in patients with familial corticosteroid deficiency and Allgrove syndrome.

Acute adrenal (addisonian) crisis is an emergency caused by insufficient cortisol. Crisis may occur in the course of treatment of chronic adrenal insufficiency, or it may be the presenting manifestation of adrenal insufficiency. Acute adrenal crisis is more commonly seen in primary adrenal insufficiency than in secondary adrenal insufficiency.

Adrenal crisis may occur in the following situations: (1) during stress (eg, infection, trauma, surgery, hyperthyroidism, or prolonged fasting) in a patient with latent or treated adrenal insufficiency; (2) following sudden withdrawal of adrenocortical hormone in a patient with chronic insufficiency or in a patient with temporary insufficiency due to suppression by exogenous corticosteroids or megestrol; (3) following bilateral adrenalectomy or removal of a functioning adrenal tumor that had suppressed the other adrenal gland; (4) following sudden destruction of the pituitary gland (pituitary necrosis), or when thyroid hormone is given to a patient with adrenal insufficiency; (5) following injury to both adrenals (by trauma, hemorrhage, anticoagulant therapy, thrombosis, infection or, rarely, metastatic carcinoma); and (6) following administration of intravenous etomidate (used for rapid anesthesia induction or intubation).

Etiology

Autoimmunity is the most common cause of Addison disease in industrialized countries, accounting for about 90% of spontaneous cases. With such autoimmunity, adrenal function decreases over several years as it progresses to overt adrenal insufficiency. Over half the cases of autoimmune Addison disease occur as part of autoimmune polyendocrine syndrome (APS-I), also known as APECED syndrome. APS-I is caused by a defect in T cell–mediated immunity inherited as an autosomal recessive trait. APS-I usually presents in early childhood with mucocutaneous candidiasis, followed by hypoparathyroidism and dystrophy of the teeth and nails; Addison disease usually appears by age 15 years. Partial or late expression of the syndrome is common. A varied spectrum of associated diseases may be seen in adulthood, including hypogonadism, hypothyroidism, pernicious anemia, alopecia, vitiligo, hepatitis, malabsorption, and Sjögren syndrome.

Tuberculosis is the most common infection of the adrenals. Coccidioidomycosis, histoplasmosis, cytomegalovirus infection, and syphilitic gummas are rare causes and usually occur in immunocompromised patients.

Infections of the adrenal glands, particularly with cytomegalovirus, are found in nearly half of patients with untreated HIV at autopsy. However, a much lower percentage have clinical Addison disease. The diagnosis of adrenal insufficiency in HIV patients is often problematic. A cortisol resistance syndrome has been described in patients with HIV, and a revision of normal range for the cosyntropin test for these patients has been advocated (normal peak cortisol over 22 mcg/dL). Also, isolated hyperkalemia occurs commonly in HIV patients, particularly during therapy with pentamidine; this is usually due to isolated hypoaldosteronism and responds to mineralocorticoid (fludrocortisone) therapy alone.

Bilateral adrenal hemorrhage may occur with sepsis, heparin-associated thrombocytopenia, anticoagulation, or the antiphospholipid antibody syndrome. It may occur in association with major surgery or trauma, presenting about 1 week later with pain, fever, and shock. It may also occur spontaneously and present with flank pain. Meningococcemia may be associated with purpura and adrenal insufficiency secondary to adrenal infarction (Waterhouse-Friderichsen syndrome).

Adrenoleukodystrophy is an X-linked peroxisomal disorder causing accumulation of very long-chain fatty acids in the adrenal cortex, testes, brain, and spinal cord. It may present at any age and accounts for one-third of cases of Addison disease in boys. Aldosterone deficiency occurs in 9%. Hypogonadism is common.

Rare causes of adrenal insufficiency include lymphoma, metastatic carcinoma, scleroderma, amyloidosis, and hemochromatosis.

Congenital adrenal insufficiency occurs in several conditions. Familial corticosteroid deficiency is an autosomal recessive disease that is caused by mutations in the adrenal ACTH receptor (melanocortin 2 receptor, MC2R). It is characterized by isolated cortisol deficiency and ACTH resistance and may present with neonatal hypoglycemia, frequent infections, and dark skin pigmentation. Triple A (Allgrove) syndrome is caused by a mutation in the AAAS gene that encodes a protein known as ALADIN (**al**achrima, **a**chalasia, a**d**renal **i**nsufficiency, **n**eurologic disorder). Cortisol deficiency usually presents in infancy but may not occur until the third decade of life.

Congenital adrenal hypoplasia causes adrenal insufficiency due to absence of the adrenal cortex; patients may also have hypogonadotropic hypogonadism, myopathy, and high-frequency hearing loss.

Congenital adrenal hyperplasia is caused by various genetic defects in the enzymes responsible for steroid synthesis. Due to defective cortisol synthesis, patients have variable degrees of adrenal insufficiency and increased levels of ACTH that causes hyperplasia of the adrenal cortex. The most common enzyme defect is P450c21 (21-hydroxylase deficiency). Patients with severely defective P450c21 (classic congenital adrenal hyperplasia) manifest a deficiency of mineralocorticoids (salt wasting) in addition to deficient cortisol and excessive androgens. Hypertension commonly develops in older adult patients. Testicular adrenal rests can be found in 44% of men with the condition. Women with milder enzyme defects have adequate cortisol, but develop hirsutism in adolescence or adulthood and are said to have "late-onset" congenital adrenal hyperplasia.

Drugs that cause primary adrenal insufficiency include mitotane and abiraterone acetate.

Clinical Findings

A. Symptoms and Signs

The onset of symptoms can occur suddenly but usually develops gradually over months or years. The diagnosis is often delayed, since many early symptoms are nonspecific. Nearly all patients complain of fatigue, reduced stamina, weakness, anorexia, and weight loss. Abdominal pain, nausea, and vomiting eventually develop in most patients; diarrhea can occur. Fevers and lymphoid tissue hyperplasia may also occur. Patients often have significant pain: arthralgias, myalgias, chest pain, abdominal pain, back pain, leg pain, or headache. Psychiatric symptoms include anxiety, irritability and depression. Cerebral edema can cause headache, vomiting, gait disturbance, and intellectual dysfunction that may progress to coma. Hypoglycemia can occur and worsen the patient's weakness and mental functioning. Patients often have salt craving. Blood pressure is usually low and orthostatic; about 90% have systolic blood pressures under 110 mm Hg; blood pressure over 130 mm Hg is rare. Hypotension is aggravated by dehydration caused by nausea or vomiting.

Skin hyperpigmentation eventually occurs in most patients due to increased pituitary secretion of alpha-MSH (melanocyte-stimulating hormone). Skin hyperpigmentation varies among affected patients (eg, from none to increased freckling to diffuse darkening that resembles a suntan or a bronze appearance). Sun-exposed areas darken the most, but nonexposed areas darken as well. Hyperpigmentation is often especially prominent over the knuckles, elbows, knees, posterior neck, palmar creases, gingival mucosa, and vermilion border of the lips. Nail beds may develop longitudinal pigmented bands. Nipples and areolas tend to darken. The skin also darkens in pressure areas, such as the belt or brassiere lines and the buttocks. Skin folds and new scars may also become pigmented. Conversely, patches of autoimmune vitiligo can be found in about 10% of patients. Scant axillary and pubic hair typically develops in women.

In pregnancy, undiagnosed adrenal insufficiency is rare, since the condition tends to cause anovulation and reduced fertility. In the first trimester, symptoms such as fatigue, nausea, vomiting, abdominal pain, and orthostasis are typically attributed to the pregnancy, thus delaying the diagnosis. Worse, the increased skin pigmentation of adrenal insufficiency may be mistaken for chloasma (melasma). Undiagnosed adrenal insufficiency can cause intrauterine growth retardation and fetal loss. Pregnant women with undiagnosed adrenal insufficiency can experience shock from adrenal crisis, particularly during the first trimester, concurrent illness, labor, or postpartum.

Patients with preexistent type 1 diabetes experience more frequent hypoglycemia with the onset of adrenal insufficiency, such that their insulin dosage must be reduced.

Acute adrenal crisis is an immediate threat to life. Nausea, vomiting, fever, dehydration, and profound hypotension progresses to life-threatening shock that does not fully respond to intravenous fluids and vasopressors.

B. Laboratory Findings

The WBC count typically shows moderate neutropenia, lymphocytosis, and eosinophilia (total eosinophil count over 300/mcL). Among patients with chronic adrenal insufficiency, the serum sodium is usually low (88%) and the potassium usually elevated (64%). However, patients with vomiting or diarrhea may not be hyperkalemic. Fasting hypoglycemia is common. Hypercalcemia may be present.

A plasma cortisol less than 3 mcg/dL (83 nmol/L) at 8 AM is diagnostic, especially if accompanied by simultaneous elevation of the plasma ACTH level greater than 200 pg/mL (44 pmol/L). The diagnosis is confirmed by a simplified cosyntropin stimulation test: (1) Synthetic ACTH_{1-24} (cosyntropin), 0.25 mg, is given intramuscularly. (2) Serum cortisol is obtained 45 minutes after cosyntropin is administered. Normally, serum cortisol rises to at least 20 mcg/dL (550 pmol/L), whereas patients with adrenal insufficiency have stimulated serum cortisol levels less than 20 mcg/dL (550 pmol/L). For patients receiving corticosteroid treatment, hydrocortisone must not be given for at least 8 hours before the test. Other corticosteroids (eg, prednisone, dexamethasone) do not interfere with specific assays for cortisol. Cosyntropin is usually well tolerated, but infrequent (less than 5%) side effects have included hypersensitivity reactions with nausea, headache, dizziness, dyspnea, palpitations, flushing, edema, and local injection site reactions. Cosyntropin may be administered during pregnancy; however, the test may lack sensitivity, since adrenal ACTH-responsiveness increases during pregnancy.

Serum DHEA levels are less than 1000 ng/mL (350 nmol/L) in 100% of patients with adrenal insufficiency but also in about 15% of the population, so the test is very sensitive but not specific.

One or more serum anti-adrenal antibodies are found in about 50% of cases of autoimmune Addison disease. Serum is assayed for four different anti-adrenal antibodies with the following sensitivities: cytoplasmic antibodies (26%), 21-hydroxylase antibodies (21%), 17-hydroxylase antibodies (21%), and side-chain cleavage antibodies (16%). Antibodies to thyroid (45%) and other tissues may also be present.

Salt-wasting congenital adrenal hyperplasia due to 21-hydroxylase deficiency is usually diagnosed at birth in females due to ambiguous genitalia. Males and patients with milder enzyme defects may present later. The diagnosis of adrenal insufficiency is made as above. The specific diagnosis requires elevated serum levels of 17-OH progesterone.

Elevated plasma renin activity (PRA) indicates the presence of depleted intravascular volume and the need for fludrocortisone administration. Serum epinephrine levels are low in patients with adrenal insufficiency, since these patients do not have the high local concentrations of cortisol that are required to induce the enzyme PNMT in adrenal medulla for the synthesis of epinephrine from norepinephrine.

Young men with idiopathic Addison disease are screened for X-linked adrenoleukodystrophy by determining plasma very long-chain fatty acid levels; affected patients have high levels.

In acute adrenal crisis, blood, sputum, or urine cultures may be positive if bacterial infection is the precipitating cause.

C. Imaging

When adrenal insufficiency is not clearly autoimmune, a CT scan of the adrenal glands should be obtained. Small, noncalcified adrenals are seen in autoimmune Addison disease. The adrenals are enlarged in about 85% of cases related to metastatic or granulomatous disease. Adrenal calcifications occur in about 50% of cases of tuberculous Addison disease but are also seen with hemorrhage, fungal infection, pheochromocytoma, and melanoma.

Differential Diagnosis

Patients with ACTH deficiency have normal mineralocorticoid production and do not develop hyperkalemia. Patients with secondary adrenal insufficiency (see Hypopituitarism) lack ACTH and have normal to decreased skin pigmentation that has been described as “alabaster skin.” This contrasts with the increased skin pigmentation in patients with Addison disease. Hemochromatosis also causes bronze skin hyperpigmentation, but hemochromatosis may in fact be the cause of Addison disease. Acute adrenal insufficiency must be distinguished from other causes of shock (eg, septic, hemorrhagic, cardiogenic).

The constitutional symptoms may be mistaken for occult cancer, anorexia nervosa, or emotional stress. Acute adrenal insufficiency must be distinguished from an acute abdomen in which neutrophilia is the rule, whereas in adrenal insufficiency there is lymphocytosis and eosinophilia. The neurologic manifestations of Allgrove syndrome and adrenoleukodystrophy (especially in women) may mimic multiple sclerosis. Hyperkalemia can be caused by hyporeninemic hypoaldosteronism related to type IV renal tubular acidosis. Hyperkalemia is also seen with gastrointestinal bleeding, rhabdomyolysis, hyperkalemic paralysis, and some drugs (eg, angiotensin-converting enzyme [ACE] inhibitors, spironolactone, and drospirenone).

Hyponatremia is seen in many other conditions (eg, hypothyroidism, diuretic use, heart failure, cirrhosis, vomiting, diarrhea, severe illness, or major surgery) (Figure 21–1). Nearly 40% of critically ill patients have low serum cortisol levels due to low serum albumin levels, such that their total serum cortisol levels may be low but their serum free cortisol levels are normal.

Complications

Any of the complications of the underlying disease (eg, tuberculosis) are more likely to occur in adrenal insufficiency, and intercurrent infections may precipitate an acute adrenal crisis. Associated autoimmune diseases are common (see above).

Treatment

A. General Measures

Patients with adrenal insufficiency (and family members) must be thoroughly educated about adrenal insufficiency. Patients are advised to wear a medical alert bracelet or medal reading, “Adrenal insufficiency—takes hydrocortisone.” They need to be provided with a dose escalation schedule for increased corticosteroids for illness, accidents, or prior to minor surgical procedures and for increased fludrocortisone for hot weather or prolonged strenuous exercise. Corticosteroids and fludrocortisone must be prescribed in liberal amounts with automatic refills to avoid the patient’s running out of medication. It is also advisable to prescribe a routine antiemetic such as ondansetron ODT 8-mg tablets to be taken every 8 hours for nausea. Parenteral hydrocortisone (Solu-Cortef) 100 mg is also prescribed for patient self-injection in the event of vomiting. Patients must also receive advance instructions to seek medical attention at an emergency facility immediately in the event of vomiting or severe illness. All infections should be treated immediately and vigorously, with hydrocortisone administered at appropriately increased doses.

B. Specific Therapy

Replacement therapy should include corticosteroids with mineralocorticoids for primary adrenal insufficiency. In mild cases, corticosteroids alone may be adequate.

1. Corticosteroid replacement therapy—Maintenance therapy for most patients with Addison disease involves 15–30 mg of hydrocortisone orally daily in two or three divided doses (eg, 10 mg at 7 AM, 10 mg at 1 PM, and 5 mg at 7 PM). Some patients respond better to prednisone or methylprednisolone in doses of about 3–6 mg daily in divided doses. Adjustments in dosage are made according to the clinical response. The corticosteroid dose should be kept at the lowest level at which the patient feels clinically well.

Plenadren MR (5- or 20-mg modified-release tablets) is a once-daily dual-release preparation of hydrocortisone that may be administered in the morning (usual dose range is 20–30 mg daily). It is not available in the United States but is available in Canada and elsewhere.

A proper corticosteroid dose usually results in clinical improvement, a normal WBC count differential, and no manifestations of Cushing syndrome. Serum ACTH levels vary substantially and should not be used to determine dosing. Increased corticosteroid dosing is required in circumstances of infection, trauma, surgery, stressful diagnostic procedures, or other forms of stress. Rifampin use increases the clearance of hydrocortisone and necessitates increased dosing of hydrocortisone by up to 50%. During the third trimester of pregnancy, corticosteroid requirements are higher, so usual corticosteroid doses are increased by 50%. For severe stress of major illness, surgery, or delivery, a maximum stress dose of hydrocortisone is given as 50–100 mg intravenously or intramuscularly, followed by 50 mg every 6 hours. Lower doses, oral or parenteral, are used for less severe stress. For immunizations that are given with an adjuvant, such as varicella zoster (Shingrix), there is sufficient local inflammation that an increased dose of hydrocortisone is recommended for 4–5 days following the immunization. The dose is reduced back to normal as the stress subsides. Decreased corticosteroid dosing is required when medications are prescribed that inhibit corticosteroid metabolism by blocking the isoenzyme CYP34A, particularly the antifungals ketoconazole or itraconazole, the antidepressant nefazodone, anti-HIV protease inhibitors, and cobicistat.

2. Mineralocorticoid replacement therapy—**Fludrocortisone acetate** has a potent sodium-retaining effect. The dosage is 0.05–0.3 mg orally daily or every other day. In the presence of postural hypotension, hyponatremia, or hyperkalemia, the dosage is increased. Similarly, in patients with fatigue, an elevated PRA indicates the need for a higher replacement dose of fludrocortisone. If edema, hypokalemia, or hypertension ensues, the dose is decreased. During treatment with hydrocortisone with maximum doses appropriate for stress, fludrocortisone replacement is not required. Some patients cannot tolerate fludrocortisone and must substitute NaCl tablets to replace renal sodium loss.

DHEA is given to some women with adrenal insufficiency. In a double-blind clinical trial, women taking DHEA 50 mg orally each morning experienced an improved sense of well-being, increased muscle mass, and a reversal in bone loss at the femoral neck. DHEA replacement did not improve fatigue, cognitive problems, or sexual dysfunction; however, its placebo effect may be significant in that regard. Older women who receive DHEA should be monitored for androgenic effects. Because over-the-counter preparations of DHEA have variable potencies, it is best to have the pharmacy formulate this with pharmaceutical-grade micronized DHEA.

3. Treatment of acute adrenal crisis—If acute adrenal crisis is suspected but the diagnosis of adrenal insufficiency is not yet established, blood is drawn for routine emergency laboratory tests and blood cultures, as well as serum cortisol and ACTH levels. Without waiting for the results, treatment is initiated immediately with hydrocortisone phosphate or hydrocortisone sodium succinate 100–300 mg intravenously along with saline solution. Thereafter, hydrocortisone is continued as intravenous infusions of 50–100 mg every 6 hours for the first day. The dosage may then be reduced according to the clinical picture and laboratory test results.

Since bacterial infection frequently precipitates acute adrenal crisis, broad-spectrum antibiotics should be administered empirically while waiting for the results of initial cultures (Table 30–5). The patient must also be treated for electrolyte abnormalities, hypoglycemia, and dehydration, as indicated.

When the patient is able to take food by mouth, hydrocortisone is administered orally in doses of 10–20 mg every 6 hours, and the dosage is reduced to maintenance levels as needed. Most patients ultimately require hydrocortisone twice daily (10–20 mg in the morning; 5–10 mg in the evening). Mineralocorticoid replacement is not needed when large amounts of hydrocortisone are being given, but as its dose is reduced, it is usually necessary to add fludrocortisone acetate, 0.05–0.2 mg orally daily. Some patients never require fludrocortisone or become edematous at doses of more than 0.05 mg once or twice weekly. Once the crisis has passed, the patient must be evaluated to assess the degree of permanent adrenal insufficiency and to establish the cause, if possible.

Prognosis

The life expectancy of patients with Addison disease is reasonably normal, as long as they are compliant with their medications and knowledgeable about their condition. However, one retrospective Swedish study of 1675 patients with Addison disease found an unexpected increase in all-cause mortality, mostly from cardiovascular disease, malignancy, and infection. Adrenal crisis can occur in patients who stop their medication or who experience stress such as infection, trauma, or surgery without appropriately higher doses of corticosteroids. Patients who take excessive doses of corticosteroid replacement can develop Cushing syndrome, which imposes its own risks.

Some patients feel residual fatigue, despite corticosteroid and mineralocorticoid replacement. This may be due, in part, to the inadequacy of oral replacement to duplicate cortisol's normal circadian rhythm. Also, patients with Addison disease are deficient in epinephrine, but replacement epinephrine is not available. Fatigue may also be an indication of suboptimal dosing of medication, electrolyte imbalance, or concurrent hypothyroidism or diabetes mellitus.

Rapid treatment is usually lifesaving in acute adrenal crisis. However, if adrenal crisis is unrecognized and untreated, shock that is unresponsive to fluid replacement and vasopressors can result in death.

CUSHING SYNDROME (Hypercortisolism)

ESSENTIALS OF DIAGNOSIS

- Central obesity, muscle wasting, hirsutism, purple striae.
- Psychological changes.
- Osteoporosis, hypertension, poor wound healing.
- Hyperglycemia, leukocytosis, lymphocytopenia, hypokalemia.
- Elevated serum cortisol and urinary free cortisol. Lack of normal suppression by dexamethasone.

General Considerations

The term Cushing “syndrome” refers to the manifestations of excessive corticosteroids, commonly due to supraphysiologic doses of corticosteroid drugs and rarely due to spontaneous production of excessive cortisol by the adrenal cortex.

Cases of spontaneous Cushing syndrome are rare, with an incidence of 2.6 new cases yearly per million population in the United States. About 68% of cases are due to Cushing “disease,” caused by a benign ACTH-secreting pituitary adenoma that is typically smaller than 5 mm and usually located in the anterior pituitary (94%); however, about 6% of such adenomas are ectopic in locations such as the cavernous sinus, sphenoid sinus, ethmoid sinus, or posterior pituitary. Cushing disease is at least three times more frequent in women than men.

About 7% of cases are due to nonpituitary ACTH-secreting neuroendocrine neoplasms that produce ectopic ACTH. Ectopic locations include the lungs (55%), pancreas (9%), mediastinum-thymus (8%), adrenal (6%), gastrointestinal tract (5%), thyroid (4%), and other sites (13%). About 15% of cases are due to ACTH from a source that cannot be initially located.

About 25% of cases are due to excessive autonomous secretion of cortisol by the adrenals. Cortisol secretion is independent of ACTH and plasma ACTH levels are usually low or low-normal. Most such cases are due to a unilateral adrenal tumor. Benign adrenal adenomas are generally small and produce mostly cortisol; adrenocortical carcinomas are usually large when discovered and can produce excessive cortisol as well as androgens but may be nonsecretory. ACTH-independent macronodular adrenal hyperplasia can also produce hypercortisolism due to the adrenal cortex cells’ abnormal stimulation by hormones such as catecholamines, arginine vasopressin, serotonin, hCG/LH, or gastric inhibitory polypeptide; in the latter case, hypercortisolism may be intermittent and food-dependent and plasma ACTH levels may not be completely suppressed.

Clinical Findings

A. Symptoms and Signs

The manifestations of Cushing syndrome vary considerably. Early in the course of the disease, patients frequently complain of nonspecific symptoms, such as fatigue or reduced endurance but may have few, if any, of the physical stigmata described below. Central obesity with a plethoric "moon face," "buffalo hump," supraclavicular fat pads, protuberant abdomen, and thin extremities eventually develop in most patients with Cushing syndrome. Muscle atrophy causes weakness, with difficulty standing up from a seated position or climbing stairs. Patients may also experience backache, headache, hypertension, osteoporosis, avascular necrosis of bone, acne, superficial skin infections, and oligomenorrhea or amenorrhea in women or erectile dysfunction in men. Patients may have thirst and polyuria (with or without glycosuria), renal calculi, glaucoma, purple striae (especially around the thighs, breasts, and abdomen), and easy bruisability. Unusual bacterial or fungal infections are common. Wound healing is impaired. Mental symptoms may range from diminished ability to concentrate to increased lability of mood to frank psychosis. Patients are susceptible to opportunistic infections. Hyperpigmentation is common with ectopic ACTH-secreting neoplasms but not with pituitary Cushing disease.

Adrenal carcinomas usually have gross metastases by the time of diagnosis. Microscopic metastases are not visible by scanning but can be inferred from the presence of detectable cortisol levels following removal of the primary adrenal tumor in patients with a cortisol-secreting carcinoma and Cushing syndrome. The ENSAT staging system is used: stage 1 is a localized tumor 5 cm or smaller; stage 2 is a localized tumor larger than 5 cm; stage 3, tumor with local metastases; and stage 4, tumor with distant metastases.

B. Laboratory Findings

Glucose tolerance is impaired as a result of insulin resistance. Polyuria is present as a result of increased free water clearance; diabetes mellitus with glycosuria may worsen it. Patients with Cushing syndrome often have leukocytosis with relative granulocytosis and lymphopenia. Hypokalemia may be present, particularly in cases of ectopic ACTH secretion.

1. Diagnostic tests for hypercortisolism—Testing for hypercortisolism involves determining whether the following characteristics of Cushing syndrome are present: (1)

lack of cortisol diurnal variation, (2) reduced suppressibility of cortisol by dexamethasone, (3) increased cortisol production rate, and (4) suppression of plasma ACTH by hypercortisolism from an adrenal nodule. Conflicting results are common.

Late-night (10–11 PM) salivary cortisol determinations are particularly useful, particularly for ACTH-dependent hypercortisolism. Late-night salivary cortisol levels are normally 150 ng/dL (4.0 nmol/L) or less. Late-night salivary cortisol levels that are consistently greater than 250 ng/dL (7.0 nmol/L) are considered very abnormal. The late-night salivary cortisol test has a relatively high sensitivity and specificity for Cushing syndrome.

The **overnight dexamethasone suppression test** is an easy screening test for hypercortisolism and is particularly sensitive for mild ACTH-independent hypercortisolism from an adrenal nodule. Dexamethasone 1 mg is given orally at 11 PM and serum is collected for cortisol determination at 8 AM the next morning; a cortisol level less than 1.8 mcg/dL (50 nmol/L, high-performance liquid chromatography [HPLC] assay) excludes Cushing syndrome with some certainty. However, 8% of established patients with pituitary Cushing disease have dexamethasone-suppressed cortisol levels less than 2 mcg/dL (55 nmol/L). Antiseizure drugs (eg, phenytoin, phenobarbital, primidone) and rifampin accelerate the metabolism of dexamethasone, causing a lack of cortisol suppression by dexamethasone. Estrogens—during pregnancy or as oral contraceptives or HRT—may also cause lack of dexamethasone suppressibility.

A 24-hour urinary free cortisol and creatinine is usually used to confirm hypercortisolism in patients with a high late-night salivary cortisol or an abnormal dexamethasone suppression test. A high 24-hour urine free cortisol (greater than 50 mcg/day or 140 nmol/day in adults), or free cortisol to creatinine ratio of greater than 95 mcg cortisol/g creatinine, helps confirm hypercortisolism. However, many patients with mild hypercortisolism have a urinary free cortisol that is misleadingly within the reference range when measured by liquid chromatography-tandem mass spectrometry. A misleadingly high urine free cortisol excretion occurs with high fluid intake. In pregnancy, urine free cortisol is increased, while 17-hydroxycorticosteroids remain normal and diurnal variability of serum cortisol is normal. Carbamazepine and fenofibrate cause false elevations of urine free cortisol when determined by HPLC.

2. Diagnostic tests for the source of hypercortisolism—Once hypercortisolism is confirmed, a plasma ACTH and plasma DHEAS are obtained. A plasma ACTH below 6 pg/mL (1.3 pmol/L), with a low serum DHEAS, indicates a probable adrenal tumor, whereas higher levels are produced by pituitary or ectopic ACTH-secreting tumors. Certain ACTH assays suffer interference and report low-normal plasma ACTH levels in patients with ACTH-independent hypercortisolism. Serum dehydroepiandrosterone sulfate (DHEAS) levels can be used as a proxy for ACTH, since DHEAS secretion is

ACTH-dependent; levels below the reference range and particularly below 40 mcg/dL (1.1 mcmol/L) imply ACTH-independent hypercortisolism.

C. Imaging

In ACTH-independent Cushing syndrome, CT of the adrenals usually detects a mass lesion, which is most often an adrenal adenoma. Adrenocortical carcinomas can usually be distinguished from benign adrenal adenomas since they are generally larger (average 11 cm diameter) and many have metastases that are visible on preoperative scans.

In ACTH-dependent Cushing syndrome, MRI of the pituitary demonstrates a pituitary lesion in about 50% of cases. Premature cerebral atrophy is often noted. When the pituitary MRI is normal or shows a tiny (less than 5 mm diameter) irregularity that may be incidental, selective catheterization of the inferior petrosal sinus veins draining the pituitary is performed. ACTH levels in the inferior petrosal sinus that are more than twice the simultaneous peripheral venous ACTH levels are indicative of pituitary Cushing disease. Inferior petrosal sinus sampling is also done during ovine CRH (oCRH or Acthrel) administration, which ordinarily causes the ACTH levels in the inferior petrosal sinus to be over three times the peripheral ACTH level when the pituitary is the source of ACTH.

When inferior petrosal sinus ACTH concentrations are not above the requisite levels, a search for an ectopic source of ACTH is undertaken. Location of ectopic sources of ACTH begins with CT scanning of the chest and abdomen, with special attention to the lungs (for carcinoid or small cell carcinomas), the thymus, the pancreas, and the adrenals. In patients with ACTH-dependent Cushing syndrome, chest masses should not be assumed to be the source of ACTH, since opportunistic infections are common, so it is prudent to biopsy a chest mass to confirm the pathologic diagnosis prior to resection.

For Cushing syndrome due to ectopic ACTH, CT scanning fails to detect the source of ACTH in about 34% of cases. In such cases, the most sensitive (82%) scanning technique is whole-body imaging with ^{68}Ga-somatostatin receptor-PET/CT (^{68}Ga-DOTATOTATE-PET/CT). The next most sensitive (58%) scanning technique is whole-body imaging with ^{18}F-DOPA-PET/CT.

Differential Diagnosis

Alcoholic patients can have hypercortisolism and many clinical manifestations of Cushing syndrome. Pregnant women have elevated serum ACTH levels, increased urine free cortisol, and high serum cortisol levels due to high serum levels of cortisol-binding globulin. Critically ill patients frequently have hypercortisolism, usually with suppression of serum ACTH. Depressed patients also have hypercortisolism that can be nearly impossible to distinguish biochemically from Cushing syndrome but without clinical signs of Cushing syndrome. Cushing syndrome can be misdiagnosed as anorexia nervosa (and vice versa) owing to the muscle wasting and extraordinarily high urine free cortisol levels found in anorexia. Patients with severe obesity frequently have an abnormal dexamethasone suppression test, but the urine free cortisol is usually normal, as is diurnal variation of serum cortisol. Patients with familial cortisol resistance have hyperandrogenism, hypertension, and hypercortisolism without actual Cushing syndrome. Excessive ingestion of gamma-hydroxybutyric acid (GHB, sodium oxybate) can also induce ACTH-dependent Cushing syndrome that resolves after the drug is stopped.

Some adolescents develop violaceous striae on the abdomen, back, and breasts; these are known as "striae distensae" and are not indicative of Cushing syndrome. Patients receiving antiretroviral therapy for HIV-1 infection frequently develop partial lipodystrophy with thin extremities and central obesity with a dorsocervical fat pad ("buffalo hump") causing pseudo-Cushing syndrome. Patients with familial partial lipodystrophy type I develop central obesity and moon facies, along with thin extremities due to atrophy of subcutaneous fat. However, these patients' muscles are strong and may be hypertrophic, distinguishing this condition from Cushing syndrome.

Treatment

Patients must receive treatment for cortisol-dependent comorbidities, including osteoporosis, psychiatric disorders, diabetes mellitus, hypertension, hypokalemia, muscle weakness, and infections. Bone densitometry is recommended for all patients and treatment is commenced for patients with osteoporosis.

A. Surgical Therapy

Pituitary Cushing disease is best treated with transsphenoidal selective resection of the pituitary adenoma. With an experienced pituitary neurosurgeon, remission rates range from 80% to 90%. Postoperative hyponatremia occurs frequently, so serum sodium should be monitored frequently for the first 2 weeks postoperatively. The patient should be screened for secondary hypothyroidism with a serum free T_4 within 1–2 weeks after surgery. After successful pituitary surgery, the rest of the pituitary usually returns to normal function; however, the pituitary corticotrophs remain suppressed and require 6–36 months to recover normal function. Therefore, patients receive empiric replacement-dose hydrocortisone postoperatively. Postoperative secondary adrenal insufficiency is a mark of successful pituitary surgery; screening may include a morning serum cortisol 8 hours following the prior evening dose of hydrocortisone. The cosyntropin test becomes abnormal by 2 weeks following successful pituitary surgery.

Patients with secondary adrenal insufficiency and their families require patient education about the condition and must continue corticosteroid replacement until a cosyntropin stimulation test is normal. A pituitary MRI is obtained about 3 months postoperatively and repeated as indicated for clinical evidence of recurrent Cushing disease or Nelson syndrome, the progressive enlargement of ACTH-secreting pituitary tumors following bilateral adrenalectomy.

Cushing disease may persist after pituitary surgery, particularly when there has been cavernous sinus involvement. After apparent successful pituitary surgery, Cushing disease recurs in 16% after a mean of 38 months. Patients must have repeated evaluations for recurrent Cushing disease for years postoperatively. For patients with persistent or recurrent Cushing disease, repeat transsphenoidal pituitary surgery may be warranted if the recurrent tumor is visible and deemed resectable. Otherwise, bilateral laparoscopic adrenalectomy is usually the best treatment option, particularly for patients with very severe disease, since it renders an immediate remission in a condition with significant morbidity and mortality. Residual or recurrent ACTH-secreting pituitary tumors may also be treated with stereotactic radiosurgery, which normalizes urine free cortisol in 70% of patients within a mean of 17 months, compared with a 23% remission rate with conventional radiation therapy. Pituitary radiosurgery can also be used to treat Nelson syndrome.

Ectopic ACTH-secreting tumors should be surgically resected. If the tumor cannot be localized or is metastatic, laparoscopic bilateral adrenalectomy is usually recommended. Medical treatment with an oral combination of mitotane (3–5 g/24 h), ketoconazole (0.4–1.2 g/24 h), and metyrapone (3–4.5 g/24 h) often suppresses the hypercortisolism.

Metastatic ACTH-producing tumors that are visible with Octreoscan or ^{68}Ga-DOTATATE-PET imaging have somatostatin receptors. Such tumors may respond to therapy with somatostatin analogs; pasireotide LAR (60 mg intramuscularly every 28 days) or octreotide LAR (30–40 mg intramuscularly every 28 days) slows progression of the malignancy and reduces ACTH secretion in up to half such patients. Potassium-sparing diuretics are often helpful. Radionuclide therapy with several cycles of ^{177}Lu-DOTATATE has produced remissions in some patients.

Patients who are successfully surgically treated for Cushing syndrome typically develop “cortisol withdrawal syndrome,” even when given replacement corticosteroids for adrenal insufficiency. Manifestations can include hypotension, nausea, fatigue, arthralgias, myalgias, pruritus, and flaking skin. Increasing the hydrocortisone replacement to 30 mg orally twice daily can improve these symptoms; the dosage is then reduced slowly as tolerated.

Benign adrenal adenomas may be resected laparoscopically if they are smaller than 6 cm in diameter; cure is achieved in most patients. However, most patients experience prolonged secondary adrenal insufficiency. Patients with bilateral adrenal macronodular hyperplasia usually require bilateral adrenalectomies and an evaluation for Carney complex that can be confirmed with a genetic evaluation for activating mutations in the gene PRKAR1A or genetic changes at chromosome 2p16.

Adrenocortical carcinomas are resected surgically. If the adrenocortical carcinoma was functional, postoperative secondary adrenal insufficiency is a good prognostic sign, with an increased chance that the tumor was completely resected without metastases; however, detectable postoperative cortisol levels predict metastases, even if no metastases are visible on scans. Patients with secretory adrenocortical carcinomas are usually treated with mitotane postoperatively, particularly if metastases are visible or cortisol is detectable postoperatively. Patients with nonsecretory metastatic adrenocortical carcinomas have also responded to mitotane. Mitotane is typically given for 2–5 years postoperatively. It is given orally with meals, beginning with 0.5 g twice daily, increasing to 1 g twice daily within 2 weeks, with subsequent increased doses every 2–3 weeks to reach serum levels of 14–20 mcg/mL. Unfortunately, only half the patients are able to reach these levels due to side effects. Mitotane can cause hypogonadism and can suppress TSH and cause hypothyroidism. Mitotane often causes primary adrenal insufficiency. Replacement hydrocortisone or prednisone should be started when mitotane doses reach 2 g daily. The replacement dose of oral hydrocortisone starts at 15 mg in the morning and 10 mg in the afternoon but must often be doubled or tripled because mitotane increases cortisol metabolism and cortisol binding globulin levels; the latter can artifactually raise serum cortisol levels. Combined chemotherapy with etoposide, doxorubicin, cisplatin, and mitotane (EDP-M) appears to be the most effective regimen for recurrent or metastatic adrenocortical carcinoma.

B. Medical Therapy

For patients with Cushing syndrome who decline surgery or for whom surgery has been unsuccessful, mineralocorticoid hypertension can be treated with spironolactone, eplerenone, and dihydropyridine calcium channel blockers. Women with hyperandrogenism may be treated with flutamide. Cabergoline, 0.5–3.5 mg orally twice weekly, reduced hypercortisolemia in 40% of patients with Cushing disease in one small study. Pasireotide, a multireceptor-targeting somatostatin analog, is a treatment option for refractory ACTH-secreting pituitary tumors causing Cushing disease or Nelson syndrome. Ketoconazole inhibits adrenal steroidogenesis and is another treatment option when given in doses of about 200 mg orally every 6 hours; however, it is marginally effective and can cause liver toxicity. Metyrapone can suppress hypercortisolism; required median oral daily doses are 1250–1500 mg/day in divided doses. It may be combined with ketoconazole. Metyrapone also may be used for patients with secretory adrenocortical carcinoma whose hypercortisolism is not fully controlled with mitotane.

Prognosis

The manifestations of Cushing syndrome regress with time, but patients may have residual cognitive or psychiatric impairment, muscle weakness, osteoporosis, and sequelae from vertebral fractures. Continued impaired quality of life is more common in women compared to men. Younger patients have a better chance for full recovery.

Patients with Cushing syndrome from a benign adrenal adenoma experience a 5-year survival of 95% and a 10-year survival of 90%, following a successful adrenalectomy. Patients with Cushing disease from a pituitary adenoma experience a similar survival if their pituitary surgery is successful, which can be predicted if the postoperative nonsuppressed serum cortisol is less than 2 mcg/dL (55 nmol/L). Following successful treatment, overall mortality remains particularly higher for patients with older age at diagnosis, higher preoperative ACTH concentrations, and longer duration of hypercortisolism.

Patients who have a complete remission after transsphenoidal surgery have about a 15–20% chance of recurrence over the next 10 years. Patients with failed pituitary surgery may require pituitary radiation therapy, which has its own morbidity. Laparoscopic bilateral adrenalectomy may be required. Recurrence of hypercortisolism may occur as a result of growth of an adrenal remnant stimulated by high levels of ACTH. The prognosis for patients with ectopic ACTH-producing tumors depends on the aggressiveness and stage of the particular tumor. Patients with ACTH of unknown source have a 5-year survival rate of 65% and a 10-year survival rate of 55%.

In patients with adrenocortical carcinoma, 5-year survival rates of treated patients have correlated with the ENSAT stage. For stage 1, the 5-year survival was 81%; for stage 2, 61%; for stage 3, 50%; and for stage 4, 13%. In patients with stage 1 or 2 disease, long-term survival does occur. Improved survival has been associated with younger age, resection of the primary tumor, stage at diagnosis, and adjuvant treatment with mitotane.

Complications

Following bilateral adrenalectomy for Cushing disease, a pituitary adenoma may enlarge progressively (Nelson syndrome), causing local destruction (eg, visual field impairment, cranial nerve palsy) and hyperpigmentation. Following successful therapy for Cushing syndrome, secondary adrenal insufficiency occurs and requires long-term corticosteroid replacement. Five years after successful surgery, secondary hypoadrenalism resolves in about 58% of patients with pituitary Cushing disease, 82%

of those with ectopic ACTH, and only 38% of those who had an adrenal tumor.

When to Refer

Dexamethasone suppression test is abnormal.

When to Admit

- Transsphenoidal hypophysectomy.
- Adrenalectomy.
- Resection of ectopic ACTH-secreting tumor.

PRIMARY ALDOSTERONISM

ESSENTIALS OF DIAGNOSIS

- Hypertension may be severe or drug-resistant.

- Hypokalemia (in minority of patients) may cause polyuria, polydipsia, muscle weakness.
- Low plasma renin; elevated plasma and urine aldosterone levels.

General Considerations

Primary aldosteronism (hyperaldosteronism) refers to an inappropriately high aldosterone secretion that does not suppress adequately with sodium loading. Most affected patients have hypertension, although some may be normotensive. Primary aldosteronism is common and is believed to account about 8% of cases of stage 2 (mild) hypertension and about 13% of cases of stage 3 (moderate) hypertension. It should be suspected with early-onset hypertension or stroke before age 50 years (or both). It may be difficult to distinguish primary aldosteronism from cases of low renin essential hypertension, with which it may overlap. Patients of all ages may be affected, but the peak incidence is between 30 years and 60 years. Excessive aldosterone production increases sodium retention and suppresses plasma renin. It increases renal potassium excretion, which can lead to hypokalemia. Cardiovascular events are more prevalent in patients with aldosteronism (35%) than in those with essential hypertension (11%).

Primary aldosteronism may be caused by a unilateral aldosterone-producing adrenal cortical adenoma (Conn syndrome, 25%) that is more common in women with a 2:1 ratio, peaking between ages 30 and 50. However, primary aldosteronism is more commonly caused by adrenal cortical hyperplasia (75%) that is more common in men with a 4:1 ratio, peaking between ages 50 and 60. It is important to distinguish the two, since a unilateral aldosteronoma (Conn syndrome) may be cured by surgical resection, whereas patients with bilateral adrenal hyperplasia are treated medically.

Clinical Findings

A. Symptoms and Signs

Primary aldosteronism is the most common cause of refractory hypertension in youths and middle-aged adults. Patients have hypertension that is typically moderate but may be severe. Some patients have only diastolic hypertension, without other symptoms and signs. Edema is rarely seen in primary aldosteronism. Hypokalemia can produce muscle weakness, paresthesias with frank tetany, headache, polyuria, and polydipsia.

B. Laboratory Findings

Plasma potassium should be determined in hypertensive individuals. However, hypokalemia, once thought to be the hallmark of hyperaldosteronism, is present in only 37% of affected patients: 50% of those with an aldosterone-producing adenoma and 17% of those with adrenal hyperplasia. An elevated serum bicarbonate (HCO_3) concentration indicates metabolic alkalosis and is commonly present.

Testing for primary aldosteronism should be done for all hypertensive patients with any of the following: (1) sustained hypertension above 150/100 mm Hg on 3 different days; (2) hypertension resistant to three conventional antihypertensive drugs, including a diuretic; (3) controlled blood pressure requiring four or more antihypertensive drugs; (4) hypokalemia, whether spontaneous or diuretic induced; (5) personal or family history of early-onset hypertension or cerebrovascular accident at age 40 or younger; (6) first-degree relative with primary aldosteronism; (7) presence of an adrenal mass; and (8) low PRA.

For at least 2 weeks prior to testing, patients should have any hypokalemia corrected and then consume a diet high in NaCl (more than 6 g/day) and ideally withhold certain medications: all diuretics, ACE inhibitors, ARBs (stimulate PRA); beta-blockers, clonidine, NSAIDs (suppress PRA); oral estrogens and oral contraceptives should also ideally be held. Medications that are allowed include slow-release verapamil, hydralazine, terazosin, and doxazosin.

For blood testing, the patient should be out of bed for at least 2 hours and seated for 15–60 minutes before the blood draw, which should preferably be obtained between 8 AM and 10 AM. The blood should be drawn slowly with a syringe and needle (rather than a vacutainer) at least 5 seconds after tourniquet release and without fist clenching. Plasma potassium, rather than the routine serum potassium, should be measured in cases of unexpected hyperkalemia, with the separation of plasma from cells within 30 minutes of collection. Plasma potassium levels must be normal, since hypokalemia suppresses aldosterone. For practical purposes, the same blood draw can be used for simultaneous assays for plasma potassium, serum aldosterone, and PRA or direct renin assay (DRA). Patients with primary aldosteronism have a suppressed PRA that is below or near 1.0 ng/mL/h or DRA less than 0.36 ng/mL. PRA of 1.0 ng/mL/h (12.8 pmol/L/min) is equivalent to a DRA of 5.2 ng/mL (8.2 milli-international units/L). Suppressed PRA or DRA with a serum aldosterone concentration greater than 15 ng/dL (416 pmol/L) indicates probable primary hyperaldosteronism. Serum aldosterone (ng/dL) to PRA (ng/mL/h) ratios less than 24 exclude primary aldosteronism; ratios between 24 and 30 are indeterminate; ratios between 30 and 67 are suspicious; a ratio above 64 helps confirm the diagnosis of primary aldosteronism. In patients with a suppressed PRA or DRA plus a serum aldosterone of 20 ng/day or higher, the diagnosis of primary hyperaldosteronism is confirmed. To further confirm the diagnosis and for patients with a suppressed PRA or DRA but lower serum aldosterone levels, a 24-hour urine is collected in an acidified container for aldosterone, cortisol, and creatinine; urine aldosterone greater than 12 mcg/24 h (33 nmol/24 h) confirms primary aldosteronism with 93% specificity.

Genetic testing is recommended for patients with confirmed primary aldosteronism by age 20 years and those with a family history of primary aldosteronism or stroke at young age (under age 40). The testing is for familial corticosteroid remediable aldosteronism.

C. Imaging

Some patients with undiagnosed primary aldosteronism are incidentally found to have an adrenal nodule (incidentaloma) during abdominal or chest imaging. All patients with biochemically confirmed primary aldosteronism require a thin-section CT scan of the adrenals to screen for a rare adrenal carcinoma. In the absence of a large adrenal carcinoma, adrenal CT scanning cannot reliably distinguish unilateral from bilateral aldosterone excess, having both a sensitivity and specificity of 78% for unilateral aldosteronism. Therefore, the decision to perform a unilateral adrenalectomy should not be based solely on the adrenal CT scan. Adrenal vein sampling is often required.

D. Adrenal Vein Sampling

Unfortunately, bilateral selective adrenal vein sampling is invasive, expensive, not widely available, and often unsuccessful. The procedure (and surgery) may not be required for patients whose blood pressure is well controlled with spironolactone or eplerenone and for those with familial hyperaldosteronism. It is indicated only if surgery is contemplated in order to direct the surgeon to the correct adrenal gland. Adrenal vein sampling is probably not required in patients who have a classic adrenal adenoma (Conn syndrome), which is characterized by spontaneous hypokalemia and a unilateral adrenal adenoma 10 mm or larger in diameter on CT.

Before this procedure, the patient must be properly prepared (see Laboratory Findings). However, patients with a persistently suppressed PRA may continue mineralocorticoid blockade. Lateralization is present when the aldosterone:cortisol ratio from one adrenal vein is at least four times that from the opposite adrenal vein.

Aldosterone hypersecretion that is lateralized to one adrenal usually indicates that adrenal has a unilateral aldosteronoma or hyperplasia, particularly when aldosterone secretion from the contralateral adrenal is suppressed, in which case unilateral surgery improves hypertension in 96%. Adrenal vein sampling has a sensitivity of 95% and a specificity of 100% but only when performed by an experienced radiologist. This procedure entails a 0.6% risk of major complications.

Differential Diagnosis

The differential diagnosis of primary aldosteronism includes other causes of hypokalemia (see Chapter 21) in patients with essential hypertension, especially diuretic therapy; chronic depletion of intravascular volume stimulates renin secretion and secondary hyperaldosteronism.

Real (black) licorice (derived from anise) or anise-flavored drinks (sambuca, pastis) contain glycyrrhizinic acid, which has a metabolite that inhibits the enzyme that normally inactivates cortisol in the renal tubule. Oral contraceptives may increase aldosterone secretion in some patients. Renal vascular disease can cause severe hypertension with hypokalemia but PRA is high. Excessive adrenal secretion of other corticosteroids (besides aldosterone), certain congenital adrenal enzyme disorders, and primary cortisol resistance may also cause hypertension with hypokalemia. The differential diagnosis also includes Liddle syndrome, an autosomal dominant cause of hypertension and hypokalemia resulting from excessive sodium absorption from the renal tubule; renin and aldosterone levels are low.

Complications

Cardiovascular complications occur more frequently in primary aldosteronism than in idiopathic hypertension. Following unilateral adrenalectomy for Conn syndrome, suppression of the contralateral adrenal may result in temporary postoperative hypoaldosteronism, characterized by hyperkalemia and hypotension.

Treatment

The **unilateral adrenal adenoma** of Conn syndrome is usually treated by laparoscopic adrenalectomy. During pregnancy, such surgery is best performed during the second trimester. However, long-term medical therapy is an option for unilateral hyperaldosteronism, if adequate blood pressure control can be maintained.

Bilateral adrenal hyperplasia is best treated with medical therapy. Medical treatment must include a potassium-sparing diuretic, particularly spironolactone, eplerenone, or amiloride. Spironolactone is the most effective drug but also has antiandrogen activity and men frequently experience breast tenderness, gynecomastia, or reduced libido; it is given at initial doses of 12.5–25 mg orally once daily; the dose may be titrated upward to 200 mg daily. Spironolactone might lead to undervirilization of male infants and is contraindicated in pregnancy; reproductive-age women are cautioned to use contraception during therapy. Eplerenone is favored during pregnancy (FDA pregnancy category B) and for men, since it does not have antiandrogen effects; it must be taken orally in doses of 25–50 mg twice daily. Blood pressure must be monitored daily when beginning these anti-mineralocorticoid medications; significant drops in blood pressure have occurred when these drugs are added to other antihypertensives. Other antihypertensive drugs may be required, particularly amlodipine, and ACE inhibitors or ARBs. Corticosteroid-remediable aldosteronism is very rare, but may respond well to suppression with low-dose corticosteroids.

Prognosis

The hypertension is reversible in about two-thirds of cases but persists or returns despite surgery in the remainder. The prognosis is much improved by early diagnosis and treatment. Only 2% of aldosterone-secreting adrenal tumors are malignant.

PHEOCHROMOCYTOMA & PARAGANGLIOMA

ESSENTIALS OF DIAGNOSIS

- “Attacks” of headache, perspiration, palpitations, anxiety. Multisystem crisis.
- **Hypertension:** sustained but often paroxysmal, especially during surgery or delivery; may be orthostatic.
- Elevated plasma free metanephrines. Normal serum T_4 and TSH.

General Considerations

Both pheochromocytomas and non–head-neck paragangliomas are rare tumors of the sympathetic nervous system. Pheochromocytomas arise from the adrenal medulla and usually secrete both epinephrine and norepinephrine. Paragangliomas ("extra-adrenal pheochromocytomas") arise from sympathetic paraganglia and often metastasize. About 50% of paragangliomas secrete norepinephrine; the rest are nonfunctional or secrete only dopamine, normetanephrine, or serum chromogranin A (CgA). Tumoral secretion of norepinephrine or neuropeptide Y cause hypertension. Excessive epinephrine causes tachyarrhythmias. These tumors may be located in either or both adrenals or anywhere along the sympathetic nervous chain, and sometimes in the mediastinum, heart, or bladder.

These tumors are particularly dangerous and deceptive and cause death in at least one-third of patients prior to diagnosis. They account for less than 0.4% of hypertension cases. The incidence is higher in children and patients with moderate to severe hypertension, particularly in the presence of suspicious symptoms of headache, significant palpitations, or diaphoretic episodes. Over 10% of cases are discovered incidentally on imaging studies. They account for about 4% of adrenal incidentalomas. The yearly incidence is 2 to 4 new cases per million. However, many cases are undiagnosed during life, since the prevalence of pheochromocytomas and paragangliomas in autopsy series is 1 in 2000.

Nonsecretory paragangliomas arise in the head or neck, particularly in the carotid body, jugular-tympanic region, or vagal body; only about 4% secrete catecholamines. They often arise in patients who have SDHD, SDHC, or SDHB germline mutations.

About 35% of patients with pheochromocytomas or paragangliomas harbor a germline mutation in 1 of at least 16 known susceptibility genes that predispose to the tumor, usually in an autosomal dominant manner with incomplete penetrance. Thorough genetic testing is recommended for all patients with these tumors.

Pheochromocytoma eventually develops in about 30% of patients with **von Hippel–Lindau (VHL) disease type 2;** it can present as early as age 5 years or later in adulthood. Pheochromocytomas in patients with VHL are usually adrenal, less likely to be malignant (3.5%), and more likely to be bilateral. About 25% of patients with VHL-1–related pheochromocytomas are asymptomatic and normotensive at diagnosis. The condition is also associated with hemangiomas of the retina, cerebellum, brainstem, and spinal cord; hyperparathyroidism; pancreatic cysts; endolymphatic sac tumors; cystadenomas of the adnexa or epididymis; pancreatic neuroendocrine tumors; and renal cysts, adenomas, and carcinomas; inheritance is autosomal dominant.

MEN 2 (MEN 2A) is associated with pheochromocytomas, hyperparathyroidism, cutaneous lichen amyloidosis, and medullary thyroid carcinoma. Pheochromocytomas are often silent in MEN 2; at diagnosis, only about 50% have symptoms and fewer are hypertensive. The lack of symptoms may be due to earlier diagnosis through yearly screening of mutation carriers. **MEN 3 (MEN 2B)** may be familial, but usually arises from a de novo ret mutation; MEN 3 is associated with pheochromocytoma (50%), aggressive medullary thyroid carcinoma, mucosal neuromas, and Marfan-like habitus.

von Recklinghausen neurofibromatosis type 1 (NF-1) is associated with an increased risk of pheochromocytomas/paragangliomas as well as cutaneous neurofibromas, optic and brainstem gliomas, astrocytomas, vascular anomalies, hamartomas, malignant nerve sheath tumors, and smooth-bordered café au lait spots.

Familial paraganglioma can be caused by mutations in the genes encoding succinate dehydrogenase (SDH) subunits A, B, C, or D. Patients with such germline mutations are more apt to have bilateral pheochromocytomas or multicentric paragangliomas; they are also prone to pulmonary chondromas and gastric stromal sarcomas.

Pheochromocytomas are also more common in patients with Carney triad, Beckwith-Wiedemann syndrome, Sturge-Weber syndrome, and tuberous sclerosis.

Clinical Findings

A. Symptoms and Signs

Pheochromocytomas can be lethal unless they are diagnosed and treated appropriately. Catastrophic hypertensive crisis and fatal cardiac arrhythmias can occur spontaneously or may be triggered by needle biopsy or manipulation of the mass, intravenous contrast dye or glucagon injection, vaginal delivery, trauma, anesthesia, or surgery (both unrelated to the tumor or for its removal). Exercise, bending, lifting, or emotional stress can trigger paroxysms. Bladder paragangliomas may present with paroxysms during micturition. Certain drugs can precipitate attacks: decongestants, amphetamines, cocaine, epinephrine, corticosteroids, fluoxetine and other selective serotonin reuptake inhibitors (SSRIs), metoclopramide, monoamine oxidase (MAO) inhibitors, caffeine, nicotine, and ionic intravenous contrast.

Manifestations are variable, but typically include hypertension (81%) that may be paroxysmal or sustained, headache (60%), palpitations (60%), or diaphoresis (52%). About 58% of patients have episodic nonspecific “spells.” Other symptoms include anxiety (often with a sense of impending doom), weakness/fatigue, dyspnea, nausea/vomiting, tremor, dizziness, chest pain, abdominal pain, paresthesias, or constipation. Vasospasm during an attack can cause Raynaud syndrome, mottled cyanosis, or facial pallor. As the attack subsides, facial flushing and drenching sweats can occur. Epinephrine secretion by an adrenal pheochromocytoma can cause episodic tachyarrhythmias and sometimes orthostatic hypotension or even syncope. Cardiac manifestations include acute coronary syndrome, cardiomyopathy, heart failure, and potentially fatal dysrhythmias. Catecholamine-induced cardiomyopathy can present with shock. Confusion, psychosis, paresthesias, seizures, transient ischemic attacks, or stroke may occur with cerebrovascular vasoconstriction or hemorrhagic stroke. Aneurysms may dissect. Abdominal pain, nausea, vomiting, and even ischemic bowel can occur. Patients may experience increased appetite, loss of weight, numbness, or fevers. During pregnancy, pheochromocytomas can produce hypertension and proteinuria, mimicking eclampsia; vaginal delivery can produce hypertensive crisis followed by postpartum shock. A minority of patients are normotensive and asymptomatic, particularly when the tumor is nonsecretory or discovered at an early stage.

Pheochromocytomas can also rarely produce other “ectopic” peptide hormones, resulting in Cushing syndrome (ACTH), Verner-Morrison syndrome (VIP), or hypercalcemia (PTHrP). **Multisystem crisis** can occur, with manifestations of severe hypertension or hypotension, acute respiratory distress syndrome (ARDS), cardiomyopathy with acute heart failure, kidney dysfunction, liver failure, and death. Multisystem crisis can occur spontaneously, or it may be provoked by surgery, vaginal delivery, or treatment of metastatic disease.

B. Laboratory Findings

Pheochromocytomas are rare tumors, but they are deadly, and a missed diagnosis can be catastrophic. However, less than 1% of biochemical evaluations in patients with suspicious symptoms lead to a diagnosis of pheochromocytoma. More commonly, testing yields misleading minor elevations in tumor markers, particularly when levels are less than three times the upper limit of normal (Table 26–11).

Table 26–11. Factors that can cause misleading catecholamine or metanephrine results.[1]

Drugs	Foods	Conditions
Acetaminophen[2]	Bananas[3]	Age (children and older adults)[4]

[1] Note that assays for metanephrine using tandem mass spectroscopy (MS/MS) are not prone to interference from drugs or foods, except those that increase catecholamine excretion.

[2] May cause confounding peaks for catecholamines or metanephrines with an HPLC-ECD chromatogram.

[3] Increases measured catecholamine excretion.

[4] Increases plasma and urinary normetanephrine and metanephrine.

[5] May decrease urine metanephrine excretion.

[6] Decreases measured catecholamine excretion.

Plasma fractionated free metanephrines is the most sensitive test for secretory pheochromocytomas and paragangliomas. However, plasma levels of free metanephrines fluctuate and are lower when the patient is supine than when ambulatory. For practicality, the blood specimen is usually obtained after the patient sits quietly in the laboratory for at least 15 minutes. The test is 97% sensitive, so normal levels rule out pheochromocytoma and paraganglioma with some certainty. The exceptions are patients who are being monitored because they harbor a germline mutation for familial pheochromocytoma; such patients with a pheochromocytoma are often asymptomatic early-on and frequently have normal testing or only mild elevations in plasma metanephrines. However, for other patients with severe hypertension or "spells" caused by a pheochromocytoma, plasma fractionated free metanephrines are ordinarily at least three times the upper limit of normal. For less dramatic elevations in plasma metanephrines, patients are retested while lying supine in a quiet room for 30–90 minutes before the blood is drawn. False-positive test results should be particularly suspected when the ratio of normetanephrine to norepinephrine is less than 0.52 or the ratio of metanephrine to epinephrine is less than 4.2. In such cases, it is best to repeat biochemical testing under optimal conditions, eg, after eliminating potentially interfering drugs. Most patients with elevated plasma fractionated free metanephrines require confirmation with a 24-hour urine for fractionated metanephrines and creatinine.

Urinary fractionated metanephrines and creatinine effectively confirms most pheochromocytomas that were detected by elevated plasma fractionated free metanephrines. A 24-hour urine specimen is usually obtained, although an overnight or shorter collection may be used; patients with pheochromocytomas generally have more than 2.2 mcg of total metanephrine per milligram of creatinine, and more than 135 mcg total catecholamines per gram creatinine. Urinary assay for total metanephrines is about 97% sensitive for detecting functioning pheochromocytomas.

Plasma fractionated catecholamines may be helpful to confirm whether an adrenal tumor is a secretory pheochromocytoma. The test may also be useful for normotensive patients with a paraganglioma; the tumor may secrete only dopamine, which can be followed as a tumor marker.

Serum CgA is elevated in about 85% of patients with pheochromocytoma or paraganglioma and the levels correlate with tumor size, being higher in patients with metastatic disease. Serum CgA must be assayed in the fasting state, since levels rise after meals. Misleading elevated CgA levels also occur in patients with azotemia or hypergastrinemia, and in those treated with corticosteroids or proton pump inhibitors. Serum CgA is not specific for pheochromocytoma, so its measurement is not very useful for the initial diagnosis.

Clonidine suppression testing can help distinguish whether elevated plasma free normetanephrine levels are physiologic or indicative of pheochromocytoma. Plasma fractionated free metanephrines are measured before the administration of clonidine (0.3 mg orally) and 3 hours afterward. A fall of plasma normetanephrine into the normal range or a fall of greater than 40% from baseline helps rule out the presence of a tumor.

Hyperglycemia is present in about 35% of patients but is usually mild. Proteinuria is present in about 10–20% of patients. Leukocytosis is common. Erythrocytosis or eosinophilia can occur. The ESR is sometimes elevated. PRA may be increased by catecholamines.

C. Imaging

1. CT and MRI scanning—When an adrenal pheochromocytoma is suspected, a noncontrast CT scan of the abdomen is performed, with thin sections through the adrenals. If an adrenal mass is present, another CT is immediately performed, infusing nonionic contrast with a “washout” protocol. Pheochromocytomas are usually avid for contrast and about 80% of tumors retain greater than 40% of contrast after 15 minutes. Glucagon should not be used during scanning, since it can provoke hypertensive crisis.

MRI scanning has the advantage of not requiring intravenous contrast dye; its lack of radiation makes it the imaging of choice during pregnancy and childhood and for serial imaging. Both CT and MRI scanning have a sensitivity of about 90% for adrenal pheochromocytoma and a sensitivity of 95% for adrenal tumors over 0.5 cm in diameter. However, both CT and MRI are less sensitive for detecting recurrent tumors, metastases, and extra-adrenal paragangliomas. If no adrenal tumor is found, the scan is extended to include the entire abdomen, pelvis, and chest.

2. Nuclear imaging—No single nuclear imaging modality is 100% sensitive for pheochromocytoma or paraganglioma. Positron emission tomography (PET) imaging gives crisper imaging than scintigraphy. Nuclear imaging is usually combined with volumetric imaging (CT or MRI) to determine the precise size and location of tumors. **^{68}Ga-DOTATOC-PET** scanning is the most sensitive scan, detecting about 90% of pheochromocytomas, paragangliomas, and metastases. However, it is not entirely specific for these tumors.

^{18}FDG-PET scanning detects about 54% of metastases but is more sensitive for patients with SDHB germline mutations. However, ^{18}FDG-PET scanning is not specific for pheochromocytoma or paraganglioma.

^{123}I-MIBG whole-body scintigraphy can lateralize and confirm adrenal pheochromocytomas with a sensitivity of over 90%, but is only about 67% sensitive for extra-adrenal (paraganglioma) tumors and metastases and is also less sensitive for MEN 2– or MEN 3–related pheochromocytomas. ^{123}I-MIBG scintigraphy is also less sensitive for particularly aggressive tumors. Prior to the scan, the patient is given KI to competitively inhibit the uptake of free ^{123}I into the thyroid. Also, drugs that reduce ^{123}I-MIBG uptake should be avoided: tricyclic antidepressants and cyclobenzaprine (6 weeks); and amphetamines, decongestants, cocaine, phenothiazines, haloperidol, labetalol, and serotonin and norepinephrine reuptake inhibitors (2 weeks). Drug interference is suspected in negative ^{123}I-MIBG scans that do not show normal uptake in salivary glands.

Differential Diagnosis

Certain conditions mimic pheochromocytoma: thyrotoxicosis, labile essential hypertension, myocarditis, glomerulonephritis or other renal lesions, eclampsia, acute intermittent porphyria, hypogonadal vascular instability (hot flushes), anxiety attacks, cocaine or amphetamine use, and clonidine withdrawal. Patients taking nonselective MAO inhibitor antidepressants can have hypertensive crisis after eating foods that contain tyramine. Patients with erythromelalgia can have hypertensive crises. Renal artery stenosis can cause severe hypertension and may coexist with pheochromocytoma. Plasma fractionated free metanephrines can be elevated in sleep apnea or with stressful illness. On CT scan, adrenal pheochromocytomas must be distinguished from adrenal adenomas and other masses. ^{123}I-MIBG scintigraphy uptake in the adrenal glands can be physiologic uptake and can sometimes occur in benign adrenal adenomas.

Complications

All of the complications of severe hypertension may be encountered. In addition, a catecholamine-induced cardiomyopathy may develop. Severe heart failure and cardiovascular collapse may develop in patients during a paroxysm. Sudden death may occur due to cardiac arrhythmia. ARDS and multisystem crisis can occur acutely and thus the initial manifestation of pheochromocytoma may be hypotension or even shock. Hypertensive crises with sudden blindness or cerebrovascular accidents are not uncommon.

After removal of the tumor, a state of severe hypotension and shock (resistant to epinephrine and norepinephrine) may ensue with precipitation of acute kidney injury or myocardial infarction. Hypotension and shock may occur from spontaneous infarction or hemorrhage of the tumor.

Pheochromocytomas and paragangliomas may metastasize. Cells can also be seeded within the peritoneum, either spontaneously or as a complication during surgical resection. Such seeding of the abdomen can result in multifocal recurrent intra-abdominal tumors, a condition known as pheochromocytomatosis.

Medical Treatment

Patients must receive adequate treatment for hypertension and tachyarrhythmias prior to surgery for pheochromocytoma/paraganglioma. Patients are advised to measure their blood pressures daily and immediately during paroxysms. Some patients with pheochromocytoma or paraganglioma are not hypertensive and do not require preoperative antihypertensive management. Alpha-blockers or calcium channel blockers can be used, either alone or in combination. Blood pressure should be controlled before cardioselective beta-blockers are added for control of tachyarrhythmias. Normotensive patients with pheochromocytoma or sympathetic paraganglioma do not require preoperative alpha blockade, which increases their requirement for vasopressors and colloid after the tumor resection.

Alpha-blockers are typically administered in preparation for surgery. Phenoxybenzamine is a long-acting nonselective alpha-blocker with a half-life of 24 hours; it is given initially in a dosage of 10 mg orally every 12 hours, increasing gradually by about 10 mg/day about every 3 days until hypertension is controlled. Maintenance doses range from 10 mg/day to 120 mg/day. Doxazosin (half-life 22 hours), a selective alpha-1-blocker, may also be used in doses of 2–32 mg daily. Preoperative preparation with phenoxybenzamine reduces intraoperative hypertension but may increase the post-resection risk of hypotension compared to patients given a preoperative selective alpha-1-blocker. Optimal alpha-blockade is achieved when supine arterial pressure is below 140/90 mm Hg or as low as possible for the patient to have a standing arterial pressure above 80/45 mm Hg.

Calcium channel blockers (nifedipine ER or nicardipine ER) are very effective and are usually added to alpha-blockers, but may be used alone. Nifedipine ER is initially given orally at a dose of 30 mg/day, increasing the dose gradually to a maximum of 60 mg twice daily. Calcium channel blockers are superior to phenoxybenzamine for long-term use, since they cause less fatigue, nasal congestion, and orthostatic hypotension. However, they should not be used for patients with severe heart failure. For acute hypertensive crisis (systolic blood pressure higher than 170 mm Hg) a nifedipine 10-mg capsule may be chewed and swallowed. Nifedipine is quite successful for treating acute hypertension in patients with pheochromocytoma/paraganglioma, even at home; it is reasonably safe as long as the blood pressure is carefully monitored.

Beta-blockers (eg, metoprolol XL) are often required after institution of alpha-blockade or calcium channel blockade. The use of a beta-blocker as initial antihypertensive therapy has resulted in an “unopposed alpha” status that causes paradoxical worsening of hypertension. Labetalol has combined alpha- and beta-blocking activity and is an effective agent, but can cause paradoxical hypertension if used as the initial antihypertensive agent. Labetalol can also interfere with catecholamine determinations in some laboratories and reduces the tumor’s uptake of radioisotopes, such that it must be discontinued for at least 4–7 days before ^{123}I-MIBG or ^{18}FDG-PET scanning or therapy with high-dose ^{131}I-MIBG.

Surgical Treatment

Surgical removal of pheochromocytomas or abdominal paragangliomas is the treatment of choice. For surgery, a team approach—endocrinologist, anesthesiologist, and surgeon—is critically important. Laparoscopic surgery is preferred, but large and invasive tumors require open laparotomy. Patients with small familial or bilateral pheochromocytomas may undergo selective resection of the tumors, sparing the adrenal cortex; however, there is a recurrence rate of 10% over 10 years.

Prior to surgery, blood pressure control should be maintained for a minimum of 4–7 days or until optimal cardiac status is established. The ECG should be monitored until it becomes stable. (It may take a week or even months to correct ECG changes in patients with catecholamine myocarditis, and it may be prudent to defer surgery until then in such cases.) Patients must be very closely monitored during surgery to promptly detect sudden changes in blood pressure or cardiac arrhythmias.

Intraoperative severe hypertension is managed with continuous intravenous nicardipine (a short-acting calcium channel blocker), 2–6 mcg/kg/min, or nitroprusside, 0.5–10 mcg/kg/min. Prolonged nitroprusside administration can cause cyanide toxicity. Tachyarrhythmia is treated with intravenous atenolol (1 mg boluses), esmolol, or lidocaine.

Autotransfusion of 1–2 units of blood at 12 hours preoperatively plus generous intraoperative volume replacement reduces the risk of postresection hypotension and shock caused by desensitization of the vascular alpha-1-receptors. Shock is treated with intravenous saline or colloid and high doses of intravenous norepinephrine. Intravenous 5% dextrose is infused postoperatively to prevent hypoglycemia.

Detecting & Managing Metastatic Pheochromocytoma & Paraganglioma

Surgical histopathology for pheochromocytoma and paraganglioma cannot reliably determine whether a tumor is malignant. Only the presence of metastases defines malignancy. Therefore, all pheochromocytomas and paragangliomas must be approached as possibly malignant. It is essential to recheck blood pressure and plasma fractionated metanephrine levels about 4–6 weeks postoperatively, at least every 6 months for 5 years, then once yearly for life and immediately if hypertension, suspicious symptoms, or metastases become evident.

Metastases from a pheochromocytoma or paraganglioma are visible in only about

35% when the primary tumor is discovered. The other 65% of metastases emerge clinically an average of 5.5 years (range 0.3 and 53 years) after the initial diagnosis. Since some metastases are indolent, it is important to tailor treatment to each individual according to their tumor's aggressiveness. Most surgeons resect the main tumor and larger metastases (debulking). Asymptomatic, indolent metastases may be kept under close surveillance without treatment.

A. Chemotherapy

Various chemotherapy regimens have been used, but there have been no controlled clinical trials to prove the effectiveness of one regimen over another or whether any regimen actually improves overall survival. The most common chemotherapy regimen combines intravenous cyclophosphamide, vincristine, and dacarbazine over 2 days in cycles that are repeated every 3 weeks (Table 39–3). About one-third of patients experience some degree of temporary remission. Sunitinib, a tyrosine kinase inhibitor, can also produce remissions, given orally in doses of 50 mg/day for 4 weeks on and then 2 weeks off; alternatively, a dose of 37.5 mg/day can be given continuously. Another chemotherapy regimen uses temozolomide, 250 mg/day orally for 5 days, repeating the cycle every 28 days; this is usually the best-tolerated chemotherapy and is particularly effective for metastatic pheochromocytoma or paraganglioma in patients with SDHB germline mutations. Each chemotherapy regimen has toxicities.

Metyrosine reduces catecholamine synthesis but does not impede the progressive growth of metastases; the initial metyrosine dosage is 250 mg four times daily, increased daily by increments of 250–500 mg to a maximum of 4 g/day. Metyrosine causes CNS side effects and crystalluria; hydration must be ensured.

B. Targeted Radioisotope Therapy

1. ^{131}I-MIBG—About 60% of patients with metastatic pheochromocytoma or paraganglioma have tumors with sufficient uptake of ^{123}I-MIBG on diagnostic scanning to allow for therapy with high-activity ^{131}I-MIBG. Azedra (^{131}Idobenguanine) is a no-carrier-added formulation that is FDA-approved for treating patients with metastatic pheochromocytoma or paraganglioma. Medications that reduce MIBG uptake must be avoided, particularly labetalol, phenothiazines, tricyclics, and sympathomimetics. Myelodysplastic syndrome and leukemia can develop several years after ^{131}I-MIBG therapy, with the risk proportional to the cumulative amount of isotope. ARDS and multisystem failure occur rarely after ^{131}I-MIBG therapy, particularly in patients with pretreatment proteinuria.

2. Peptide receptor radionuclide treatment (PRRT)—This therapy uses a radioisotope-tagged somatostatin analog against neuroendocrine tumors that express somatostatin receptors. ^{177}Lu-DOTATATE (Lutathera) is FDA-approved for treating patients with metastatic gastroenteropancreatic neuroendocrine tumors (GEP-NETs); it is being used off-label and on protocol to treat patients with metastatic pheochromocytoma and paraganglioma tumors, 90% of which are avid for PRRT.

C. Treatment for Bone Metastases

Patients with significant osteolytic bone metastases may be treated with external beam radiation therapy, which is often helpful in relieving pain and stabilizing local osseous disease. Patients with vertebral metastases and spinal cord compression require surgical decompression and kyphoplasty. Intravenous zoledronic acid or subcutaneous denosumab may also be administered to patients with osteolytic bone metastases.

Prognosis

A pheochromocytoma or sympathetic paraganglioma is considered malignant if metastases are present, but metastases may take many years to become clinically evident. Therefore, lifetime surveillance is recommended. Malignancy is more likely for larger tumors and for paragangliomas. The prognosis is good for patients with pheochromocytomas that are resected before causing cardiovascular damage. Hypertension usually resolves after successful surgery, but may persist or return in 25% of patients despite successful surgery. In such cases, biochemical reevaluation is required to detect a possible second or metastatic pheochromocytoma.

The surgical mortality is under 3% with the use of laparoscopic surgical techniques, intraoperative monitoring, and preoperative blood pressure control with alpha-blockers or calcium channel blockers.

Patients with metastatic pheochromocytoma or paraganglioma have an extremely variable prognosis. Some metastases are extremely indolent and may not progress or may present clinically for several decades after the primary tumor diagnosis. Metastases from head-neck paragangliomas are particularly slow-growing. However, some of these tumors are extremely aggressive. Rapid disease progression has been associated with male sex, older age, larger primary tumor size, dopamine hypersecretion, failure to undergo primary tumor resection, very high tumor burden, and metastases that are visible at the time of primary tumor diagnosis.

INCIDENTALLY DISCOVERED ADRENAL MASSES

Adrenal incidentalomas are defined as adrenal nodules that are discovered incidentally on up to 4% of abdominal CT or MRI scans obtained for other reasons. Although the overwhelming majority of adrenal incidentalomas are benign adrenal adenomas, it is always necessary to determine whether such masses are malignant or pheochromocytomas and whether they secrete excessive cortisol or aldosterone. Patients with an adrenal nodule and any possible manifestation of hypercortisolism should be screened for Cushing syndrome with a plasma ACTH, serum cortisol, and serum DHEAS; patients with a low or low-normal ACTH, a suppressed DHEAS, or a high cortisol should then be assessed with a 1-mg dexamethasone suppression test (see Cushing syndrome). Patients with hypertension are screened for primary aldosteronism with a PRA and serum aldosterone (see Primary Aldosteronism). Most adrenal incidentalomas should be assessed for pheochromocytoma, particularly when their diameter exceeds 3 cm, density exceeds 10 HU, and in patients with hypertension or suspicious symptoms; screening is done with plasma fractionated free metanephrines.

When an adrenal incidentaloma larger than 4 cm in diameter is detected in a patient without a history of malignancy, it should be resected, unless it is an unmistakably benign myelolipoma, hemorrhage, or adrenal cyst. Masses 3–4 cm in diameter may be resected if they have suspicious features (heterogeneity or irregularity). Smaller adrenal incidentalomas are usually observed after endocrine testing. A noncontrast CT scan can determine the density of the mass; adrenal incidentalomas with a density less than 10 HU on CT are unlikely to be a pheochromocytoma or metastasis. For small adrenal incidentalomas with a density of greater than or equal to 10 HU, an adrenal intravenous contrast “washout” CT scan may be obtained; the density of the adrenal incidentaloma in HU is calculated 60 seconds after contrast and again 15 minutes after contrast; a reduction (washout) of 40% or more is consistent with a benign adrenal adenoma. However, adrenal washout studies are only suggestive and about 20% of pheochromocytomas have adrenal washout of 40% or more; so, if the adrenal incidentaloma is not clinically a pheochromocytoma and not resected, a follow-up CT of the adrenals in 6–12 months is recommended to look for growth.

GASTROENTEROPANCREATIC NEUROENDOCRINE TUMORS (GEP-NETS) & CARCINOID TUMORS

ESSENTIALS OF DIAGNOSIS

- GEP-NETs are neuroendocrine tumors that originate in the gastrointestinal tract.
- About 60% GEP-NETs are nonsecretory or secretory without clinical manifestations; they may be detected incidentally or may present with weight loss, abdominal pain, or jaundice.
- Carcinoid tumors arise from the intestines or lung, secrete serotonin, and may metastasize.

General Considerations

GEP-NETs are a subset of neuroendocrine tumors (NETs) that arise from the stomach, intestines, or endocrine pancreas.

The reported incidence of GEP-NETs has increased to about 37 per million yearly in the United States due to the incidental detection of small tumors on abdominal scans. About 40% are functional, producing hormones that also serve as tumor markers, important for diagnosis and follow-up. At presentation, 65% of GEP-NETs are unresectable or metastatic. Up to 25% of GEP-NETs are associated with one of four different inherited disorders: MEN 1, von Hippel-Lindau disease (VHL), neurofibromatosis 1 (NF-1), and tuberous sclerosis complex (TSC). In MEN 1, GEP-NETs are usually gastrinomas, carcinoids, or nonfunctioning tumors and are a common cause of death. In VHL, GEP-NETs are usually benign and multiple.

Insulinomas are the most common functional type of GEP-NET and are usually small, intrapancreatic, and benign (90%) and secrete excessive amounts of insulin. Insulinomas also produce proinsulin and C-peptide. Insulinomas are solitary in 95% of sporadic cases but are multiple in about 90% of cases arising in MEN 1. (See Chapter 27.)

Gastrinomas secrete excessive quantities of the hormone gastrin (as well as “big” gastrin). About 50% of gastrinomas are malignant and metastasize to the liver. Gastrinomas are typically found in the duodenum (49%), pancreas (24%), or lymph nodes (11%). Sporadic gastrinoma is rarely suspected at the onset of symptoms; typically, there is a 5-year delay in diagnosis. About 22% of gastrinomas arise in patients with MEN 1, who usually present at a younger age, often with multiple tumors; hyperparathyroidism can occur many years before or after the discovery of a gastrinoma.

Glucagonomas are rare and usually malignant, despite their benign histologic appearance. They usually arise as a large intrapancreatic tumor with 60% having liver metastases apparent by the time of diagnosis. Besides glucagon, they usually secrete additional hormones, including gastrin.

Somatostatinomas are very rare and usually single. They arise in the pancreas (50%) or small intestine. They secrete somatostatin.

VIPomas are very rare and usually single intrapancreatic tumors with metastases usually evident (80%) at diagnosis. They produce vasoactive intestinal polypeptide (VIP).

CCKomas are rare tumors of the endocrine pancreas that secrete cholecystokinin.

Carcinoid tumors can arise from the small bowel (53%, particularly terminal ileum), colon (12%), esophagus through duodenum (6%), or lung (bronchial carcinoid [5%]). About 20% of cases present with metastases without a known primary location. Carcinoids are multiple in about 28% of cases. Although tumors are usually indolent, metastases are common, particularly to liver, lymph nodes, and peritoneum.

Clinical Findings

A. Symptoms and Signs

Nonfunctioning tumors typically present with mass effect and metastases, such as pancreatitis, jaundice, abdominal pain, or weight loss.

Insulinomas secrete insulin and present with the symptoms of fasting hypoglycemia. (See Chapter 27.)

Gastrinomas usually present with peptic ulcer disease—abdominal pain (75%), heartburn (44%), bleeding (25%)—or weight loss (17%) (Zollinger-Ellison syndrome). Endoscopy usually shows hyperplastic gastric rugae (94%).

Glucagonomas usually present with weight loss caused by glucagon-stimulated protein hepatic gluconeogenesis and related protein catabolism. Other common manifestations include diarrhea, nausea, peptic ulcer, hypoaminoacidemia, or necrolytic migratory erythema, known as "glucagonoma syndrome." Diabetes mellitus develops in about 35% of patients. The median survival is 34 months after diagnosis.

Somatostatinomas can present with a classic triad of symptoms: diabetes mellitus due to its inhibition of insulin and glucagon secretion; cholelithiasis due to its inhibition of gallbladder motility; and steatorrhea due to its inhibition of pancreatic exocrine function. Diarrhea, hypochlorhydria, and anemia can also occur.

VIPomas present with profuse **w**atery **d**iarrhea (unremitting), **h**ypokalemia, and **a**chlorhydria ("WDHA"), the so-called Verner-Morrison syndrome.

CCKomas may present with liver metastases and symptoms of diarrhea, peptic ulcer disease, and weight loss. Patients have elevated serum levels of cholecystokinin and CgA.

Carcinoid tumors can produce "carcinoid syndrome": episodes of abdominal pain, diarrhea, bronchospasm, and weight loss. Dry skin and flushing typically affect the upper chest, neck, and face and lasts from 30 seconds to 30 minutes, although flushing with bronchial carcinoids can persist for days. Although abdominal pain and diarrhea may occur at the same time as flushing, they usually occur at other times. Flushing can be unprovoked or precipitated by exercise, anesthesia, emotional stimuli, or foods (bananas, tomatoes, cheese, kiwi, eggplant, and alcohol). However, the full-blown carcinoid syndrome occurs with only about 10% of tumors. Other manifestations include carcinoid heart disease caused by endocardial fibrotic plaques. Tumor-induced fibrosis can also occur in the retroperitoneum causing ureteral obstruction or in the penis causing Peyronie disease. Pellagra (glossitis, confusion, dry skin), which results from the conversion of tryptophan (a precursor to niacin) to serotonin by tumor cells, may develop in affected patients with widespread metastases.

Bronchial carcinoids secrete serotonin and can produce carcinoid syndrome even without hepatic metastases. Foregut carcinoids secrete serotonin that is metabolized by the liver and produce carcinoid syndrome only when they have metastasized to the liver. Appendiceal carcinoids are typically discovered incidentally during appendectomy;

hemicolectomy is required if the tumor is 2 cm or larger or has unfavorable histopathology. Cecal carcinoids often present with intestinal obstruction or intestinal bleeding. Hindgut carcinoids rarely produce serotonin and do not cause carcinoid syndrome.

Ectopic hormones can be secreted by GEP-NETs. Ectopic ACTH secretion from bronchial carcinoids or pancreatic neuroendocrine tumors (pNETs) can produce Cushing syndrome.

B. Laboratory Findings

About 40% of GEP-NETs are functional, producing hormones that serve as tumor markers, which are important for diagnosis and follow-up. For carcinoid tumors, serum serotonin may be elevated along with urinary 5-hydroindoleacetic acid (5-HIAA). Additionally, serum CgA may be elevated in neuroendocrine tumors and can be another useful tumor marker.

C. Imaging

Localization of noninsulinoma GEP-NETs and their metastases is best done with PET scanning with ^{68}Ga-DOTATATE, a radiolabeled somatostatin analog; it is extremely sensitive. ^{111}In-pentreotide (Octreoscan) detects about 75% of noninsulinomas. ^{18}F-DOPA PET/CT may also be helpful in detecting occult carcinoid tumors. MRI scanning is more useful than CT for imaging and following hepatic metastases.

For insulinomas, preoperative localization studies are less successful and have the following sensitivities: ultrasonography 25%, CT 25%, endoscopic ultrasonography 27%, transhepatic portal vein sampling 40%, and arteriography 45%. Nearly all insulinomas can be successfully located at surgery by the combination of intraoperative palpation (sensitivity 55%) and ultrasound (sensitivity 75%). An abdominal CT scan is usually obtained, but extensive preoperative localization procedures, especially with invasive methods, are not required. Tumors may be located in the pancreatic head or neck (57%), body (15%), or tail (19%) or in the duodenum (9%). MRI is used to screen members of kindreds with genetic syndromes that predispose them to GEP-NETs.

Treatment

Surgery is the primary initial treatment for all types of GEP-NETs and is a reasonable option even for patients with stage IV disease. The aggressiveness of the surgery may vary from conservative debulking to radical resection and even liver transplantation.

With gastrinomas, the gastric hyperacidity of Zollinger-Ellison syndrome is treated with a proton pump inhibitor at quadruple the usual doses. Proton pump inhibitors increase serum gastrin, which would otherwise be useful as a tumor marker for gastrinoma recurrence after surgical resection.

Tumor visualization on octreotide scanning indicates that they may respond to long-acting preparations of somatostatin analogs, including lanreotide (Somatuline Depot) and octreotide (Sandostatin LAR Depot). Subcutaneous injections of Octreotide LAR 20–30 mg are required every 4 weeks. Treatment improves symptoms in patients with functioning tumors and also appears to improve progression-free survival in patients with either functioning or nonfunctioning GEP-NETs. Enlarging hepatic metastases may be embolized with ^{90}Y-labeled resin or glass microspheres. For patients with progressive metastatic disease, chemotherapy improves progression-free survival when added to somatostatin analog therapy (Table 39–2).

Prognosis

The prognosis for patients with GEP-NETs is variable, depending on the tumor grade and stage. Patients with well or moderately well differentiated GEP-NETs (Ki-67, a marker for cellular proliferation, less than 20%) have a much better survival than those with poorly differentiated tumors. Smaller tumors without detectable metastases have a much lower chance of recurrence after surgery. However, most patients with GEP-NETs are stage IV with hepatic metastases by the time of diagnosis. Nevertheless, low-grade metastases may be indolent or slow-growing and may respond to octreotide or lanreotide. The overall prognosis for patients with GEP-NETs is much better than that for adenocarcinomas that arise from the same organs. The prognosis is worse for patients with serum pancreastatin levels above 500 pmol/L, since it correlates with the amount of hepatic metastases.

The surgical complication rate for GEP-NETs is about 40%, with patients commonly developing fistulas and infections. Extensive pancreatic resection may cause diabetes mellitus. The overall 5-year survival is higher with functional tumors (77%) than with nonfunctional ones (55%) and higher with benign tumors (91%) than with malignant ones (55%). For patients with gastrinomas, the 5-, 10-, and 20-year survival rates with MEN 1 are 94%, 75%, and 58%, respectively, while the survival rates for patients with sporadic gastrinomas are 62%, 50%, and 31%, respectively.

MULTIPLE ENDOCRINE NEOPLASIA (MEN)

MEN TYPES 1–4

ESSENTIALS OF DIAGNOSIS

- **MEN 1:** tumors of the parathyroid glands, endocrine pancreas and duodenum, anterior pituitary, adrenal, thyroid; carcinoid tumors; lipomas and facial angiofibromas.
- **MEN 2 (MEN 2A)**: medullary thyroid cancers, hyperparathyroidism, pheochromocytomas, Hirschsprung disease.
- **MEN 3 (MEN 2B)**: medullary thyroid cancers, pheochromocytomas, Marfan-like habitus, mucosal neuromas, intestinal ganglioneuroma, delayed puberty.
- **MEN 4**: tumors of the parathyroid glands, anterior pituitary gland, adrenal gland, ovary, testicle, kidney.

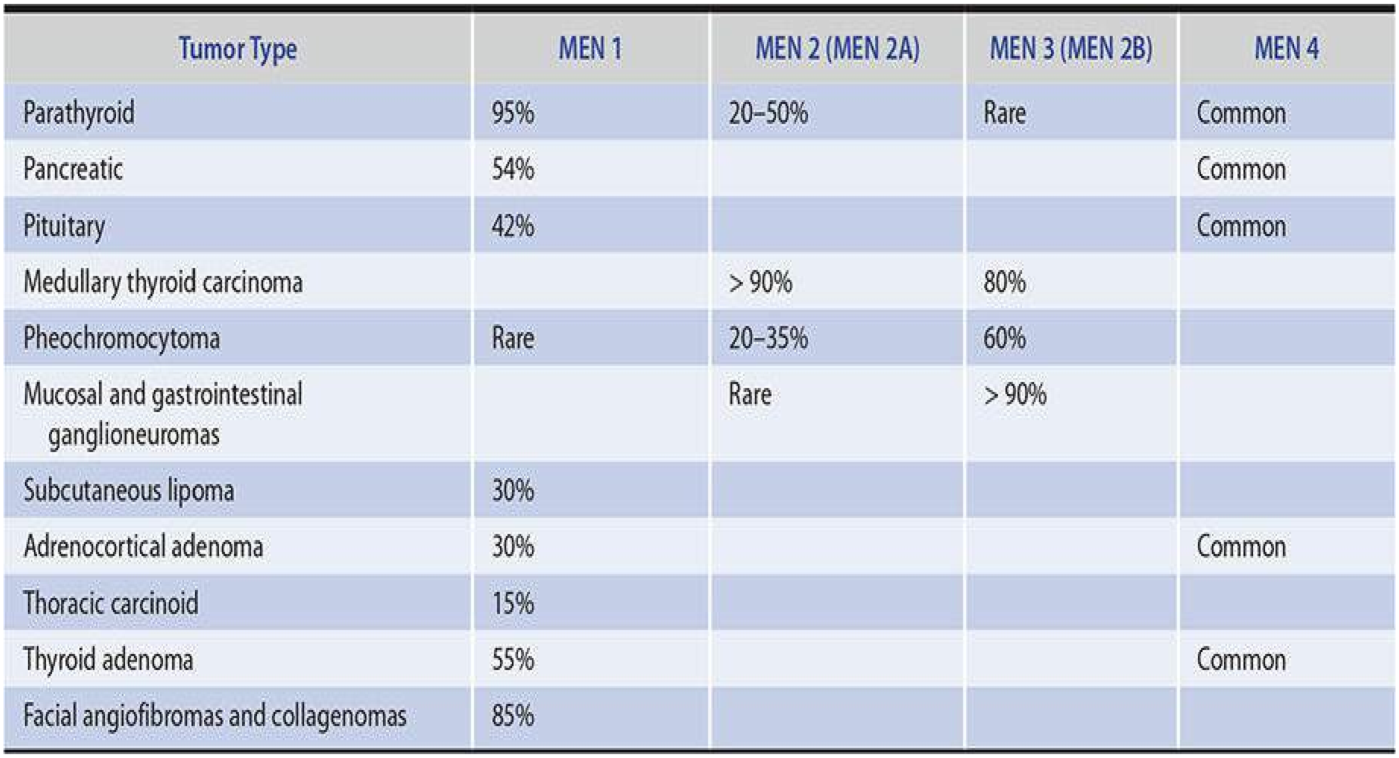
Syndromes of MEN are inherited as autosomal dominant traits that cause a predisposition to the development of tumors of two or more different endocrine glands (Table 26–12). MEN syndromes are caused by different germline mutations and tumors arising when certain additional somatic mutations occur in predisposed organs. Patients with MEN should have genetic testing so that their first-degree relatives may then be tested for the specific mutation.

1. MEN 1

Multiple endocrine neoplasia type 1 (MEN 1, Wermer syndrome) is a tumor syndrome with a prevalence of 2–10 per 100,000 persons in the United States. About 90% of affected patients harbor a detectable germline mutation in the menin gene.

The presentation of MEN 1 is quite variable, even in the same kindred. Affected patients are prone to many different tumors, particularly involving the parathyroids, endocrine pancreas and duodenum, and anterior pituitary (Table 26–12). The initial biochemical manifestations (usually hypercalcemia) can often be detected as early as age 14–18 years in patients with a MEN 1 gene mutation, although clinical manifestations usually present in the third or fourth decade.

Table 26–12. Multiple endocrine neoplasia (MEN) syndromes: incidence of tumor types.



Tumor Type	MEN 1	MEN 2 (MEN 2A)	MEN 3 (MEN 2B)	MEN 4
Parathyroid	95%	20–50%	Rare	Common
Pancreatic	54%			Common
Pituitary	42%			Common
Medullary thyroid carcinoma		> 90%	80%	
Pheochromocytoma	Rare	20–35%	60%	
Mucosal and gastrointestinal ganglioneuromas		Rare	> 90%	
Subcutaneous lipoma	30%			
Adrenocortical adenoma	30%			Common
Thoracic carcinoid	15%			
Thyroid adenoma	55%			Common
Facial angiofibromas and collagenomas	85%			

Hyperparathyroidism is the first clinical manifestation of MEN 1 in two-thirds of affected patients, but it may present at any time of life.

GEP-NETs and carcinoids occur in up to 70% of patients with MEN 1. The GEP-NETs may secrete only pancreatic polypeptide or be nonsecretory altogether (20–55%). **Gastrinomas** occur in about 40% of patients with MEN 1. Concurrent hypercalcemia, due to hyperparathyroidism in MEN 1, stimulates gastrin and worsens gastric acid secretion; control of the hypercalcemia often reduces serum gastrin levels and gastric acid secretion. Carcinoid tumors can arise in the lung or abdomen and can metastasize, especially to the liver.

Insulinomas occur in about 10% of patients with MEN 1. Extrapancreatic neuroendocrine tumors are common in MEN 1, are frequently malignant, and include carcinoid tumors usually in foregut locations (69%), such as the lung, thymus, duodenum, or stomach.

Pituitary adenomas are the presenting tumor in 29% of patients with MEN 1 and eventually are found in about 42% of patients with MEN 1. About 42% of such pituitary adenomas are nonsecretory. While nonsecretory pituitary microadenomas (less than 1 cm diameter and detected on routine MRI screening) are usually indolent, about 25% of nonsecretory pituitary adenomas are macroadenomas (1 cm or more in diameter) and more aggressive.

Adrenal adenomas or hyperplasia occur in about 40% of patients with MEN 1 and 50% are bilateral. They are generally benign and nonfunctional. These adrenal lesions are ACTH-independent.

Thymic neuroendocrine tumors occur in 3.4% of affected patients, mostly in males, with a 10-year survival of 25%. Lung neuroendocrine tumors occur in 13%, with a 10-year survival of 71%.

Benign thyroid adenomas or multinodular goiter occurs in about 55% of MEN 1 patients. Patients may undergo a thyroidectomy at the time of parathyroidectomy.

Nonendocrine tumors occur commonly in MEN 1, particularly small head-neck angiofibromas (85%) and lipomas (30%). Collagenomas are common (70%), presenting as firm dermal nodules. Affected patients may also be more prone to meningiomas, breast cancer, colorectal cancers, prostate cancer, and malignant melanomas.

Overall, patients with MEN 1 have an increased mortality rate with a mean life expectancy of only 55 years.

2. MEN 2 (MEN 2A)

Multiple endocrine neoplasia type 2 (MEN 2A, Sipple syndrome) is a rare autosomal-dominant tumor syndrome that arises in patients with a germline gain-of-function ret protooncogene mutation. Genetic testing identifies about 95% of affected individuals.

Medullary thyroid carcinoma (greater than 90%); **hyperparathyroidism** (30%), with hyperplasia or adenomas of multiple parathyroid glands developing in most cases; **pheochromocytomas** (30%), which are often bilateral and frequently asymptomatic; and **Hirschsprung disease** may develop. No patients with MEN 2 should receive therapy for diabetes with glucagon-like peptide 1 (GLP 1) agonists that may increase the risk for medullary thyroid carcinoma. Before any surgical procedure, MEN 2 (2A) carriers should be screened for pheochromocytoma (see above) and for medullary thyroid carcinoma.

3. MEN 3 (MEN 2B)

Multiple endocrine neoplasia type 3 (MEN 2B) is a familial, autosomal dominant multiglandular syndrome that is also caused by a germline gain-of-function mutation of the ret protooncogene. MEN 3 (2B) is characterized by mucosal neuromas (in more than

90% of affected patients) with bumpy and enlarged lips and tongue, Marfan-like habitus (75% of cases), and adrenal pheochromocytomas (60%) that are rarely malignant and often bilateral. Patients also have intestinal abnormalities (75%) such as intestinal ganglioneuromas, skeletal abnormalities (87%), and delayed puberty (43%). Medullary thyroid carcinoma (80%) is aggressive and presents early in life.

4. MEN 4

Multiple endocrine neoplasia type 4 (MEN 4) is a rare autosomal-dominant familial tumor syndrome caused by germline mutations in the gene CDKN1B. Affected patients are particularly prone to adenomas of the pituitary and parathyroid glands and neuroendocrine tumors of the pancreas. Unlike patients with MEN 1, those with MEN 4 are also appear to be prone to adrenal tumors, renal tumors, testicular cancer, and neuroendocrine cervical carcinoma.

OTHER SYNDROMES OF MULTIPLE ENDOCRINE NEOPLASIA

Patients with **Carney complex** develop adrenocortical nodular hyperplasia, pituitary adenomas, thyroid tumors, gonadal Sertoli cell tumors, and cardiac myxomas. With **McCune-Albright syndrome,** precocious puberty (particularly girls) develops due to gonadal hypersecretion. Multiple adrenal nodules can rarely cause Cushing syndrome. Hyperthyroidism results from autonomously functioning thyroid nodules. Acromegaly is caused by GH-secreting pituitary tumors. Patients also have fibrous dysplasia of bones and hypophosphatemia, and bone fractures are common. Sudden death has been reported. **Type 2 von Hippel Lindau (VHL) syndrome** is associated with pheochromocytomas, pancreatic/duodenal neuroendocrine tumors, hyperparathyroidism, and pituitary tumors as well as hemangiomas and renal cell carcinomas. **Hypoxia inducible factor 2A (HIF2A) germline mutations** predispose to pheochromocytomas, pancreatic/duodenal somatostatinomas, as well as erythrocytosis and retinal abnormalities. **Neurofibromatosis type 1 (NF-1)** is associated with pheochromocytomas and pancreatic/duodenal somatostatinomas as well as neurofibromas and hypothalamic hamartomas.

DISEASES OF THE TESTES & MALE BREAST

MALE HYPOGONADISM

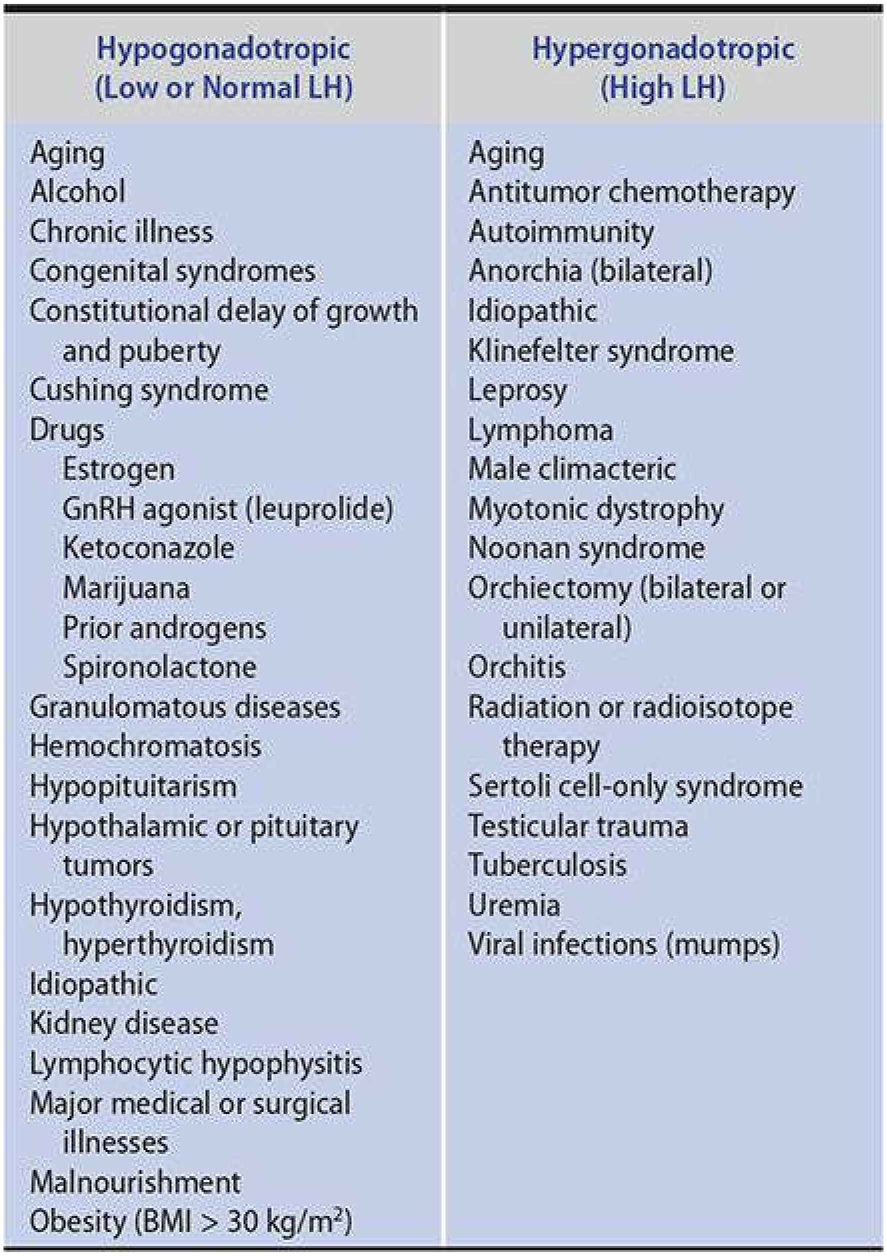
ESSENTIALS OF DIAGNOSIS

- Diminished libido and erections.
- Fatigue, depression, reduced exercise endurance.
- Decreased growth of body hair.
- Testes small or normal in size.
- Low serum total testosterone or free testosterone.
- Serum LH and FSH are low or normal in hypogonadotropic hypogonadism; they are high in testicular failure (hypergonadotropic hypogonadism).

General Considerations

Male hypogonadism is caused by deficient testosterone secretion by the testes. It may be classified according to whether it is due to (1) insufficient gonadotropin secretion by the pituitary (hypogonadotropic); (2) pathology in the testes themselves (hypergonadotropic); or (3) both (Table 26–13). Partial male hypogonadism may be difficult to distinguish from the physiologic reduction in serum testosterone seen in normal aging, obesity, and illness.

Table 26–13. Causes of male hypogonadism.



Hypogonadotropic (Low or Normal LH)	Hypergonadotropic (High LH)
Aging	Aging
Alcohol	Antitumor chemotherapy
Chronic illness	Autoimmunity
Congenital syndromes	Anorchia (bilateral)
Constitutional delay of growth and puberty	Idiopathic
Cushing syndrome	Klinefelter syndrome
Drugs	Leprosy
Estrogen	Lymphoma
GnRH agonist (leuprolide)	Male climacteric
Ketoconazole	Myotonic dystrophy
Marijuana	Noonan syndrome
Prior androgens	Orchiectomy (bilateral or unilateral)
Spironolactone	Orchitis
Granulomatous diseases	Radiation or radioisotope therapy
Hemochromatosis	Sertoli cell-only syndrome
Hypopituitarism	Testicular trauma
Hypothalamic or pituitary tumors	Tuberculosis
Hypothyroidism, hyperthyroidism	Uremia
Idiopathic	Viral infections (mumps)
Kidney disease	
Lymphocytic hypophysitis	
Major medical or surgical illnesses	
Malnourishment	
Obesity (BMI > 30 kg/m^2)	

BMI, body mass index; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Etiology

A. Hypogonadotropic Hypogonadism (Low Testosterone With Normal or Low LH)

A deficiency in FSH and LH may be isolated or associated with other pituitary hormonal abnormalities. (See Hypopituitarism.) Hypogonadotropic hypogonadism can be primary, defined as failure to enter puberty by age 14, with causes including isolated hypogonadotropic hypogonadism, hypopituitarism, or simple constitutional delay of growth and puberty; or it can be acquired, with causes listed in Table 26–13. Genetic conditions (eg, Kallmann syndrome or PROKR2 mutations, X-linked congenital adrenal hypoplasia, 17-ketosteroid reductase deficiency, Prader-Willis syndrome) account for about 40% of cases of isolated, and apparently idiopathic, acquired hypogonadotropic hypogonadism with a serum testosterone level less than 150 ng/dL (5.2 nmol/L).

Partial male hypogonadotropic hypogonadism is defined as a serum testosterone in the range of 150–300 ng/dL (5.2–10.4 nmol/L). The main causes of acquired partial male hypogonadotropic hypogonadism include obesity, poor health, or normal aging, such that it is termed **age-related hypogonadism**. Spermatogenesis is usually preserved.

B. Hypergonadotropic Hypogonadism (Testicular Failure With High LH)

A failure of the testicular Leydig cells to secrete adequate testosterone causes a rise in LH and FSH. Acquired conditions that can cause testicular failure are listed in Table 26–13. Male hypergonadotropic hypogonadism can also be caused by XY gonadal dysgenesis, partial 17-ketosteroid reductase deficiency and a congenital partial deficiency in the steroidogenic enzyme CYP17 (17-hydroxylase). CYP17 may be deliberately inhibited by abiraterone acetate, a drug for prostate cancer. In men who have had a unilateral orchiectomy for cancer, the remaining testicle frequently fails, even in the absence of radiation or chemotherapy.

Klinefelter syndrome (47,XXY and its variants) is the most common chromosomal abnormality among males, with an incidence of about 1:500 (see Chapter 40). Although puberty occurs at the normal time, the degree of virilization is variable. Serum testosterone is usually low and gonadotropins are elevated. Other common findings include tall stature and abnormal body proportions that are unusual for hypogonadal men (eg, height more than 3 cm greater than arm span).

XY gonadal dysgenesis describes several conditions that result in the failure of the testes to develop normally. SRY is a gene on the Y chromosome that initiates male sexual development. Mutations in SRY result in testicular dysgenesis. Affected individuals lack testosterone, which results in sex reversal: female external genitalia with a blind vaginal pouch, no uterus, and intra-abdominal dysgenetic gonads. Affected individuals appear as normal girls until their lack of pubertal development and amenorrhea leads to the diagnosis. Intra-abdominal rudimentary testes have an increased risk of developing a malignancy and are usually resected.

C. Androgen Insensitivity

Partial resistance to testosterone is a rare condition in which phenotypic males have variable degrees of apparent hypogonadism, hypospadias, cryptorchism, and gynecomastia. Serum testosterone levels are normal.

Clinical Findings

A. Symptoms and Signs

Hypogonadism that is congenital or acquired during childhood presents as delayed puberty. Men with acquired hypogonadism have variable manifestations, known as “testosterone deficiency syndrome.” Most men experience decreased libido. Others complain of erectile dysfunction, poor morning erection, or hot sweats. Men often have depression, fatigue, or decreased ability to perform vigorous physical activity. The presenting complaint may also be infertility, gynecomastia, headache, fracture, or other symptoms related to the cause or result of the hypogonadism. The patient’s history often gives a clue to the cause (Table 26–13).

Physical signs associated with hypogonadism may include decreased body, axillary, beard, or pubic hair, but only after years of severe hypogonadism. Men with hypogonadism lose muscle mass and gain weight due to an increase in subcutaneous fat. Examination should include measurements of arm span and height. Testicular size should be assessed with an orchidometer (normal volume is about 10–25 mL; normal length is usually over 6 cm). Testicular size may decrease but usually remains within the normal range in men with postpubertal hypogonadotropic hypogonadism, but it may be diminished with testicular injury or Klinefelter syndrome. The testes must also be carefully palpated for masses, since Leydig cell tumors may secrete estrogen and present with hypogonadism. The testicles must be carefully examined for evidence of trauma, infiltrative lesions (eg, lymphoma), or infection (eg, leprosy, tuberculosis).

B. Laboratory Findings

The evaluation for hypogonadism begins with a morning (before 10 AM) serum testosterone and free testosterone measurement. In men with low serum testosterone levels, testing is repeated in order to confirm the diagnosis. Serum testosterone levels are considered low if they are confirmed to be less than 240 ng/dL (8.3 nmol/L). For men ages 18–69, serum free testosterone levels are considered low if they are confirmed to be less than 35 pg/mL (120 pmol/L) or less than 30 pg/mL (100 pg/L) for men ages 70 and over.

Normal ranges for serum testosterone have been derived from nonfasting morning blood specimens, which tend to be the highest of the day. Later in the day, serum testosterone levels can be 25–50% lower. Therefore, a serum testosterone drawn fasting or late in the day may be misleadingly below the “reference range.”

Serum testosterone levels in men are highest at age 20–30 years and slightly lower at age 30–40 years. After age 40, serum total testosterone declines variably by an average of 1–2% annually; serum free testosterone levels decline even faster, since sex hormone binding globulin increases with age. Serum levels of free testosterone are lower in men aged 40–70 compared with younger men, without any increase in serum LH. A problem with the diagnosis of age-related hypogonadism is that most laboratories provide reference ranges for testosterone that are derived from young men and may not provide age-adjusted reference ranges for serum testosterone and free testosterone. The main conditions that contribute to the general decline in serum testosterone with aging include obesity, illness, and opioids. After age 70, LH levels tend to rise, indicating a contribution of primary gonadal dysfunction with advancing age. Testing for serum free testosterone is especially important for detecting hypogonadism in elderly men, who generally have high levels of sex hormone binding globulin. A low serum testosterone or free testosterone should be verified with a repeat morning nonfasting assay, along with serum LH and PRL levels. Serum LH levels are high in patients with hypergonadotropic hypogonadism but low or inappropriately normal in men with hypogonadotropic hypogonadism or normal aging. High serum estradiol levels are seen in men with obesity-related hypogonadotropic hypogonadism.

Testosterone stimulates erythropoiesis in men, causing the normal red blood count range to be higher in men than in women; mild anemia is common in men with hypogonadism. For men with longstanding severe male hypogonadism, osteoporosis is common, so a bone densitometry is recommended.

1. Hypogonadotropic hypogonadism—A serum PRL determination is obtained to screen for a pituitary prolactinoma and other pituitary/hypothalamic lesions, but serum PRL may be elevated for many other reasons (see Table 26–1). The serum estradiol level may be elevated in patients with cirrhosis and in rare cases of estrogen-secreting tumors (testicular Leydig cell tumor or adrenal carcinoma). Men with no discernible definite cause for hypogonadotropic hypogonadism should be screened for hemochromatosis. Men with hypogonadotropic hypogonadism should have an MRI of the pituitary/hypothalamus to search for a mass lesion in presence of one or more of the following: (1) severe hypogonadism (serum testosterone below 150 ng/mL or 5.2 nmol/L), (2) elevated serum PRL, (3) other pituitary hormone deficiencies, or (4) symptoms of a mass lesion (headaches or visual field deficits).

2. Hypergonadotropic hypogonadism—Men with hypergonadotropic hypogonadism have low serum testosterone levels with a compensatory increase in FSH and LH. Klinefelter syndrome can be confirmed by karyotyping or by measurement of leukocyte XIST. Testicular biopsy is usually reserved for younger patients in whom the reason for primary hypogonadism is unclear.

Treatment

Testosterone replacement is reasonable for boys who have not entered puberty by age 14 years. It is also beneficial for most men with primary testicular failure (hypergonadotropic hypogonadism). Testosterone replacement or gonadal stimulation therapy is also warranted for men with severe hypogonadotropic hypogonadism of any etiology with serum testosterone levels less than 150 ng/mL (5.2 nmol/L). Testosterone therapy should also be considered for men with low or low-normal serum testosterone or free testosterone, along with elevated serum LH levels. For other men without elevated serum LH levels and an average of at least two morning serum total testosterone levels below 275 ng/dL (9.5 nmol/L, "physiologic hypogonadism"), a trial of testosterone therapy may be considered, particularly if they have at least three of the following six symptoms: erectile dysfunction, poor morning erection, low libido, depression, fatigue, and inability to perform vigorous activity. Testosterone replacement should be continued only if they clearly derive clinical benefit from therapy. Therapy can be adjusted with an aim to improve clinical symptoms while maintaining normal serum levels of testosterone or free testosterone. Men with physiologic low-normal serum testosterone levels above 325 ng/dL (11.3 nmol/L) are unlikely to benefit from testosterone therapy.

Testosterone replacement or stimulation therapy carries certain risks. Therefore, testosterone therapy should only be given to men who have a documented low serum total or free testosterone. Testosterone therapy should not be given to men with active breast cancer or prostate cancer. It is also prudent to monitor the hematocrit and lipid profile of men receiving testosterone, since therapy can cause erythrocytosis and hyperlipidemia. Testosterone therapy can also cause gynecomastia. Testosterone therapy is not given to men with untreated sleep apnea or heart failure.

Drug interactions can occur. Testosterone should be administered cautiously to men receiving coumadin, since the combination can increase the INR and risk of bleeding. Similarly, testosterone therapy can increase serum levels of cyclosporine, tacrolimus, and tolvaptan. Testosterone can predispose to hypoglycemia in diabetic men receiving insulin or oral hypoglycemic agents, so close monitoring of blood sugars is advisable during initiation of testosterone therapy.

Oral androgen therapy with methyltestosterone is not advisable due to the potential for causing liver tumors, peliosis hepatis, and cholestatic jaundice.

Men with severe osteoporosis may require treatment with bisphosphonates and vitamin D, in addition to testosterone replacement therapy.

A. Therapies for Male Hypogonadism

1. Testosterone topical gels—Topical testosterone is usually applied once daily in the morning after showering. One or two fingers are used to apply the gel evenly to skin. Afterwards, the hands should be washed. Topical testosterone should not be applied to the breast or genitals. The gel should be allowed to air-dry (about 10 minutes) before dressing. Before close contact with women or children, a shirt must be worn or the areas of application washed with soap and water to prevent transfer of testosterone to them. The patient should avoid swimming, showering, or washing the application area for at least 2 hours following application.

Testosterone topical generic 1% gel is available in packets (12.5 mg/1.25 g, 25 mg/2.5 g, or 50 mg/5g) or tubes (50 mg/5 g). The recommended dose is 50–100 mg daily. Testosterone topical generic 2% gel is available in a gel pump (10 mg/0.5 g actuation). The recommended dose is 40–70 mg daily. Androgel 1% gel is available in 2.5-g packets (25 mg testosterone) and 5-g packets (50 mg testosterone) and in a pump that dispenses 12.5 mg testosterone per pump actuation: the recommended dose is 50–100 mg applied daily to the shoulders. Androgel 1.6% gel is available in a pump that dispenses 20.25 mg testosterone per pump actuation; the recommended dose is 40.5–81 mg daily. Testim 1% gel is available in 5-g tubes (50 mg testosterone); the recommended dose is 50–100 mg applied daily. Fortesta 2% gel is available in a pump that dispenses 10 mg testosterone per pump actuation; the recommended dose is 40–70 mg daily. Testogel is distributed in 5-g sachets (50 mg testosterone); this brand is not available in the United States. Testim, Fortesta, and Testogel may be applied to shoulders, upper arms, or abdomen. Axiron 2% solution is available in a pump that dispenses 30 mg per actuation; the recommended dose is 30–60 mg applied to each axilla daily. Vogelxo is a 1% testosterone gel that is available in packets or tubes (50 mg/5 g) or a gel pump (12.5 mg/1.25 g); it is applied to the shoulders in doses of 50–100 mg once daily.

The serum testosterone level should be determined about 14 days after starting therapy; if the level remains below normal or the clinical response is inadequate, the daily dose may be increased to 1.5 to 2 times the initial dose. Unfortunately, serum testosterone levels vary considerably during the day after topical testosterone gel application, such that a single serum testosterone level may not accurately reflect the average serum testosterone for that individual.

2. Transdermal testosterone patches—Testosterone transdermal systems (skin patches) are applied to nongenital skin. Androderm (2 or 4 mg/day) patches may be applied at bedtime in doses of 4–8 mg; it adheres tightly to the skin and may cause skin irritation.

3. Parenteral testosterone—The dose and injection intervals are adjusted according to the patient’s clinical response and serum testosterone levels drawn just before the next injection is due. A target serum testosterone level of 500 ng/dL (17.3 nmol/L) is suggested. **Testosterone cypionate** has been in use for decades; it is an intramuscular testosterone formulation that is available in solutions containing 200 mg/mL. Its main advantage is low cost. The usual dose is 200 mg every 2 weeks or 300 mg every 3 weeks. It is usually injected into the gluteus medius muscle in the upper lateral buttock, alternating sides. The injection technique must include sterile precautions and draw-back prior to injection to ensure against intravenous injection, which can result in pulmonary oil embolism.

Testosterone pellets (Testopel) are a very long-lasting depot testosterone formulation that is available as individual vials containing a single 75 mg implantable pellet in each vial. With sterile technique, the skin of the upper-outer buttock is anesthetized with lidocaine; using a trochar, the pellets are injected subcutaneously in doses of 150–450 mg every 3–6 months as an in-office procedure.

Testosterone undecanoate (Aveed, Nebido) is a long-lasting depot testosterone formulation. Its use is restricted to qualified health care facilities. It is usually injected into the gluteus medius muscle in the upper lateral buttock, alternating sides. Care must be taken to avoid intravascular injection by pulling back on the syringe plunger before injection; if any blood appears in the syringe, the needle is withdrawn and the syringe is discarded. Testosterone undecanoate (Aveed) is formulated as individual vials containing 750 mg/3 mL oily solution for intramuscular injection. The initial injection of 750 mg is followed by another 750 mg injection 4 weeks later and maintenance doses of 750 mg every 10 weeks. Testosterone undecanoate (Nebido) is formulated as individual vials containing 1000 mg/4 mL oily solution for intramuscular injection. The initial injection of 1000 mg is followed by another 1000 mg injection 6 weeks later and maintenance doses of 1000 mg every 12 weeks. A serum testosterone level is measured before the fourth dose; if the serum testosterone remains low, the dosing interval is shortened to every 10 weeks.

Caution: Testosterone undecanoate injections have caused serious pulmonary oil microembolism reactions that present with cough, dyspnea, tight throat, chest pain, and syncope. Anaphylaxis can also occur. Patients must be observed in the health care setting for 30 minutes after the injection in order to provide appropriate medical care for the complication.

4. Buccal testosterone—Testosterone buccal tablets (Striant) are placed between the upper lip and gingivae. One or two 30-mg tablets are thus retained and changed every 12 hours. They should not be chewed or swallowed.

5. Testosterone nasal gel—Intranasal gel testosterone (Natesto) is self-administered by a metered-dose nasal pump: one pump actuation (5.5 mg) into each nostril three times daily. The nasal pump needs to be primed by inverting it and pressing the pump 10 times before it is used the first time. It should not be used concurrently with intranasal sympathomimetic decongestants. Adverse effects include nasopharyngitis, sinusitis, bronchitis, epistaxis, nasal discomfort, and headache.

6. Oral methyltestosterone—Oral testosterone supplementation is available as methyltestosterone 10-mg tablets. The usual dose is 10–50 mg daily, given either once daily or in divided doses. Oral methyltestosterone can produce acute hepatitis and chronic high-dose use can cause peliosis hepatis, cholestatic hepatitis, and hepatocellular carcinoma. Therefore, its use is not recommended, and it is no longer available in some countries.

7. Clomiphene citrate—Men with functional hypogonadotropic hypogonadism usually respond well to clomiphene citrate that is administered orally in doses that are titrated to achieve the desired clinical response with a serum testosterone level of about 500 ng/dL (17.3 nmol/L). Treatment with clomiphene is commenced with 25 mg on alternate days and increased to 50 mg on alternate days if necessary, with a maximum dose of 50 mg daily. Serum testosterone levels usually normalize while spermatogenesis usually improves.

8. Gonadotropins—Patients with hypogonadotropic hypogonadism may require therapy with gonadotropins, particularly to induce fertility. Men may receive hCG 1000 units subcutaneously three times weekly for 6 months; if the semen analysis shows inadequate sperm, FSH 75 units subcutaneously three times weekly is added. Many men prefer long-term therapy with hCG over testosterone therapy, but cost is an issue.

9. Weight loss—When hypogonadotropic hypogonadism is due to morbid obesity, significant weight loss will improve serum testosterone levels. The rise in serum testosterone is proportionate to the weight loss. Although diet-induced weight loss is beneficial, bariatric surgery has been much more effective and serum testosterone levels may normalize after dramatic weight loss.

B. Benefits of Testosterone Replacement Therapy

Testosterone therapy given for the indications listed under Treatment, above, usually benefits men with low serum testosterone and at least three manifestations of hypogonadism. Testosterone therapy can improve overall mood, sense of well-being, sexual desire, and erectile function. It also increases physical vigor and muscle strength. Testosterone replacement also improves exercise endurance and stair climbing ability. Long-term testosterone replacement causes significant weight loss and a reduction in waist circumference. After 2 years of testosterone replacement, muscle mass increases about 4.5%, while fat mass decreases by about 9.1%. Appropriate testosterone replacement therapy also appears to improve longevity.

C. Risks of Testosterone Replacement or Stimulation Therapy

Testosterone therapy does not appear to significantly increase the risk of prostate cancer or benign prostatic hypertrophy above that of normal men, as long as serum testosterone levels are maintained in the normal reference range on therapy. However, testosterone therapy is contraindicated in the presence of active prostate cancer. Hypogonadal men who have had a prostatectomy for low-grade prostate cancer, and who have remained in complete remission for several years, may have testosterone therapy given cautiously while monitoring serum PSA levels.

Erythrocytosis develops in some men who are treated with testosterone. Erythrocytosis is more common with intramuscular injections of testosterone enanthate than with transcutaneous testosterone. However, no increase in the incidence of thromboembolic events has been reported.

Testosterone therapy tends to aggravate sleep apnea in older men, likely through CNS effects. Surveillance for sleep apnea is recommended during testosterone therapy and a formal evaluation is recommended for all high-risk patients with snoring, obesity, partner's report of apneic episodes, nocturnal awakening, unrefreshing sleep with daytime fatigue, or hypertension.

Men who are treated with testosterone frequently experience some increase in acne that is usually mild and tolerated; topical antiacne therapy or a reduction in testosterone replacement dosage may be required. Increases in intraocular pressure have occurred during testosterone therapy. During the initiation of testosterone replacement therapy, gynecomastia develops in some men, which usually is mild and tends to resolve spontaneously; switching from testosterone injections to testosterone transdermal gel may help this condition.

D. Risks of Performance-Enhancing Anabolic Steroids

Performance-enhancing agents, particularly androgenic anabolic steroids, are used by up to 2% of young athletes and by 20–65% of power sport athletes. They are often used as part of a "stacking" polypharmacy that may include nandrolone decanoate, dimethandrolone, testosterone propionate, or testosterone enanthate. These androgens are usually illegal and often contaminated by toxic substances and can produce toxic hepatitis, dependence, aggression, depression, dyslipidemias, gynecomastia, acne, male pattern baldness, hepatitis, thromboembolism, and cardiomyopathy. Shared needles may transmit hepatitis or HIV. Arsenic contamination has been reported to cause multiorgan failure and death.

Prognosis of Male Hypogonadism

If hypogonadism is due to a pituitary lesion, the prognosis is that of the primary disease (eg, tumor, necrosis). The prognosis for restoration of virility is good if testosterone is given. In one large study, cardiovascular risk was reduced in hypogonadal men over age 40 who were receiving testosterone replacement therapy to maintain serum testosterone levels within the normal reference range.

CRYPTORCHISM

Cryptorchidism is found in 1–2% of males after 1 year of age but must be distinguished from retractile testes, which require no treatment. Infertility or subfertility occurs in up to 75% of men with bilateral cryptorchism and in 50% of men with unilateral cryptorchism. Some patients have underlying hypogonadism, including hypogonadotropic hypogonadism.

For a testis that is not palpable, it is important to locate the testis and bring it into the scrotum or prove its absence. About one-third of nonpalpable testes are located within the inguinal canal, one-third are intra-abdominal, and one-third are absent.

Ultrasound can detect an inguinal testis. If ultrasound is negative, MRI is performed to locate the testis.

The lifetime risk of testicular neoplasia is 0.002% in normal males. The risk of malignancy is higher for cryptorchid testes (0.06%) and for intra-abdominal testes (5%). Orchiopexy decreases the risk of neoplasia when performed before 10 years of age. Orchiectomy after puberty is an option for intra-abdominal testes.

GYNECOMASTIA

ESSENTIALS OF DIAGNOSIS

- Palpable enlargement of the male breast, often asymmetric or unilateral.
- **Glandular gynecomastia:** typically tender.
- **Fatty gynecomastia:** typically nontender.
- Must be distinguished from carcinoma or mastitis.

General Considerations

Gynecomastia is defined as the presence of palpable glandular breast tissue in males. Pubertal gynecomastia develops in about 60% of boys; the swelling usually subsides spontaneously within a year. It is particularly common in teenagers who are very tall or overweight. The causes are multiple and diverse (Table 26–14). About 20% of adult gynecomastia is caused by drug therapy. It can develop in HIV-infected patients treated with antiretroviral therapy, especially in men receiving efavirenz or didanosine; breast enlargement resolves spontaneously in 73% of patients within 9 months. Gynecomastia develops in about 50% of athletes who abuse androgens and anabolic steroids. Fatty pseudogynecomastia is common among elderly men, particularly when there is associated weight gain. However, true glandular gynecomastia can be the first sign of a serious disorder in older men (Table 26–14).

Table 26–14. Causes of gynecomastia.

Physiologic causes

- Aging
- Neonatal period, puberty
- Obesity

Endocrine diseases

- Androgen insensitivity syndrome
- Aromatase excess syndrome (sporadic or familial)
- Diabetic lymphocytic mastitis
- Hyperprolactinemia
- Hyperthyroidism
- Klinefelter syndrome
- Male hypogonadism (primary or secondary)
- Partial 17-ketosteroid reductase deficiency

Systemic diseases

- Chronic liver disease
- Chronic kidney disease
- Hansen disease
- Neurologic disorders
- Refeeding after starvation
- Spinal cord injury

Neoplasms

- Adrenal tumors
- Bronchogenic carcinoma
- Carcinoma of the breast
- Ectopic hCG: CNS germinoma, lung, hepatocellular, gastric, renal carcinomas
- Pituitary prolactinoma
- Testicular hCG-secreting tumors

Drugs (partial list)

- Alcohol
- Alkylating chemotherapeutic agents
- Amiodarone
- Anabolic steroids
- Androgens (testosterone)
- Anti-androgens

Drugs (partial list) (cont.)

- Antipsychotics (first- and second-generation)
- Antiretroviral agents
- Calcium channel blockers (rare)
- Chorionic gonadotropin
- Cimetidine
- Clomiphene
- Diazepam
- Digitalis preparations
- Dutasteride
- Estrogens (oral or topical)
- Ethionamide
- Famotidine (rare)
- Fenofibrate (rare)
- Finasteride
- GnRH analogs
- Growth hormone
- Hydroxyzine
- Isoniazid
- Ketoconazole
- Lavender (topical)
- Marijuana
- Methadone
- Methotrexate (rare)
- Methyldopa
- Metoclopramide
- Metronidazole
- Omeprazole (rare)
- Opioids
- Phenothiazines
- Progestins
- Proton pump inhibitors (uncommon)
- Ranitidine (rare)
- Soy ingestion
- Statins (rare)
- Spironolactone (common)
- Sunitinib
- Tea tree oil (topical)
- Tricyclics
- Verapamil

GnRH, gonadotropin-releasing hormone.

Clinical Findings

A. Symptoms and Signs

The male breasts must be palpated carefully to distinguish firm true glandular gynecomastia from softer fatty pseudogynecomastia in which only adipose tissue is felt. The breasts are best examined both seated and supine. Using the thumb and forefinger as pincers, the subareolar tissue is compared to nearby adipose tissue. Fatty tissue is usually diffuse and nontender. True glandular enlargement beneath the areola may be tender. Pubertal gynecomastia is characterized by tender discoid enlargement of breast tissue 2–3 cm in diameter beneath the areola. The following characteristics are worrisome for malignancy: asymmetry; location not immediately below the areola; unusual firmness; or nipple retraction, bleeding, or discharge. The examination must also include an assessment of masculinization, examination of the testes for size and masses, and examination of the penis for hypospadias.

B. Laboratory Findings

In the presence of true glandular gynecomastia, a laboratory assessment should include liver biochemical tests, serum BUN, and creatinine. Endocrine testing, including serum testosterone, free testosterone, LH, FSH, is obtained to determine whether primary or secondary hypogonadism or androgen resistance may be present. Primary hypogonadism is characterized by a low serum testosterone with a high LH. Secondary hypogonadism is present in men with a low serum testosterone with a low or normal serum LH. High serum testosterone levels plus high LH levels characterize partial androgen insensitivity syndrome. A serum PRL is obtained to screen for hyperprolactinemia and pituitary/hypothalamic lesions. Serum beta-hCG and estradiol levels are obtained to screen for malignancy-associated gynecomastia. Detectable levels of beta-hCG implicate a testicular tumor (germ cell or Sertoli cell) or other malignancy (usually lung or liver). Increased serum estradiol levels may result from testicular tumors, increased beta-hCG, liver disease, obesity, adrenal tumors (rare), true hermaphroditism (rare), or aromatase gene gain-of-function mutations (rare). Serum TSH and FT_4 levels are also obtained to screen for hyperthyroidism and hypothyroidism. A karyotype for Klinefelter syndrome is obtained in men with persistent gynecomastia without obvious cause.

C. Imaging and Biopsy

Investigation of unclear cases should include bilateral mammography and a chest CT to search for bronchogenic or metastatic carcinoma. Benign mammographic findings make malignancy very unlikely. Suspicious mammographic findings require ultrasound examination that includes the axilla. Needle biopsy with cytologic examination may be performed on suspicious male breast lesions to distinguish gynecomastia from benign lesions (pseudogynecomastia, lipoma, posttraumatic hematoma/fat necrosis, epidermal inclusion cyst), lymphoma, and male breast cancer. Male breast cancer and gynecomastia may coexist.

Men with a high serum hCG or estradiol levels should have the test confirmed with repeat testing. Confirmed increased levels warrant a testicular ultrasound. If the testicular ultrasound is normal, high serum estradiol levels may warrant a CT of the adrenals; high serum hCG levels may warrant additional CT scanning to detect rare hCG-secreting carcinomas of the lung, mediastinum, liver, stomach, or kidney.

Treatment

Pubertal gynecomastia often resolves spontaneously within 1–2 years. Drug-induced gynecomastia resolves after the offending drug is removed (eg, spironolactone stopped, with substitution of eplerenone). Patients with painful or persistent gynecomastia may be treated with medical therapy, usually for 9–12 months. Generally, it is prudent to treat patients for gynecomastia only when it is a continuing troubling problem.

Selective estrogen receptor modulator (SERM) therapy is effective for true glandular gynecomastia. Raloxifene, 60 mg orally daily, may be somewhat more effective than tamoxifen, 10–20 mg orally daily.

Aromatase inhibitor (AI) therapy is also reasonably effective; anastrozole reduces breast volume significantly over 6 months in adolescents given in a dose of 1 mg orally daily. Serum estradiol levels fall slightly while serum testosterone levels rise. Long-term AI therapy in adolescents is not recommended because of the possibility of inducing osteoporosis and of delaying epiphyseal fusion, which could cause an increase in adult height.

Testosterone therapy for men with hypogonadism may improve or worsen preexistent gynecomastia.

Radiation therapy has been used prophylactically to prevent gynecomastia in men with prostate cancer being treated with antiandrogen therapy. Low-dose prophylactic radiation therapy reduces its incidence from 71% to 28%. Existing gynecomastia improves in 33% with radiation therapy. However, the long-term breast and other cancer risks of such radiation are unknown.

Surgical correction is reserved for patients with persistent or severe gynecomastia.

HIRSUTISM & VIRILIZATION

ESSENTIALS OF DIAGNOSIS

- Hirsutism, acne, menstrual disorders.
- Virilization: muscularity, androgenic alopecia, deepening voice, clitoromegaly.
- Rarely, a palpable pelvic tumor.
- Urinary 17-ketosteroids, serum DHEAS and androstenedione elevated in adrenal disorders; variable in others.
- Serum testosterone is often elevated.

General Considerations

Hirsutism is defined as cosmetically unacceptable terminal hair growth that appears in women in a male pattern. Significant hirsutism affects about 5–10% of non-Asian women of reproductive age and over 40% of women at some point during their life. The amount of hair growth deemed unacceptable depends on a woman’s ethnicity and familial and cultural norms. Virilization is defined as the development of male physical characteristics in women, such as pronounced muscle development, deep voice, male pattern baldness, and more severe hirsutism.

Etiology

Hirsutism may be idiopathic or familial or be caused by the following disorders: polycystic ovary syndrome (PCOS), ovarian hyperthecosis, steroidogenic enzyme defects, neoplastic disorders; or rarely by medications, acromegaly, or ACTH-induced Cushing disease.

A. Idiopathic or Familial

Most women with hirsutism or androgenic alopecia have no detectable hyperandrogenism. Patients often have a strong familial predisposition to hirsutism that may be considered normal in the context of their genetic background. Such patients may have elevated serum levels of androstenediol glucuronide, a metabolite of dihydrotestosterone that is produced by skin in cosmetically unacceptable amounts.

B. Polycystic Ovary Syndrome (PCOS, Hyperthecosis, Stein-Leventhal Syndrome)

PCOS is a common functional disorder of the ovaries of unknown etiology (see Chapter 18). It accounts for at least 50% of all cases of hirsutism associated with elevated serum testosterone levels. It is familial and transmitted as a complex polygenic disorder whose phenotypic expression may involve both protective and susceptible genomic variants.

A diagnosis of PCOS must meet three criteria: (1) androgen excess with clinical hyperandrogenism or elevated serum free or total testosterone; (2) ovarian dysfunction with oligoanovulation or polycystic ovary morphology; and (3) absence of other causes of testosterone excess or anovulation such as pregnancy, thyroid dysfunction, 21-hydroxylase deficiency, neoplastic testosterone secretion, Cushing syndrome, or hyperprolactinemia.

Affected women usually have signs of hyperandrogenism, including hirsutism, acne, or male-pattern thinning of scalp hair; this persists after natural menopause. However, women of East Asian ancestry are less likely to exhibit hirsutism. Most women also have elevated serum testosterone or free testosterone levels. About 70% of affected women have polycystic ovaries on pelvic ultrasound and 50% have oligomenorrhea or amenorrhea with anovulation. Of note, about 30% of women with PCOS do not have cystic ovaries and 25–30% of normal menstruating women have cystic ovaries.

Obesity and high serum insulin levels (due to insulin resistance) contribute to the syndrome in 70% of women. The serum LH:FSH ratio is often greater than 2.0. Both adrenal and ovarian androgen hypersecretion are commonly present.

C. Steroidogenic Enzyme Defects

Congenital adrenal steroidogenic enzyme defects result in reduced cortisol secretion with a compensatory increase in ACTH that causes adrenal hyperplasia. The most common enzyme defect is 21-hydroxylase deficiency, with a prevalence of about 1:18,000.

Partial deficiency in adrenal 21-hydroxylase can present in women as hirsutism. About 2% of patients with adult-onset hirsutism have been found to have a partial defect in adrenal 21-hydroxylase. The condition is more common in Ashkenazi Jews, Yupic Alaskans, and natives of La Reunion Island. The phenotypic expression is delayed until adolescence or adulthood; such patients do not have salt wasting. Polycystic ovaries and adrenal adenomas are more likely to develop in these women.

D. Neoplastic Disorders

Ovarian tumors are uncommon causes of hirsutism (0.8%) and include arrhenoblastomas, Sertoli-Leydig cell tumors, dysgerminomas, and hilar cell tumors. Adrenal carcinoma is a rare cause of Cushing syndrome and hyperandrogenism that can be quite virilizing. Pure androgen-secreting adrenal tumors occur very rarely; about 50% are malignant.

E. Rare Causes of Hirsutism & Virilization

Acromegaly and ACTH-induced Cushing syndrome are rare causes of hirsutism and virilization. Porphyria cutanea tarda can cause periorbital hair growth in addition to dermatitis in sun-exposed areas. Maternal virilization during pregnancy may occur as a result of a luteoma of pregnancy, hyperreactio luteinalis, or polycystic ovaries. In postmenopausal women, diffuse stromal Leydig cell hyperplasia is a rare cause of hyperandrogenism. Acquired hypertrichosis lanuginosa is manifested by the appearance of diffuse fine lanugo hair growth on the face and body along with stomatologic symptoms; the disorder is usually associated with an internal malignancy, especially colorectal cancer, and may regress after tumor removal. Pharmacologic causes include minoxidil, cyclosporine, phenytoin, anabolic steroids, interferon, cetuximab, diazoxide, and certain progestins.

Clinical Findings

A. Symptoms and Signs

Modest androgen excess from any source increases sexual hair (chin, upper lip, abdomen, and chest) and increases sebaceous gland activity, producing acne. Menstrual irregularities, anovulation, and amenorrhea are common. If androgen excess is pronounced, defeminization (decrease in breast size, loss of feminine adipose tissue) and virilization (frontal balding, muscularity, clitoromegaly, and deepening of the voice) occur. Virilization points to the presence of an androgen-producing neoplasm.

Hirsutism is quantitated using the Ferriman-Gallwey score in which hirsutism is graded from 0 (none) to 4 (severe) in nine areas of the body with a maximum possible score of 36. Scores below 8 are considered mild hirsutism and normal variants. Scores of 8–15 indicate moderate hirsutism. Scores over 15 indicate severe hirsutism. Of note, the normal score is lower in Asian women and higher in Mediterranean women. The Endocrine Society's Ferriman-Gallwey hirsutism scoring system (https://education.endocrine.org/ferriman-gallwey-hirsutism-system) is recommended.

A pelvic examination may disclose clitoromegaly or ovarian enlargement that may be cystic or neoplastic. Hypertension may be present in Cushing syndrome, adrenal 11-hydroxylase deficiency, or cortisol resistance syndrome.

B. Laboratory Testing and Imaging

Serum androgen testing is mainly useful to screen for rare occult adrenal or ovarian neoplasms. Testing is warranted for women with moderate to severe hirsutism, mild hirsutism with menstrual disturbances, and women with worsening hirsutism despite therapy.

Serum is assayed for total testosterone and free testosterone. A serum testosterone level greater than 200 ng/dL (6.9 nmol/L) or free testosterone greater than 40 ng/dL (140 pmol/L) indicates the need for a manual pelvic examination and ultrasound. If that is negative, an adrenal CT scan is performed. A serum androstenedione level greater than 1000 ng/dL (34.9 nmol/L) also points to an ovarian or adrenal neoplasm.

Patients with a serum DHEAS greater than 700 mcg/dL (35 nmol/L) have an adrenal source of androgen. This usually is due to adrenal hyperplasia and rarely to adrenal carcinoma. Patients with any clinical signs of Cushing syndrome should receive a screening test.

Screening for nonclassical "late-onset" congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency is warranted for women with (1) high serum testosterone or free testosterone levels and (2) hirsutism with normal serum testosterone levels who are at high risk for CAH due to having a family history of hirsutism or being a member of a high-risk ethnic group (eg, Ashkenazi Jews, Croatians, Iranians, Yupik Inuit). The evaluation requires an early morning blood draw for serum 17-hydroxyprogesterone, ideally during the follicular (early) phase of the menstrual cycle or on a random day for women with irregular menses or amenorrhea. Patients with congenital adrenal hyperplasia usually have a baseline 17-hydroxyprogesterone level greater than 300 ng/dL (9.1 nmol/L). Serum levels of FSH and LH are elevated if amenorrhea is due to ovarian failure. An LH:FSH ratio greater than 2.0 is common in patients with PCOS. On abdominal ultrasound, about 25–30% of normal young women have polycystic ovaries, so the appearance of ovarian cysts on ultrasound is not helpful. Pelvic ultrasound or MRI usually detects virilizing tumors of the ovary. However, small virilizing ovarian tumors may not be detectable on imaging studies; selective venous sampling for testosterone may be used for diagnosis in such patients.

Treatment

Any drugs causing hirsutism (see above) should be stopped. Any underlying medical causes of hirsutism (eg, Cushing syndrome, acromegaly) should be treated.

A. Surgery

Androgenizing tumors of the adrenal or ovary are resected laparoscopically. Postmenopausal women with severe hyperandrogenism should undergo laparoscopic bilateral oophorectomy (if CT scan of the adrenals and ovaries is normal), since small hilar cell tumors of the ovary may not be visible on scans. Women with classic salt-wasting congenital adrenal hyperplasia and infertility or treatment-resistant hyperandrogenism may be treated with laparoscopic bilateral adrenalectomy.

B. Laser and Topical Treatments

Laser therapy (photoepilation) can be a very effective treatment for facial hirsutism, particularly for women with dark hair and light skin. For women of color, a longer-wavelength laser such as Nd:YAG or diode laser given with skin cooling is used. In such women, laser removal of facial hair significantly improves their appearance and quality of life. Repeated laser treatments are usually required. Accidental eye injuries have been reported; eye shields should be used during treatments. Laser therapy is not recommended for Middle Eastern and Mediterranean women with facial hirsutism, since they have a particularly increased risk of paradoxical hypertrichosis with laser therapy.

Local treatment of facial hirsutism is by shaving or depilatories, waxing, electrolysis, or bleaching. Eflornithine (Vaniqa) 13.9% topical cream retards hair growth when applied twice daily to unwanted facial hair; improvement is noted within 4–8 weeks. Eflornithine may be used during laser therapy for a more dramatic response. However, local skin irritation may occur. Hirsutism returns with discontinuation, unless it is given with laser therapy.

Topical minoxidil may be used to treat androgenic alopecia and is mildly effective when applied to the scalp twice daily. Only the 2% formulation is FDA approved for women.

C. Medications

Oral contraceptives are warranted as an initial therapy for women with hirsutism who are not actively pursuing pregnancy. To reduce the risk of deep venous thrombosis, particularly in women who are obese or over age 39 years, an oral contraceptive with a low-dose of estradiol (20 mcg) is recommended, with a progestin having a relatively low risk of venous thrombosis (norethindrone, norgestimate, levonorgestrel); nevertheless, such oral contraceptives confer over 2-fold increased risk of deep venous thrombosis. Also, levonorgestrel causes insulin resistance, so its use is problematic in women with polycystic ovary syndrome. Oral contraceptives that contain particularly antiandrogenic progestins such as desogestrel (Azurette, Kariva), drospirenone (Yaz, Gianvi), norgestimate (Ortho Tri-Cyclen Lo), or cyproterone acetate (Diane 35, not available in United States) more effectively reduce hirsutism and acne; however, such antiandrogenic oral contraceptives confer a 4-fold risk of deep venous thrombosis, such that their use is discouraged in high-risk patients. Oral contraceptives for hirsutism are given daily and a favored formulation contains norethindrone 1 mg with ethinyl estradiol 20 mcg.

Cyproterone acetate is a unique progestin that is used to treat women with hirsutism worldwide, except in the United States, where it is not FDA-approved. Cyproterone acetate blocks androgen receptors as well as 5-alpha-reductase activity while also suppressing testosterone levels. It is typically prescribed as an oral contraceptive in a dose of 2 mg with ethinyl estradiol 35 mcg.

The risk for arterial thrombosis is increased by 50–100% for all combined oral contraceptives. For this reason, combined oral contraceptives are relatively contraindicated for women who are predisposed to thromboembolism, such as women who are smokers or who have migraines, women who are obese, those with hypertension or a personal history of thromboembolism. Metabolic syndrome and hypertriglyceridemia are seen, particularly with antiandrogenic progestins.

Spironolactone is effective for reducing hirsutism, acne, and androgenic alopecia in women and is a first-line medical strategy for these women. It may be taken in doses of 100–200 mg orally daily (taken as a single dose or in two divided doses) on days 5–25 of the menstrual cycle or daily if used concomitantly with an oral contraceptive. Spironolactone is contraindicated in pregnancy, so reproductive-age women must use reliable contraception during this therapy. Hyperkalemia is an uncommon side effect, but serum potassium should be checked 1 month after beginning therapy or after dosage increases. Spironolactone should be avoided or used cautiously in women who are prone to hyperkalemia, including women with kidney disease or who are taking an ACE inhibitor or ARB for hypertension. Spironolactone should not be given with an oral contraceptive containing drospirenone because the progestin has an anti-mineralocorticoid effect that predisposes to hyperkalemia. Trimethoprim-sulfamethoxazole should not be taken along with high-dose spironolactone. Trimethoprim has potassium-sparing diuretic effects and combining it with spironolactone increases the risk of severe hyperkalemia and sudden death. Side effects of spironolactone include breast tenderness, menstrual irregularity, headaches, nausea, and fatigue, which may improve with continued treatment or dose reduction; paradoxical scalp hair loss has been reported at higher doses. If necessary, metformin can be added and may enhance the anti-hirsutism effect of low-dose spironolactone.

Flutamide and **bicalutamide** inhibit testosterone binding to androgen receptors and also suppress serum testosterone. These drugs can rarely cause severe hepatotoxicity with liver failure. Also, exposure during pregnancy causes fetal malformations and disorders of sexual development in male infants. Therefore, the use of these drugs for hirsutism is discouraged. They should only be used as a last resort for women with severe hirsutism/virilization and only with strict contraceptive precautions and very close monitoring for hepatic toxicity. Flutamide is given orally in a dosage of 250 mg twice daily for the first year and then 125–250 mg/day for maintenance. Flutamide decreases cortisol renal clearance and corticosteroid replacement doses (eg, in congenital adrenal hyperplasia) should be reduced when flutamide is added. Bicalutamide is given in a dosage of 50 mg once daily.

Finasteride inhibits 5-alpha-reductase, the enzyme that converts testosterone to active dihydrotestosterone in the skin. It provides inconsistent reduction in hirsutism and androgenic alopecia over 6 months. Also, this drug causes pseudohermaphroditism in male infants if mistakenly taken during pregnancy. Therefore, the use of finasteride for hirsutism is strongly discouraged.

Metformin alone is ineffective in improving hirsutism, but can enhance the anti-hirsutism effect of spironolactone. Metformin therapy is usually given orally with meals and is started at a dose of 500 mg/day with breakfast for 1 week, then increased to 500 mg with breakfast and dinner. If this dose is clinically insufficient but tolerated, the dose may be increased to 850–1000 mg twice daily. The most common side effects are dose-related gastrointestinal upset and diarrhea or constipation. Metformin appears to be nonteratogenic. Although metformin reduces insulin resistance, it does not cause hypoglycemia in nondiabetic patients. Metformin is contraindicated in severe kidney or liver disease. **GLP-1 agonist** therapy reduced weight and serum testosterone levels in women with PCOS in one short-term study. However, an effect on hirsutism has not been demonstrated clinically.

Simvastatin can reduce hirsutism in women with PCOS. In one study, simvastatin 20 mg orally daily was given to women receiving an oral contraceptive for PCOS. Besides improving their serum lipid profiles, women receiving simvastatin had greater decreases in hirsutism and serum free testosterone levels than the women receiving an oral contraceptive alone. Atorvastatin also reduced serum testosterone by an average of 25% in women with PCOS.

Glucocorticoid replacement is necessary for women with classical congenital adrenal hyperplasia (21-hydroxylase deficiency) with hirsutism and adrenal insufficiency that requires glucocorticoid and mineralocorticoid replacement. However, women with partial “late onset” 21-hydroxylase deficiency are not cortisol deficient and do not require glucocorticoid replacement. Also, glucocorticoids are ineffective in reducing hirsutism in these women. However, such women may require replacement doses of glucocorticoids (prednisone, methylprednisolone) to normalize menses and for ovulation induction. Dexamethasone is not recommended due to its potency and risk of causing iatrogenic Cushing syndrome.

GnRH agonist therapy has been successful in treating postmenopausal women with severe ovarian hyperandrogenism when laparoscopic oophorectomy is contraindicated or declined by the patient.

AMENORRHEA & MENOPAUSE

PRIMARY AMENORRHEA

Menarche ordinarily occurs between ages 11 and 15 years (average in the United States: 12.7 years) (see also Chapter 18). The failure of any menses to appear is termed "primary amenorrhea," and evaluation is commenced (1) at age 14 years if neither menarche nor any breast development has occurred or if height is in the lowest 3%, or (2) at age 16 years if menarche has not occurred.

Etiology of Primary Amenorrhea

The differential diagnoses for primary amenorrhea include hypothalamic-pituitary causes, hyperandrogenism, ovarian causes (gonadal dysgenesis, Müllerian dysgenesis), disorders of sexual development (pseudohermaphroditism), uterine causes, and pregnancy.

A. Hypothalamic-Pituitary Causes (With Low or Normal FSH)

The most common cause of primary amenorrhea is a variant of normal known as constitutional delay of growth and puberty, which accounts for about 30% of delayed puberty cases. There is a strong genetic basis for this condition; over 50% of girls with it have a family history of delayed puberty. However, constitutional delay of growth and puberty is a diagnosis of exclusion.

A genetic deficiency of GnRH and gonadotropins may be isolated or associated with other pituitary deficiencies or diminished olfaction (Kallmann syndrome). Hypothalamic lesions, particularly craniopharyngioma, may be present. Pituitary tumors may be nonsecreting or may secrete PRL or GH. Cushing syndrome may be caused by corticosteroid treatment, a cortisol-secreting adrenal tumor, or an ACTH-secreting pituitary tumor. Hypothyroidism can delay adolescence. Head trauma or encephalitis can cause gonadotropin deficiency. Primary amenorrhea may also be caused by severe illness, vigorous exercise (eg, ballet dancing, running), stressful life events, dieting, or anorexia nervosa; however, these conditions should not be assumed to account for amenorrhea without a full endocrinologic evaluation.

B. Uterine Causes (With Normal FSH)

Müllerian agenesis (Mayer-Rokitansky-Küster-Hauser syndrome) results in a missing uterus and variable degrees of upper vaginal hypoplasia. It is the most common cause of permanent primary amenorrhea. Affected women have intact ovaries and undergo an otherwise normal puberty. Such women ovulate and fertility is possible with in vitro fertilization and surrogacy.

An imperforate hymen is occasionally the reason for the absence of visible menses.

C. Hyperandrogenism (With Low or Normal FSH)

Polycystic ovaries and ovarian tumors can secrete excessive testosterone. Excess testosterone can also be secreted by adrenal tumors or by adrenal hyperplasia caused by steroidogenic enzyme defects such as P450c21 deficiency (salt-wasting) or P450c11 deficiency (hypertension). Androgenic steroid abuse may also cause this syndrome.

D. Ovarian Causes (With High FSH)

Gonadal dysgenesis (Turner syndrome and variants) is a frequent cause of primary amenorrhea. Autoimmune ovarian failure is another cause. Rare deficiencies in certain ovarian steroidogenic enzymes are causes of primary hypogonadism without virilization: 3-beta-hydroxysteroid dehydrogenase deficiency (adrenal insufficiency with low serum 17-hydroxyprogesterone) and P450c17 deficiency (hypertension and hypokalemia with high serum 17-hydroxyprogesterone). Deficiency in P450 aromatase (P450arom) activity produces female hypogonadism associated with polycystic ovaries, tall stature, osteoporosis, and virilization.

E. 46 XY Disorders of Sexual Development (Pseudohermaphroditism)

Complete androgen insensitivity syndrome is caused by homozygous inactivating mutations in the androgen receptor. 46 XY individuals with complete androgen insensitivity syndrome are born with completely normal external female genitalia, although some may have labial or inguinal swellings due to cryptorchid testes. Affected individuals are phenotypic girls and experience normal breast development at puberty, but fail to develop sexual hair and have primary amenorrhea.

Partial androgen insensitivity syndrome in 46 XY individuals results in variable degrees of ambiguous genitalia. Newborns have micropenis, hypospadias, and bifid scrotum.

F. Pregnancy (With High hCG)

Pregnancy may be the cause of primary amenorrhea even when the patient refutes having had sexual intercourse.

Clinical Findings

A. Symptoms and Signs

Patients with primary amenorrhea require a thorough history and physical examination to look for signs of the conditions noted above. Headaches or visual field abnormalities implicate a hypothalamic or pituitary tumor. Signs of pregnancy may be present. Blood pressure elevation, acne, and hirsutism should be noted. Short stature may be seen with an associated GH or thyroid hormone deficiency. Short stature with manifestations of gonadal dysgenesis indicates Turner syndrome. Olfactory deficits are seen in Kallmann syndrome. Obesity and short stature may be signs of Cushing syndrome. Tall stature may be due to eunuchoidism or acromegaly. Hirsutism or virilization suggests excessive testosterone.

An external pelvic examination plus a rectal examination should be performed to assess hymen patency and the presence of a uterus.

B. Laboratory and Radiologic Findings

The initial endocrine evaluation should include serum determinations of FSH, LH, PRL, testosterone, TSH, FT_4, and beta-hCG (pregnancy test). Patients who are virilized or hypertensive require serum electrolyte determinations and further hormonal evaluation (see Hirsutism & Virilization, above). MRI of the hypothalamus and pituitary is used to evaluate teens with primary amenorrhea and low or normal FSH and LH—especially those with high PRL levels. Pelvic duplex/color sonography is very useful. Girls who have a normal uterus and high FSH without the classic features of Turner syndrome may require a karyotype to diagnose X chromosome mosaicism.

Treatment

Treatment of primary amenorrhea is directed at the underlying cause. Girls with permanent hypogonadism are treated with HRT.

SECONDARY AMENORRHEA & MENOPAUSE

Secondary amenorrhea is defined as the absence of menses for 3 consecutive months in women who have passed menarche. Menopause is defined as the terminal episode of naturally occurring menses; it is a retrospective diagnosis, usually made after 6 months of amenorrhea.

Etiology

The causes of secondary amenorrhea include pregnancy, hypothalamic-pituitary causes, hyperandrogenism, uterine causes, premature ovarian failure, and menopause.

A. Pregnancy (High hCG)

Pregnancy is the most common cause for secondary amenorrhea in premenopausal women. The differential diagnosis includes rare ectopic secretion of hCG by a choriocarcinoma or bronchogenic carcinoma.

B. Hypothalamic-Pituitary Causes (With Low or Normal FSH)

The hypothalamus must release GnRH in a pulsatile manner for the pituitary to secrete gonadotropins. GnRH pulses occurring more than once per hour favor LH secretion, while less frequent pulses favor FSH secretion. In normal ovulatory cycles, GnRH pulses in the follicular phase are rapid and favor LH synthesis and ovulation; ovarian luteal progesterone is then secreted that slows GnRH pulses, causing FSH secretion during the luteal phase. Most women with hypothalamic amenorrhea have a persistently low frequency of GnRH pulses.

Secondary “hypothalamic” amenorrhea may be caused by stressful life events such as school examinations or leaving home. Such women usually have a history of normal sexual development and irregular menses since menarche. Amenorrhea may also be the result of strict dieting, vigorous exercise, organic illness, or anorexia nervosa. Intrathecal infusion of opioids causes amenorrhea in most women. These conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation. Young women in whom the results of evaluation and progestin withdrawal test are normal have noncyclic secretion of gonadotropins resulting in anovulation. Such women typically recover spontaneously but should have regular evaluations and a progestin withdrawal test about every 3 months to detect loss of estrogen effect.

PRL elevation due to any cause may cause amenorrhea. Pituitary tumors or other lesions may cause hypopituitarism. Corticosteroid excess of any cause suppresses gonadotropins.

C. Hyperandrogenism (With Low-Normal FSH)

Elevated serum levels of testosterone can cause hirsutism, virilization, and amenorrhea. In PCOS, GnRH pulses are persistently rapid, favoring LH synthesis with excessive androgen secretion; reduced FSH secretion impairs follicular maturation. Progesterone administration can slow the GnRH pulses, thus favoring FSH secretion that induces follicular maturation. Rare causes of secondary amenorrhea include adrenal P450c21 deficiency, ovarian or adrenal malignancies, and Cushing syndrome. Anabolic steroids also cause amenorrhea.

D. Uterine Causes (With Normal FSH)

Infection of the uterus commonly occurs following delivery or D&C but may occur spontaneously. Endometritis due to tuberculosis or schistosomiasis should be suspected in endemic areas. Endometrial scarring may result, causing amenorrhea (Asherman syndrome). Such women typically continue to have monthly premenstrual symptoms. The vaginal estrogen effect is normal.

E. Early and Premature Menopause (With High FSH)

Early menopause refers to primary ovarian failure that occurs before age 45. It affects approximately 5% of women. About 1% of women experience **premature menopause** that is defined as ovarian failure before age 40; about 30% of such cases are due to autoimmunity against the ovary. X chromosome mosaicism accounts for 8% of cases of premature menopause. Other causes include surgical bilateral oophorectomy, radiation therapy for pelvic malignancy, and chemotherapy. Women who have undergone hysterectomy are prone to premature ovarian failure even though the ovaries were left intact. Myotonic dystrophy, galactosemia, and mumps oophoritis are additional causes. Early or premature menopause is frequently familial. Ovarian failure is usually irreversible.

F. Normal Menopause (With High FSH)

Normal menopause refers to primary ovarian failure that occurs after age 45. “Climacteric” is defined as the period of natural physiologic decline in ovarian function, generally occurring over about 10 years. By about age 40 years, the remaining ovarian follicles are those that are the least sensitive to gonadotropins. Increasing titers of FSH are required to stimulate estradiol secretion. Estradiol levels may actually rise during early climacteric.

The normal age for menopause in the United States ranges between 48 and 55 years, with an average of about 51.5 years. Serum estradiol levels fall and the remaining estrogen after menopause is estrone, derived mainly from peripheral aromatization of adrenal androstenedione. Such peripheral production of estrone is enhanced by obesity and liver disease. Individual differences in estrone levels partly explain why the symptoms noted above may be minimal in some women but severe in others.

Clinical Findings

A. Symptoms and Signs

See Chapter 18 for symptoms and signs of the menopausal syndrome. Women with premature menopause (before age 45 years), compared to women with normal menopause, have an 50% increased risk of coronary disease, a 23% increased risk for stroke, and a 12% increased overall mortality.

A careful pelvic examination is useful to check for uterine or adnexal enlargement and to obtain a Papanicolaou smear and a vaginal smear for assessment of estrogen effect.

B. Laboratory Findings

1. Premature amenorrhea

An elevated hCG overwhelmingly indicates pregnancy; false-positive testing may occur very rarely with ectopic hCG secretion (eg, choriocarcinoma or bronchogenic carcinoma). Further laboratory evaluation for women who are not pregnant includes serum PRL, FSH and LH (both elevated in menopause), and TSH. Hyperprolactinemia or hypopituitarism (without obvious cause) should prompt an MRI study of the pituitary region. Routine testing of kidney and liver function (BUN, serum creatinine, bilirubin, alkaline phosphatase, and alanine aminotransferase) is also performed. A serum testosterone level is obtained in hirsute or virilized women. Patients with manifestations of hypercortisolism receive a 1-mg overnight dexamethasone suppression test for initial screening. Nonpregnant women without any laboratory abnormality may receive a 10-day course of a progestin (eg, medroxyprogesterone acetate, 10 mg/day); absence of withdrawal menses typically indicates a lack of estrogen or a uterine abnormality.

2. Typical menopause—No laboratory testing is required to diagnose menopause, when amenorrhea occurs at the expected age. The expected age of menopause correlates with a woman's mother's age at menopause and varies among different kindreds and ethnic groups. An elevated serum FSH with a low or low-normal serum estradiol helps confirm the diagnosis.

Treatment

See Menopausal Syndrome, Chapter 18. Women with night sweats should sleep in a cool room and avoid the use of down comforters. They can try avoiding triggers for hot flushes, such as smoking, alcohol, caffeine, and hot spicy foods. Slow, deep breathing can ameliorate hot flushes. **Aerobic training** for 50 minutes four times weekly reduced all menopausal symptoms except vaginal dryness in a randomized controlled trial. **Clinical hypnosis** reduced hot flushes over 12 weeks in one study. Acupuncture may help alleviate symptoms in some women. Vaginal lubricants can be used daily or 2 hours prior to intercourse.

A. Non-Estrogen Medications

For women with severe hot flushes who cannot take estrogen, SSRIs may offer modest relief effective within a week; escitalopram (10–20 mg/day) can reduce hot flushes significantly, but must not be used by women taking tamoxifen for breast cancer, since it inhibits its metabolism to its active metabolite. Venlafaxine extended release (75 mg/day) may also be effective and does not have a drug interaction with tamoxifen. Sexual dysfunction has not been as significant with the latter drugs when used for vasomotor symptoms, compared to their use for depression. Gabapentin is also quite effective in oral doses titrated up to 200–800 mg every 8 hours. Side effects such as drowsiness, fatigue, dizziness, and headache, which are most pronounced during the first 2 weeks of therapy, often improve within 4 weeks. An herb, black cohosh, may possibly relieve hot flushes. Tamoxifen and raloxifene offer bone protection but aggravate hot flushes. Women with low serum testosterone levels may experience hypoactive sexual desire disorder that may respond to low-dose testosterone replacement.

B. Estrogen Replacement Therapy

Overall survival is improved among women who begin HRT before age 60 or within 10 years of menopause. However, no survival advantage was found in older women, according to a meta-analysis of 43 randomized controlled trials. Specifically, HRT does not increase the risk of cardiac death or stroke. Breast cancer risk is increased among women taking combined daily estrogen and progestin HRT. Women taking estrogen alone have been variably found to have a decreased risk (Women's Health Initiative, WHI) or an increased risk of breast cancer (California Teachers' Study). Venous thromboembolic disease and stroke are increased by oral but not transdermal estrogen. Osteoporosis risk is reduced by even low-dose systemic estrogen replacement.

In light of these considerations, estrogen replacement is most commonly prescribed for women in early menopause, when symptoms are worst and the benefits are greatest. Transdermal estrogen is favored over oral therapy to reduce the risk of thromboembolism. In women with an intact uterus, estrogen replacement without a progestin risks endometrial hypertrophy and dysfunctional uterine bleeding. The addition of a progestin, however, increases the risk of breast cancer. Therefore, only the smallest effective dose of estrogen should be used to avoid the need for progestins or use them in lower doses or intermittently. Also, progestin may be delivered directly to uterus with progesterone-eluting intrauterine devices. The decision to prescribe menopausal hormonal therapy and its type and duration are dictated by individual symptoms, risk profile, and personal preferences, while considering potential benefits and risks.

1. Benefits of HRT—Estrogen replacement is the best treatment for hot flushes and sweats and eliminates these symptoms or improves them by more than 70%, usually within a month. Vaginal moisture is improved and libido is enhanced in some women. Estradiol vaginal rings can improve symptoms of an overactive bladder and vaginal dryness. Sleep disturbances are common in menopause and can be reversed with estrogen replacement. Some women notice a mild impairment in memory and cognitive function at menopause that may improve with HRT that is commenced soon after menopause. HRT does not reduce the risk of Alzheimer dementia. However, short-term transdermal estradiol has been demonstrated to slightly improve memory in women with existent mild to moderate Alzheimer disease. Estrogen replacement may also improve the joint pains, generalized body pain, and reduced physical function experienced by some women at the time of menopause. Women with perimenopausal depression typically experience a significantly improved mood and overall sense of well-being with estrogen replacement. Estrogen replacement does not prevent facial skin wrinkling; however, it may improve facial skin moisture and thickness, reducing seborrhea and atrophy.

Estrogen replacement prevents postmenopausal osteoporosis. The WHI study found that women who received estrogen therapy experienced a reduced number of hip fractures (six fewer fractures/year per 10,000 women) compared with placebo. Even “microdose” transdermal estradiol (0.014 mg/day) preserves bone density.

Women aged 50–59 years in the WHI who received estrogen alone developed significantly lower CT coronary calcium scores (a marker for coronary atherosclerosis) than women receiving placebo. In the California Teachers Study, HRT in women under age 60 was associated with a dramatic 46% reduction in all-cause mortality, particularly cardiovascular disease. This association of HRT and lower mortality may suffer from self-selection bias. Nevertheless, there appears to be a survival advantage of HRT that requires longer-term administration (more than 5 years) to become apparent. The survival advantage is particularly strong for women under age 60 and diminishes with age; no reduction in mortality was noted in the group of women aged 85–94 years. The reduction in cardiovascular disease among younger postmenopausal women taking HRT may be explained by the reduction in serum levels of atherogenic lipoprotein(a) with HRT, with or without a progestin. Improvement in serum HDL cholesterol is greatest with unopposed estrogen but is also seen with the addition of a progestin.

A. ESTROGEN REPLACEMENT WITHOUT PROGESTIN (UNOPPOSED HRT)—The WHI study reported that postmenopausal women taking unopposed estrogen had a reduction in breast cancer risk, whereas the California Teachers’ Study reported an increase in breast cancer risk among such women. Unopposed estrogen replacement improves glycemic control in women with type 2 diabetes mellitus. Perimenopause-related depression is improved by unopposed estrogen replacement; the addition of a progestin may negate this effect. A 20-year study of 8801 women living in a retirement community found that estrogen use was associated with improved survival. Age-adjusted mortality rates were 56.4 (per 1000 person-years) among nonusers and 50.4 among women who had used estrogen for 15 years or longer.

B. ESTROGEN REPLACEMENT THERAPY WITH PROGESTINS (COMBINED HRT)—Women receiving conventional-dose daily conjugated estrogen and medroxyprogesterone acetate (0.625 mg and 2.5 mg, respectively) for an average of 5.6 years, experienced a lower risk of developing diabetes mellitus (3.5%) versus those taking a placebo (4.2%).

2. Risks of HRT—Oral estrogen increases the risk of arterial and venous thrombotic events in a dose-dependent manner, although the absolute risk is small. The WHI study found that women who received long-term conventional oral combined HRT had an increased risk of deep venous thrombosis (3.5 per 1000 person-years) compared with women receiving placebo (1.7 per 1000 person-years). Oral estrogen also increases the risk of ischemic stroke by about 30%. Oral estrogen causes a particularly increased risk for thromboembolic disease among older women and those with increased stroke proclivity (current smokers and those with hypertension, atrial fibrillation, prior thromboembolic event). Long-term use of oral conjugated estrogens in women over age 65 has been associated with poorer cognitive performance, perhaps due to small strokes. Transdermal or vaginal estrogen administration avoids this risk. Urinary stress incontinence appears to be increased by conventional-dose oral estrogen replacement, whereas topical vaginal estrogen may have a beneficial effect. Estrogen replacement may cause mastalgia that typically responds to dose reduction. Estrogen replacement also appears to increase the risk of seizures in women with epilepsy. Estrogen can stimulate the growth of untreated large pituitary prolactinomas. Oral estrogen and SERMs also increase the risk of gastroesophageal reflux disease. Oral HRT can increase the size of hepatic hemangiomas, but significant enlargement is uncommon. Conventional doses of estrogen carry higher risks than lower doses. The risks for HRT also depend on whether estrogen is administered alone (unopposed HRT) or with a progestin (combined HRT).

A. ESTROGEN REPLACEMENT WITHOUT PROGESTIN (UNOPPOSED HRT)—The California Teachers' Study reported an increased breast cancer risk among such women while the WHI study reported that postmenopausal women taking unopposed estrogen had a reduced breast cancer risk. Women taking lower-dose unopposed estrogen therapy would be expected to have a lower long-term risk of breast cancer compared to women taking high-dose estrogens.

Conventional-dose unopposed conjugated estrogen replacement (0.625–1.25 mg daily) increases the risk of endometrial hyperplasia and dysfunctional uterine bleeding, which often prompts patients to stop the estrogen. However, lower-dose unopposed estrogen confers a much lower risk of dysfunctional uterine bleeding. Recurrent dysfunctional bleeding necessitates a pelvic examination and possibly an endometrial biopsy. There has been considerable concern that unopposed estrogen replacement might increase the risk for endometrial carcinoma. However, a Cochrane Database Review found no increased risk of endometrial carcinoma in a review of 30 randomized controlled trials. Therefore, lower-dose unopposed estrogen replacement does not appear to confer any significant increased risk for endometrial cancer.

Long-term conventional-dose unopposed estrogen increases the mortality risk from ovarian cancer, although the absolute risk is small. The annual age-adjusted ovarian cancer death rates for women taking estrogen replacement for 10 years or longer are 64:100,000 for current users, 38:100,000 for former users, and 26:100,000 for women who had never taken estrogen. Lower-dose estrogen replacement is believed to confer a negligible increased risk for ovarian cancer.

The risk of stroke among women taking a conventional dose of unopposed estrogen is increased; the risk is about 44 strokes per 10,000 person-years versus about 32 per 10,000 person-years in women taking placebo. Transdermal or transvaginal estrogen is not thought to increase the risk of stroke.

Oral estrogens can cause hypertriglyceridemia, particularly in women with preexistent hyperlipidemia, rarely resulting in pancreatitis. Postmenopausal estrogen therapy also slightly increases the risk of gallstones and cholecystitis. These side effects may be reduced or avoided by using transdermal or vaginal estrogen replacement.

B. ESTROGEN REPLACEMENT WITH A PROGESTIN (COMBINED HRT)—Long-term conventional-dose oral combined HRT increases breast density and the risk for abnormal mammograms (9.4% versus 5.4% for placebo). There is also a higher risk of breast cancer (8 cases per 10,000 women/year versus 6.5 cases per 10,000 women/year for placebo); the increased risk of breast cancer is highest shortly after menopause (about 2 cases per 1000 women annually). This increased risk for breast cancer appears to mostly affect relatively thin women with a BMI less than 24.4. The Iowa Women’s Health Study reported an increase in breast cancer with HRT only in women consuming more than 1 oz of alcohol weekly. No accelerated risk of breast cancer has been seen in users of HRT who have benign breast disease or a family history of breast cancer. Women in whom new-onset breast tenderness develops with combined HRT have an increased risk of breast cancer, compared with women without breast tenderness.

The Women’s Health Initiative Mental Study (WHIMS) followed the effect of combined conventional-dose oral HRT on cognitive function in women 65–79 years old. HRT did not protect these older women from cognitive decline. In fact, they experienced an increased risk for severe dementia at a rate of 23 more cases/year for every 10,000 women over age 65 years. It is unknown whether this finding applies to younger postmenopausal women.

In the WHI study, women receiving conventional-dose combined oral HRT experienced an increased risk of stroke (31 strokes per 10,000 women/year versus 26 strokes per 10,000 women/year for placebo). Stroke risk was also increased by hypertension, diabetes, and smoking.

Women taking combined oral estrogen–progestin replacement do not experience an increased risk of ovarian cancer. They do experience a slightly increased risk of developing asthma.

Progestins may cause moodiness, particularly in women with a history of premenstrual dysphoric disorder. Cycled progestins may trigger migraines in certain women. Many other adverse reactions have been reported, including breast tenderness, alopecia, and fluid retention. Contraindications to the use of progestins include thromboembolic disorders, liver disease, breast cancer, and pregnancy.

3. HRT agents—Hormone replacement needs to be individualized. Ideally, in women with an intact uterus, very low-dose transdermal estradiol may be used alone or with intermittent progestin or a progesterone-eluting intrauterine device, in order to reduce the risk of endometrial hyperplasia, while avoiding the need for daily oral progestin. Vaginal estrogen can be added if low-dose systemic estradiol replacement is insufficient to relieve symptoms of vulvovaginal atrophy. Women who have had a hysterectomy may receive transdermal estrogen at whatever is the lowest dose that adequately relieves symptoms. However, some women cannot find sufficient relief with transdermal estradiol and must use an oral preparation.

A. TRANSDERMAL ESTRADIOL—Estradiol can be delivered systemically with different systems of skin patches, mists, or gels. Transdermal estradiol works for most women, but some women have poor transdermal absorption. If a woman has a skin reaction to an estradiol patch, then a gel or mist may be tried at different doses until the ideal formulation is found.

(1) Estradiol patches mixed with adhesive—These systems tend to cause minimal skin irritation. Generic estradiol transdermal is available as a patch that is replaced biweekly (0.025, 0.0375, 0.05, 0.075, 0.1 mg/day) or weekly (0.025, 0.0375, 0.05, 0.06, 0.075, 0.1 mg/day). Brand products include: Vivelle-Dot (0.025) or Minivivelle (0.0375, 0.05, 0.075, or 0.1 mg/day) or Alora (0.025, 0.05, 0.075, or 0.1 mg/day), replaced twice weekly; Climara (0.025, 0.0375, 0.05, 0.06, 0.075, or 0.1 mg/day), replaced weekly; and Menostar (0.014 mg/day), replaced weekly. This type of estradiol skin patch can be cut in half and applied to the skin without proportionately greater loss of potency. Minivivelle patches are the smallest.

(2) Estradiol mists and gels—Evamist is available as a topical mist dispenser that dispenses 1.53 mg estradiol/spray; 1–3 sprays are applied to the inner forearm daily; a single daily spray may provide sufficiently low-dose estradiol to possibly obviate the need for daily progestin in women with an intact uterus. EstroGel 0.06% is available in a metered-dose pump that dispenses 1.25 g gel per actuation (dose: half to 2 actuations/day). Elestrin 0.06% is available in a metered-dose pump that dispenses 0.87 g gel per activation (dose: half to 2 actuations/day). These gels are applied daily to one arm from the wrist to the shoulder after bathing. Divigel 0.1% gel (0.25, 0.5, 1 g/packet) is applied to the upper thigh daily. Estrasorb 2.5% is available in 1.74-g pouches (4.35 mg estradiol); 1–2 pouches of lotion are applied to the thigh/calf daily. To avoid spreading topical estradiol to others, the hands should be washed and precautions taken to avoid prolonged skin contact with children. Application of sunscreen prior to estradiol gel has been reported to increase the transdermal absorption of estradiol.

(3) Estradiol patches with progestin mixed with adhesive—These preparations mix estradiol with either norethindrone acetate or levonorgestrel. Combipatch (0.05 mg E with 0.14 mg norethindrone acetate daily or 0.05 mg E with 0.25 mg norethindrone acetate daily) is replaced twice weekly. Climara Pro (0.045 mg E with 0.015 mg levonorgestrel daily) is replaced once weekly. The addition of a progestin reduces the risk of endometrial hyperplasia, but breakthrough bleeding occurs commonly. The combined patch increases the risk of breast cancer. Scalp hair loss, acne, weight gain, skin reactions, and poor skin adherence have been reported with these patches.

B. ORAL ESTROGEN—

(1) Oral estrogen-only preparations—These preparations include conjugated equine estrogens that are available as Premarin (0.3, 0.45, 0.625, 0.9, and 1.25 mg), conjugated plant-derived estrogens (eg, Menest, 0.3, 0.625, and 2.5 mg), and conjugated synthetic estrogens that are available as Cenestin (0.3, 0.45, 0.625, 0.9, and 1.25 mg) and Enjuvia (0.3, 0.45, 0.625, 0.9, and 1.25 mg). Other preparations include estradiol (0.5, 1, and 2 mg), and estropipate (0.75, 1.5, and 3 mg).

(2) Oral estrogen plus progestin preparations—Conjugated equine estrogens with medroxyprogesterone acetate is available as Prempro (0.3/1.5, 0.45/1.5, 0.625/2.5, and 0.625 mg/5 mg); conjugated equine estrogens for 14 days cycled with conjugated equine estrogens plus medroxyprogesterone acetate for 14 days is available as Premphase (0.625/0, then 0.625 mg/5 mg); estradiol with norethindrone acetate (0.5/0.1 and 1 mg/0.5 mg); ethinyl estradiol with norethindrone acetate is available as Femhrt (2.5/0.5 and 5 mcg/1 mg) and Jinteli (5 mcg/1 mg); estradiol with drospirenone is available as Angeliq (0.5 mg/0.25 mg, and 1.0 mg/0.5 mg); estradiol with norgestimate is available as Prefest (estradiol 1 mg/day for 3 days, alternating with 1 mg estradiol/0.09 mg norgestimate daily for 3 days). Oral contraceptives can also be used for combined HRT.

C. VAGINAL ESTROGEN—Vaginal estrogen is intended to deliver estrogen directly to local tissues and is moderately effective in reducing symptoms of urogenital atrophy, while minimizing systemic estrogen exposure. Some estrogen is absorbed systemically and can relieve menopausal symptoms. Vaginal estrogen can be used without a break at low doses or in women who have had a hysterectomy. To reduce the risk of endometrial proliferation and dysfunctional bleeding, manufacturers recommend that these preparations be used for only 3–6 months and for only 3 out of every 4 weeks in women with an intact uterus, since vaginal estrogen can cause endometrial proliferation. However, most clinicians use them for longer periods and without cycling. Vaginal estrogen can be administered in three different ways: creams, tablets, and rings.

(1) Estrogen vaginal creams—These creams are administered intravaginally with a measured-dose applicator daily for 2 weeks for atrophic vaginitis, then administered one to three times weekly. Available preparations include conjugated equine estrogens, which is available as Premarin Vaginal (0.625 mg/g cream), dosed as 0.25–2 g cream administered vaginally one to three times weekly. Estradiol is available as Estrace Vaginal (0.1 mg/g cream), 1 g cream administered vaginally one to two times weekly.

(2) Estradiol vaginal tablets and softgel inserts—Vagifem and Yuvafem (generic equivalent) are available as 10 mcg tablets. Imvexxy is a softgel vaginal insert (4 mcg or 10 mcg estradiol in a coconut oil base). Either preparation can be administered intravaginally daily for 2 weeks for atrophic vaginitis, then twice weekly.

(3) Estradiol vaginal rings—These rings are inserted manually into the upper third of the vagina, worn continuously, and replaced every 3 months. Only a small amount of the released estradiol enters the systemic circulation. Vaginal rings do not usually interfere with sexual intercourse. If a ring is removed or descends into the introitus, it may be washed in warm water and reinserted. Estring (2 mg estradiol/ring) releases 17-beta-estradiol 7.5 mcg/day with only 8% entering the systemic circulation, resulting in mean serum estradiol concentrations of only about 10 pg/mL; it is most effective for local vaginal symptoms. Femring releases estradiol acetate that is quickly hydrolyzed to estradiol and is available in two strengths: 12.4 mg/ring releases estradiol acetate 0.05 mg/day or 24.8 mg/ring releases estradiol acetate 0.1 mg/day, resulting in mean serum estradiol concentrations of about 40 pg/mL and 80 pg/mL, respectively; it is effective for both systemic and local vaginal symptoms. Both rings are replaced every 90 days. For women with postmenopausal urinary urgency and frequency, even the low-dose Estring can successfully reduce urinary symptoms.

(4) Estradiol with progestin vaginal rings—The available preparation is NuvaRing that releases a mixture of ethinyl estradiol 0.015 mg/day and etonogestrel 0.12 mg/day. It is a contraceptive vaginal ring that is placed in the vagina on or before day 5 of the menstrual cycle, left for 3 weeks, removed for 1 week, and then replaced.

D. ESTRADIOL INJECTIONS—Parenteral estradiol should be used only for particularly severe menopausal symptoms when other measures have failed or are contraindicated. Estradiol cypionate (Depo-Estradiol 5 mg/mL) may be administered intramuscularly in doses of 1–5 mg every 3–4 weeks. Estradiol valerate (20 or 40 mg/mL) may be administered intramuscularly in doses of 10–20 mg every 4 weeks. Women with an intact uterus should receive progestin for the last 10 days of each cycle.

E. ORAL PROGESTINS—For a woman with an intact uterus, long-term conventional-dose unopposed systemic estrogen therapy can cause endometrial hyperplasia, which typically results in dysfunctional uterine bleeding and might rarely lead to endometrial cancer. Progestin therapy transforms proliferative into secretory endometrium, causing a possible menses when given intermittently or no bleeding when given continuously.

The type of progestin preparation, its dosage, and the timing of administration may be tailored to the given situation. Progestins may be given daily, monthly, or at longer intervals. When given episodically, progestins are usually administered for 7- to 14-day periods. Bedtime administration may improve sleep. Some women find that progestins produce adverse effects, such as irritability, nausea, fatigue, or headache; long-term progestins given with estrogen replacement increase the risk for breast cancer.

Oral progestins are available in different formulations: Micronized progesterone (100 mg and 200 mg/capsule), medroxyprogesterone (2.5, 5.0, and 10 mg/tablet), norethindrone acetate (5 mg/tablet), and norethindrone (0.35 mg/tablet). Topical progesterone (20–50 mg/day) may reduce hot flushes in women who are intolerant to oral HRT. It may be applied to the upper arms, thighs, or inner wrists daily. It may be compounded as micronized progesterone 250 mg/mL in a transdermal gel. Its effects upon the breast and endometrium are unknown. Progesterone is also available as vaginal gels (eg, Prochieve, 4% = 45 mg/applicatorful, and 8% = 90 mg/applicatorful) that are typically given for secondary amenorrhea and administered vaginally every other day for six doses.

F. VAGINAL PROGESTERONE—Vaginal progesterone minimizes dysfunctional uterine bleeding while reducing systemic progesterone exposure. Crinone and Prochieve are available as a 4% and 8% gel with 45 mg and 90 mg per applicatorful, respectively. Endometrin comes as a 100 mg vaginal insert. Administered twice weekly with daily estrogen, most women experience no endometrial hypertrophy or dysfunctional uterine bleeding.

G. PROGESTIN-RELEASING INTRAUTERINE DEVICES—Intrauterine devices that release progestins can be useful for women receiving ERT, since they can reduce the incidence of dysfunctional uterine bleeding and endometrial carcinoma without exposing women to the significant risks of systemic progestins. The Mirena intrauterine device releases levonorgestrel and is inserted into the uterus by a clinician within 7 days of the onset of menses. It is equally effective at reducing endometrial hyperplasia as cycled medroxyprogesterone acetate and is associated with less hirsutism. It remains effective for up to 5 years. Parous women are generally better able to tolerate the Mirena intrauterine device than nulliparous women.

H. SELECTIVE ESTROGEN RECEPTOR MODULATORS—SERMs (eg, raloxifene, ospemifene, tamoxifen) are an alternative to estrogen replacement for hypogonadal women at risk for osteoporosis who prefer not to take estrogens because of their contraindications (eg, breast or uterine cancer) or side effects (see Osteoporosis, above). Raloxifene (Evista) does not reduce hot flushes, vaginal dryness, skin wrinkling, or breast atrophy; it does not improve cognition. However, in doses of 60 mg/day orally, it inhibits bone loss without stimulating effects upon the breasts or endometrium. Raloxifene does not stimulate the endometrium and actually reduces the risk of endometrial carcinoma, so concomitant progesterone therapy is not required. Another advantage to raloxifene is that it reduces the risk of invasive breast cancer by about 50%. Raloxifene slightly increases the risk of venous thromboembolism (though less so than tamoxifen), so it should not be used by women at prolonged bed rest or otherwise prone to thrombosis. Ospemifene (Osphena) is a SERM that has unique estrogen-like effects on the vaginal epithelium and is indicated for the treatment of postmenopausal dyspareunia when other therapies are ineffective. Given orally in doses of 60 mg/day, it commonly aggravates hot flushes but has an estrogenic effect upon bone and slows bone loss in menopause. It does not usually cause endometrial hypertrophy. Ospemifene has unknown long-term effects upon the breast.

Tibolone (Livial) is a SERM whose metabolites have mixed estrogenic, progestogenic, and weak androgenic activity. It is comparable to HRT for the treatment of climacteric-related complaints. It does not appear to significantly stimulate proliferation of breast or endometrial tissue. It depresses both serum triglycerides and HDL cholesterol. Long-term studies are lacking. It is not available in the United States.

I. ANDROGEN REPLACEMENT THERAPY IN WOMEN—In premenopausal women, serum testosterone levels decline with age. Between 25 and 45 years of age, women's testosterone levels fall 50%. After natural menopause, the ovaries remain a significant source for testosterone and serum testosterone levels do not fall abruptly. In contrast, very low serum testosterone levels are found in women after bilateral oophorectomy, autoimmune ovarian failure, or adrenalectomy, and in hypopituitarism. Testosterone deficiency contributes to hot flushes, loss of sexual hair, muscle atrophy, osteoporosis, and diminished libido, also known as hypoactive sexual desire disorder (see Chapter 25). Selected women may be treated with low-dose testosterone. Methyltestosterone can be compounded into capsules and taken orally in doses of 1.25–2.5 mg daily. Testosterone can also be compounded as a cream containing 1 mg/mL, with 1 mL applied to the abdomen daily. Methyltestosterone also is available combined with esterified estrogens: 1.25 mg methyltestosterone/0.626 mg esterified estrogens or 2.5 mg methyltestosterone/1.25 mg esterified estrogens. The latter formulations are convenient but carry the same disadvantages as oral estrogen—particularly an increased risk of thromboembolism.

Women receiving androgen therapy must be monitored for the appearance of any acne or hirsutism, and serum testosterone levels are determined periodically if women feel that they are benefitting and long-term testosterone therapy is instituted. Side effects of low-dose testosterone therapy are usually minimal but may include erythrocytosis, emotional changes, hirsutism, acne, an adverse effect on lipids, and potentiation of warfarin anticoagulation therapy. Testosterone therapy tends to reduce both triglyceride and HDL cholesterol levels. Hepatocellular neoplasms and peliosis hepatis, rare complications of oral androgens at higher doses, have not been reported with oral methyltestosterone doses of 2.5 mg or less daily.

Vaginal androgen is an option for postmenopausal women who are experiencing vaginal dryness and reduced sexual satisfaction. It is also an option for women who cannot use systemic or vaginal estrogen due to breast cancer. Testosterone cream 150–300 mcg (formulated) is administered vaginally daily for 2 weeks and then three times weekly. It improves sexual satisfaction while reducing vaginal dryness and dyspareunia without increasing systemic estrogen or testosterone levels. Prasterone 0.5% vaginal (Intrarosa) is a formulation of DHEA that is available as a 6.5 mg tablet that is inserted vaginally nightly at bedtime. It is indicated for relief of moderate to severe dyspareunia of menopause. However, it is contraindicated in women with breast cancer.

Caution: Androgens should not be given to women with liver disease or during pregnancy or breastfeeding. Testosterone replacement therapy for women should be used judiciously, since long-term prospective clinical trials are lacking. An analysis of the Nurses' Health Study found that women who had been taking conjugated equine estrogens plus methyltestosterone experienced an increased risk of breast cancer, so breast cancer screening is recommended.

TURNER SYNDROME (Gonadal Dysgenesis)

ESSENTIALS OF DIAGNOSIS

- Short stature with normal GH levels.
- Primary amenorrhea or early ovarian failure.
- Epicanthal folds, webbed neck, short fourth metacarpals.
- Renal and cardiovascular anomalies.

Turner syndrome comprises a group of X chromosome disorders that are associated with spontaneous abortion, primary hypogonadism, short stature, and other phenotypic anomalies (Table 26–15). It affects 1–2% of fetuses, of which about 97% abort, accounting for about 10% of all spontaneous abortions. Nevertheless, it affects about 1 in every 2500 live female births. Patients with the classic syndrome (about 50% of cases) lack one of the two X chromosomes (45,XO karyotype). About 12% of patients harbor mosaicism for Y chromosome sequences. Other patients with Turner syndrome have X chromosome abnormalities, such as ring X or Xq (X/abnormal X) or X chromosome deletions affecting all or some somatic cells (mosaicism, XX/XO).

Table 26–15. Manifestations of Turner syndrome.

- Short stature (98%)
- Head and neck features
  - High-arched palate (35%)
  - Low posterior hairline (40%)
  - Micrognathia (60%)
  - Pterygium colli (40% webbed neck)
- Eye abnormalities
  - Cataracts, corneal opacities
  - Epicanthal folds (20%), strabismus (15%), ptosis (10%)
- Gonadal abnormalities
  - Gonadal dysgenesis (primary amenorrhea 80%) or early ovarian failure (20%)
- Skeletal and extremity abnormalities
  - Broad (shield) chest (30%) with wide-spaced hypoplastic nipples
  - Cubitus valgus of arms (50%) and knock knees (35%)
  - Lymphedema of hands and feet (30%)
  - Madelung wrist deformity (5%)
  - Osteopenia (65%)
  - Scoliosis (10%)
  - Short fourth metacarpals (40%)
- Ear abnormalities
  - Conductive hearing loss (30%) and recurrent otitis media (60%)
  - Low-set and posteriorly rotated ears
- Cardiovascular anomalies
  - Aortic dilation or aneurysm (25% with bicuspid aortic valve)
  - Bicuspid aortic valve (30%) with aortic stenosis or regurgitation
  - Coarctation (14%) and cystic medial necrosis of the aorta
  - Hypertension (50%, idiopathic or due to coarctation or kidney disease)
  - Partial anomalous pulmonary venous return (18%)
- Gastrointestinal disorders
  - Achlorhydria
  - Celiac disease (8%)
  - Colon carcinoma
  - Hepatic transaminases elevated (65%)
  - Inflammatory bowel disease (3%)
  - Telangiectasias with bleeding
- Kidney abnormalities (60%)
  - Horseshoe kidney (10%), duplication or abnormal positioning of renal pelvis or ureters (15%)
- CNS disorders
  - Emotional immaturity (40%)
  - Learning disabilities and ADHD (40%)
  - Sensorineural hearing loss
- Skin and nail disorders
  - Hyperconvex nails
  - Keloid formation
  - Pigmented nevi
- Associated conditions
  - Diabetes mellitus (10%) or glucose intolerance (35%)
  - Dyslipidemia
  - Hashimoto thyroiditis (37%)
  - Hyperuricemia
  - Neuroblastoma (1%)
  - Obesity
  - Rheumatoid arthritis

ADHD, attention deficit/hyperactivity disorder; CNS, central nervous system.

1. Classic Turner Syndrome (45,XO Gonadal Dysgenesis)

Clinical Findings

A. Symptoms and Signs

Features of Turner syndrome are variable and may be subtle in girls with mosaicism. Turner syndrome may be diagnosed in infant girls at birth, since they tend to be small and may exhibit severe lymphedema. Evaluation for childhood short stature often leads to the diagnosis. Girls and women with Turner syndrome have an increased risk of aortic coarctation and bicuspid aortic valves; these cardiac abnormalities are more common in patients with a webbed neck. Typical manifestations in adulthood include short stature, hypogonadism, webbed neck, high-arched palate, wide-spaced nipples, hypertension, and kidney abnormalities (Table 26–15). Emotional disorders are common. Affected women are also more prone to autoimmune disease, particularly thyroiditis, inflammatory bowel disease, and celiac disease.

Hypogonadism presents as “delayed adolescence” (primary amenorrhea, 80%) or early ovarian failure (20%); girls with 45,XO Turner (blood karyotyping) who enter puberty are typically found to have mosaicism if other tissues are karyotyped.

B. Laboratory Findings

Hypogonadism is confirmed in girls who have high serum levels of FSH and LH. A blood karyotype showing 45,XO (or X chromosome abnormalities or mosaicism) establishes the diagnosis. GH and IGF-1 levels are normal.

C. Imaging

A transthoracic ultrasound and MRI scan of the chest and abdomen should be done in all patients with Turner syndrome to determine whether cardiac, aortic, and renal abnormalities are present.

Treatment

For short stature, GH therapy should be started early, ideally by age 4–6 and before age 12 years. GH is given subcutaneously in doses of 50 mcg/kg/day or 4.5 international units/m^2/day; the GH dose is titrated to keep the serum IGF-I levels within 3 SD above the mean for age. Rarely, GH treatment causes pseudotumor cerebri. The oral androgen oxandrolone (0.03–0.05 mg/kg/day) is added after age 10 for girls whose growth is inadequate with GH therapy alone. After age 12 years, estrogen therapy is begun with low doses of transdermal estradiol, with a gradual increase in dose over 2–3 years.

Progesterone is added after 2 years of estrogen therapy or if menstrual bleeding occurs. For girls age 12 years or older with Turner mosaicism and spontaneous menses, early oocyte retrieval and cryopreservation should be considered, while weighing the risks of pregnancy.

Complications & Surveillance

Women with Turner syndrome have a reduced life expectancy due in part to their increased risk of diabetes mellitus (types 1 and 2), hypertension, dyslipidemia, and osteoporosis. Patients are prone to keloid formation after surgery or ear piercing. Annual surveillance should include a blood pressure determination and laboratory evaluations that include a serum TSH, liver enzymes, BUN, creatinine, and fasting serum lipids and glucose. Celiac disease screening (serum TTG IgA Ab) is warranted every 2–5 years for school-age girls and then whenever indicated clinically. Audiology exams are recommended every 1–5 years. Bone mineral densitometries should be measured periodically for women over age 18 years.

Bicuspid aortic valves are common and are associated with an increased risk of infective endocarditis, aortic valvular stenosis or regurgitation, and ascending aortic root dilation and dissection. The risk of aortic dissection is increased more than 100-fold in women with Turner syndrome, particularly those with pronounced neck webbing and shield chest. Patients with aortic root enlargement are usually treated with beta-blockade and serial imaging.

About 5% of women with Turner syndrome experience natural pregnancy and even more can become pregnant with oocyte donation. Such pregnancies are very high-risk, with increased fetal morbidity and preeclampsia. During pregnancy, women with Turner syndrome have a 2% risk of aortic dissection or rupture, so they require close monitoring with repeated echocardiography; those with aortic root diameter 4 cm or more are delivered by elective caesarean section, whereas those with an aortic root diameter less than 4 cm may deliver vaginally.

Partial anomalous pulmonary vein connections can lead to left-to-right shunting of blood. Adults with Turner syndrome also have a high incidence of ECG abnormalities, such as long QT syndrome.

Patients with the classic 45,XO karyotype have a high risk of renal structural abnormalities, whereas those with 46 X/abnormal X are more prone to malformations of the urinary collecting system.

2. Turner Syndrome Variants

A. 46,X (Abnormal X) Karyotype

Patients with small distal short arm deletions of the X chromosome (Xp-) that include the SHOX gene often have short stature and skeletal abnormalities but have a low risk of ovarian failure. Transmission of Turner syndrome from mother to daughter can occur. There may be an increased risk of trisomy 21 in the conceptuses of women with Turner syndrome. Patients with deletions of the long arm of the X chromosome (distal to Xq24) often have amenorrhea without short stature or other features of Turner syndrome. Abnormalities or deletions of other genes located on both the long and short arms of the X chromosome can produce gonadal dysgenesis with few other somatic features.

B. 45,XO/46,XX and 45,XO/46,XY Mosaicism

45,XO/46,XX mosaicism results in a modified form of Turner syndrome. Such girls tend to be taller and may have more gonadal function and fewer other manifestations of Turner syndrome.

45,XO/46,XY mosaicism can produce some manifestations of Turner syndrome. Patients may have ambiguous genitalia or male infertility with an otherwise normal phenotype. Germ cell tumors, such as gonadoblastomas and seminomas, develop in about 10% of patients with 45,XO/46,XY mosaicism; most such tumors are benign.

Gravholt CH et al; International Turner Syndrome Consensus Group. Clinical practice guidelines for the care of girls and women with Turner syndrome: proceedings from the 2016 Cincinnati International Turner Syndrome Meeting. Eur J Endocrinol. 2017 Sep;177(3):G1–70. [PMID: 28705803]

CLINICAL USE OF CORTICOSTEROIDS

Prolonged treatment with high-dose corticosteroids causes toxic effects that can be life threatening. Besides oral and parenteral administration, transdermal and inhaled corticosteroids have some systemic absorption and can cause similar adverse effects. Patients should be thoroughly informed of the major possible side effects of treatment: insomnia, cognitive and personality changes, weight gain with central obesity, skin thinning and bruising, striae, muscle weakness, polyuria, renal calculi, diabetes mellitus, glaucoma, cataracts, sex hormone suppression, candidiasis, and opportunistic infections. Prolonged high-dose corticosteroids also increase the risk of hypertension, dyslipidemia, myocardial infarction, stroke, atrial fibrillation or flutter, and heart failure. Gastric ulceration is more common with high-dose corticosteroids, particularly when patients take NSAIDs concurrently. Prolonged oral, inhaled, intravenous, or high-dose topical corticosteroid therapy commonly suppresses pituitary ACTH secretion, causing secondary adrenal insufficiency. High-dose inhaled corticosteroids predispose to oral thrush and pulmonary nontuberculous mycobacterial infection. To reduce risks, the dosage and duration of corticosteroid administration must be minimized. Immediately following inhaled corticosteroids, proper mouth-washing and gargling can reduce systemic absorption.

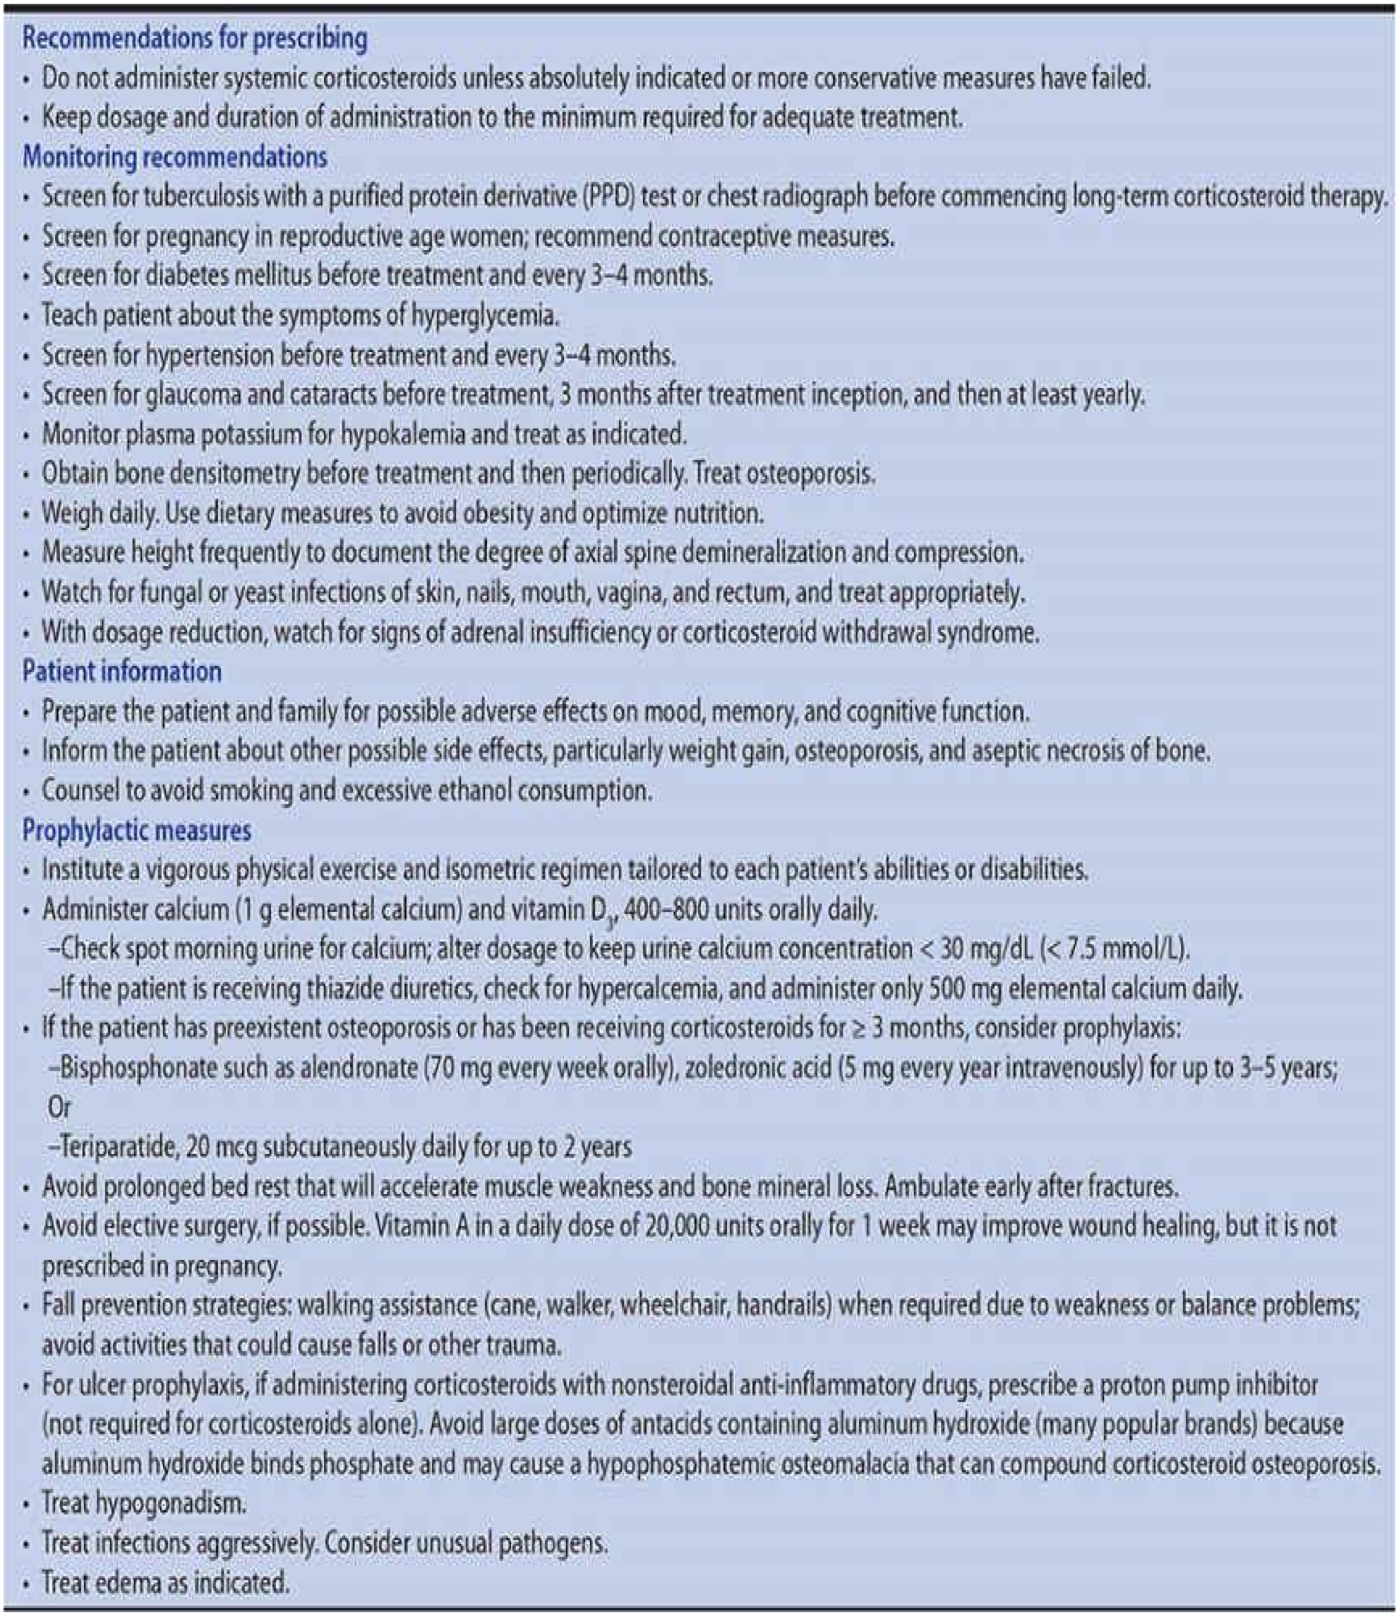
Most corticosteroids (dexamethasone, prednisone, hydrocortisone, deflazacort, budesonide) are metabolized by the enzyme CYP34A. When drugs that inhibit CYP34A are administered along with even modest doses of corticosteroids (oral, inhaled, intravenous), the blood levels of the corticosteroids rise and can cause iatrogenic Cushing syndrome and secondary adrenal insufficiency. Medications that strongly inhibit CYP34A include itraconazole, ketoconazole, and nefazodone. Other strong CYP34A inhibitors include protease inhibitors and cobicistat that is an antiretroviral booster for the treatment of patients with HIV.

In pregnancy, corticosteroids taken by the mother are transmitted across the placenta to the fetus, causing adverse effects on fetal growth and development as well as childhood cognition and behavior. Therefore, women who are to receive high-dose corticosteroids should be screened for pregnancy and counseled to use contraception.

Osteoporotic fractures (especially vertebral) ultimately occur in about 40% of patients receiving long-term corticosteroid therapy. Osteoporotic fractures can occur even in patients receiving long-term corticosteroid therapy at relatively low doses (eg, 5–7.5 mg prednisone daily). The risk of vertebral fractures increases 14-fold and the risk of hip fractures increases 3-fold. Patients at increased risk for corticosteroid osteoporotic fractures include those who are over age 60 or who have a low body mass index, pretreatment osteoporosis, a family history of osteoporosis, or concurrent disease that limits mobility. Avascular necrosis of bone (especially hips) develops in about 15% of patients who receive corticosteroids at high doses (eg, prednisone 15 mg daily or more) for more than 1 month with cumulative prednisone doses of 10 g or more.

Bisphosphonates (eg, alendronate) prevent the development of osteoporosis among patients receiving prolonged courses of corticosteroids (Table 26–16). For patients who are unable to tolerate oral bisphosphonates (due to esophagitis, hiatal hernia, or gastritis), parenteral bisphosphonates can be used. Denosumab inhibits bone resorption, but may increase the risk of infection compared to bisphosphonates; so, the use of denosumab is not recommended for patients receiving high-dose corticosteroid therapy who are already at an increased risk for infection.

Table 26–16. Management of patients receiving systemic corticosteroids.



Recommendations for prescribing

- Do not administer systemic corticosteroids unless absolutely indicated or more conservative measures have failed.
- Keep dosage and duration of administration to the minimum required for adequate treatment.

Monitoring recommendations

- Screen for tuberculosis with a purified protein derivative (PPD) test or chest radiograph before commencing long-term corticosteroid therapy.
- Screen for pregnancy in reproductive age women; recommend contraceptive measures.
- Screen for diabetes mellitus before treatment and every 3–4 months.
- Teach patient about the symptoms of hyperglycemia.
- Screen for hypertension before treatment and every 3–4 months.
- Screen for glaucoma and cataracts before treatment, 3 months after treatment inception, and then at least yearly.
- Monitor plasma potassium for hypokalemia and treat as indicated.
- Obtain bone densitometry before treatment and then periodically. Treat osteoporosis.
- Weigh daily. Use dietary measures to avoid obesity and optimize nutrition.
- Measure height frequently to document the degree of axial spine demineralization and compression.
- Watch for fungal or yeast infections of skin, nails, mouth, vagina, and rectum, and treat appropriately.
- With dosage reduction, watch for signs of adrenal insufficiency or corticosteroid withdrawal syndrome.

Patient information

- Prepare the patient and family for possible adverse effects on mood, memory, and cognitive function.
- Inform the patient about other possible side effects, particularly weight gain, osteoporosis, and aseptic necrosis of bone.
- Counsel to avoid smoking and excessive ethanol consumption.

Prophylactic measures

- Institute a vigorous physical exercise and isometric regimen tailored to each patient's abilities or disabilities.
- Administer calcium (1 g elemental calcium) and vitamin D_3, 400–800 units orally daily.
  –Check spot morning urine for calcium; alter dosage to keep urine calcium concentration < 30 mg/dL (< 7.5 mmol/L).
  –If the patient is receiving thiazide diuretics, check for hypercalcemia, and administer only 500 mg elemental calcium daily.
- If the patient has preexistent osteoporosis or has been receiving corticosteroids for ≥ 3 months, consider prophylaxis:
  –Bisphosphonate such as alendronate (70 mg every week orally), zoledronic acid (5 mg every year intravenously) for up to 3–5 years;
  Or
  –Teriparatide, 20 mcg subcutaneously daily for up to 2 years
- Avoid prolonged bed rest that will accelerate muscle weakness and bone mineral loss. Ambulate early after fractures.
- Avoid elective surgery, if possible. Vitamin A in a daily dose of 20,000 units orally for 1 week may improve wound healing, but it is not prescribed in pregnancy.
- Fall prevention strategies: walking assistance (cane, walker, wheelchair, handrails) when required due to weakness or balance problems; avoid activities that could cause falls or other trauma.
- For ulcer prophylaxis, if administering corticosteroids with nonsteroidal anti-inflammatory drugs, prescribe a proton pump inhibitor (not required for corticosteroids alone). Avoid large doses of antacids containing aluminum hydroxide (many popular brands) because aluminum hydroxide binds phosphate and may cause a hypophosphatemic osteomalacia that can compound corticosteroid osteoporosis.
- Treat hypogonadism.
- Treat infections aggressively. Consider unusual pathogens.
- Treat edema as indicated.

The PTH/PTHrP analogs teriparatide and abaloparatide are anabolic agents that are also effective against corticosteroid-induced osteoporosis. They can be given for a 2-year course and increase bone density more effectively than bisphosphonates. For patients who are currently receiving corticosteroid therapy, however, these analogs increase the risk of hypercalcemia and must be used with great caution; they are most useful for patients with osteoporosis who have stopped high-dose corticosteroid therapy. Following a 2-year course of therapy with these analogs, bone loss and fractures occur quickly after discontinuation, so such therapy is usually followed by bisphosphonate therapy in patients with a history of fracture or osteoporosis by bone densitometry. (See Osteoporosis.) It is wise to follow an organized treatment plan such as the one outlined in Table 26–16.

Diabetes Mellitus & Hypoglycemia

Umesh Masharani, MB, BS, MRCP (UK)

DIABETES MELLITUS

ESSENTIALS OF DIAGNOSIS

Type 1 diabetes

- Polyuria, polydipsia, and weight loss associated with random plasma glucose of 200 mg/dL (11.1 mmol/L) or more.
- Plasma glucose of 126 mg/dL (7.0 mmol/L) or more after an overnight fast, documented on more than one occasion.
- Ketonemia, ketonuria, or both.
- Islet autoantibodies are frequently present.

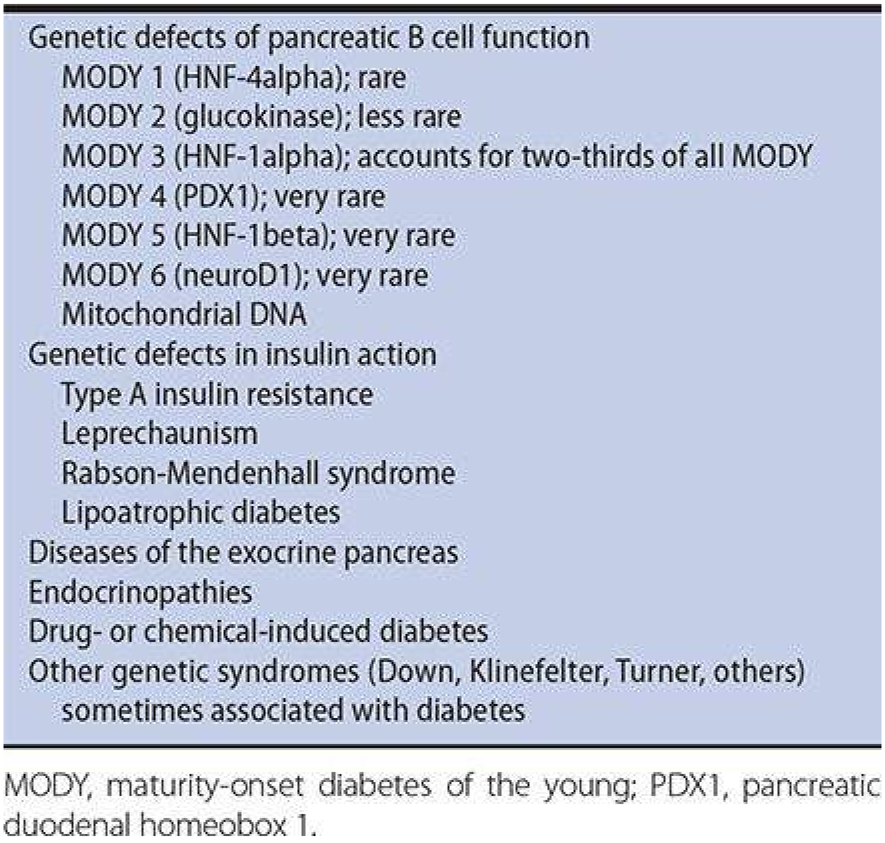
Type 2 diabetes

- Many patients are over 40 years of age and obese.
- Polyuria and polydipsia. Ketonuria and weight loss are uncommon at time of diagnosis. Candidal vaginitis in women may be an initial manifestation. Many patients have few or no symptoms.
- Plasma glucose of 126 mg/dL or more after an overnight fast on more than one occasion. Two hours after 75 g oral glucose, diagnostic values are 200 mg/dL (11.1 mmol) or more.
- HbA_{1c} 6.5% or more.
- Hypertension, dyslipidemia, and atherosclerosis are often associated.

Epidemiologic Considerations

An estimated 30.3 million people (9.4%) in the United States have diabetes mellitus, of which approximately 1.5 million have type 1 diabetes and most of the rest have type 2 diabetes. A third group designated as “other specific types” by the American Diabetes Association (ADA) (Table 27–1) number in the thousands.

Table 27–1. Other specific types of diabetes mellitus.



- Genetic defects of pancreatic B cell function
  - MODY 1 (HNF-4alpha); rare
  - MODY 2 (glucokinase); less rare
  - MODY 3 (HNF-1alpha); accounts for two-thirds of all MODY
  - MODY 4 (PDX1); very rare
  - MODY 5 (HNF-1beta); very rare
  - MODY 6 (neuroD1); very rare
  - Mitochondrial DNA
- Genetic defects in insulin action
  - Type A insulin resistance
  - Leprechaunism
  - Rabson-Mendenhall syndrome
  - Lipoatrophic diabetes
- Diseases of the exocrine pancreas
- Endocrinopathies
- Drug- or chemical-induced diabetes
- Other genetic syndromes (Down, Klinefelter, Turner, others) sometimes associated with diabetes

MODY, maturity-onset diabetes of the young; PDX1, pancreatic duodenal homeobox 1.

Classification & Pathogenesis

Diabetes mellitus is a syndrome with disordered metabolism and inappropriate hyperglycemia due to either a deficiency of insulin secretion or to a combination of insulin resistance and inadequate insulin secretion to compensate for the resistance.

A. Type 1 Diabetes Mellitus

This form of diabetes is due to pancreatic islet B cell destruction predominantly by an autoimmune process in over 95% of cases (type 1A) and idiopathic in less than 5% (type 1B). The rate of pancreatic B cell destruction is quite variable, being rapid in some individuals and slow in others. It occurs at any age but most commonly arises in children and young adults with a peak incidence before school age and again at around puberty. It is a catabolic disorder in which circulating insulin is virtually absent, plasma glucagon is elevated, and the pancreatic B cells fail to respond to all insulinogenic stimuli. Type 1 diabetes is usually associated with ketosis in its untreated state. Exogenous insulin is therefore required to reverse the catabolic state, prevent ketosis, reduce the hyperglucagonemia, and reduce blood glucose.

1. Immune-mediated type 1 diabetes mellitus (type 1A)—Approximately one-third of the disease susceptibility is due to genes and two-thirds to environmental factors. Genes that are related to the HLA locus contribute about 40% of the genetic risk. About 95% of patients with type 1 diabetes possess either HLA-DR3 or HLA-DR4, compared with 45–50% of white controls. HLA-DQ genes are even more specific markers of type 1 susceptibility, since a particular variety (HLA-DQB1*0302) is found in the DR4 patients with type 1, while a "protective" gene (HLA-DQB1*0602) is often present in the DR4 controls. The other important gene that contributes to about 10% of the genetic risk is found at the 5′ polymorphic region of the insulin gene. Mutations in genes associated with T cell tolerance can also cause autoimmune diabetes. The autoimmune regulatory gene (AIRE) product regulates the expression of several proteins in the thymus causing the deletion of self-reactive T cells. Type 1 diabetes mellitus as well as other autoimmune disorders (autoimmune polyglandular syndrome 1) develop in 20% of individuals with homozygote mutations in AIRE. Most patients with type 1 diabetes mellitus have circulating antibodies to islet cells (ICA), glutamic acid decarboxylase 65 (GAD65), insulin (IAA), tyrosine phosphatase IA2 (ICA-512), and zinc transporter 8 (ZnT8) at the time the diagnosis is made (Table 27–2). These antibodies facilitate screening for an autoimmune cause of diabetes, particularly screening siblings of affected children, as well as adults with atypical features of type 2 diabetes mellitus. Also, low levels of anti-insulin antibodies develop in almost all patients once they are treated with insulin.

Table 27–2. Diagnostic sensitivity and specificity of autoimmune markers in patients with newly diagnosed type 1 diabetes mellitus.

	Sensitivity	Specificity
Islet cell antibodies (ICA)	44–100%	96%
Glutamic acid decarboxylase (GAD65)	70–90%	99%
Insulin (IAA)	40–70%	99%
Tyrosine phosphatase (IA-2)	50–70%	99%
Zinc transporter 8 (ZnT8)	50–70%	99%

Family members of diabetic probands are at increased lifetime risk for developing type 1 diabetes mellitus. A child whose mother has type 1 diabetes has a 3% risk of developing the disease and a 6% risk if the child's father has it. The risk in siblings is related to the number of HLA haplotypes that the sibling shares with the diabetic proband. If one haplotype is shared, the risk is 6% and if two haplotypes are shared, the risk increases to 12–25%. The highest risk is for identical twins, where the concordance rate is 25–50%.

Some patients with a milder expression of type 1 diabetes mellitus initially retain enough B cell function to avoid ketosis, but as their B cell mass diminishes later in life, dependence on insulin therapy develops. Islet cell antibody surveys among northern Europeans indicate that up to 15% of "type 2" diabetic patients may actually have this mild form of type 1 diabetes (latent autoimmune diabetes of adulthood; LADA). Evidence for environmental factors playing a role in the development of type 1 diabetes include the observation that the disease is more common in Scandinavian countries and becomes progressively less frequent in countries nearer and nearer to the equator. Also, the risk for type 1 diabetes increases when individuals who normally have a low risk emigrate to the Northern Hemisphere. For example, Pakistani children born and raised in Bradford, England, have a higher risk for developing type 1 diabetes compared with children who lived in Pakistan all their lives.

Which environmental factor is responsible for the increased risk is not known. Breastfeeding in the first 6 months of life appears to be protective. There is accumulating evidence that improvements in public health and reduced infections (especially parasitic) lead to immune system dysregulation and development of autoimmune disorders such as asthma and type 1 diabetes.

Check point inhibitor immunotherapies for advanced malignancies, such as nivolumab, pembrolizumab, and ipilimumab, can precipitate autoimmune disorders, including type 1 diabetes. Patients receiving these drugs should be monitored for the development of diabetes.

2. Idiopathic type 1 diabetes mellitus (type 1B)—Approximately 5% of subjects have no evidence of pancreatic B cell autoimmunity to explain their insulinopenia and ketoacidosis. This subgroup has been classified as "idiopathic type 1 diabetes" and designated as "type 1B." Although only a minority of patients with type 1 diabetes fall into this group, most of these individuals are of Asian or African origin. About 4% of the West Africans with ketosis-prone diabetes are homozygous for a mutation in PAX-4 (Arg133Trp)—a transcription factor that is essential for the development of pancreatic islets.

B. Type 2 Diabetes Mellitus

This represents a heterogeneous group of conditions that used to occur predominantly in adults, but it is now more frequently encountered in children and adolescents. Circulating endogenous insulin is sufficient to prevent ketoacidosis but is inadequate to prevent hyperglycemia in the face of increased needs owing to tissue insensitivity (insulin resistance).

Genetic and environmental factors combine to cause both the insulin resistance and the beta cell loss. Most epidemiologic data indicate strong genetic influences, since in monozygotic twins over 40 years of age, concordance develops in over 70% of cases within a year whenever type 2 diabetes develops in one twin. So far, more than 30 genetic loci have been associated with an increased risk of type 2 diabetes. A significant number of the identified loci appear to code for proteins that have a role in beta cell function or development. One of the genetic loci with the largest risk effect is TCF7L2. This gene codes for a transcription factor involved in the WNT signaling pathway that is required for normal pancreatic development.

Early in the disease process, hyperplasia of pancreatic B cells occurs and probably accounts for the fasting hyperinsulinism and exaggerated insulin and proinsulin responses to glucose and other stimuli. With time, chronic deposition of amyloid in the islets may combine with inherited genetic defects progressively to impair B cell function.

Obesity is the most important environmental factor causing insulin resistance. The degree and prevalence of obesity varies among different racial groups with type 2 diabetes. While obesity is apparent in no more than 30% of Chinese and Japanese patients with type 2, it is found in 60–70% of North Americans, Europeans, or Africans with type 2 and approaches 100% of patients with type 2 among Pima Indians or Pacific Islanders from Nauru or Samoa.

Visceral obesity, due to accumulation of fat in the omental and mesenteric regions, correlates with insulin resistance; subcutaneous abdominal fat seems to have less of an association with insulin insensitivity. There are many patients with type 2 diabetes who, while not overtly obese, have increased visceral fat; they are termed the “metabolically obese.” Exercise may affect the deposition of visceral fat as suggested by CT scans of Japanese wrestlers, whose extreme obesity is predominantly subcutaneous. Their daily vigorous exercise program prevents accumulation of visceral fat, and they have normal serum lipids and euglycemia despite daily intakes of 5000–7000 kcal and development of massive subcutaneous obesity.

C. Other Specific Types of Diabetes Mellitus

1. Maturity-onset diabetes of the young (MODY)—This subgroup of monogenic disorders is characterized by noninsulin requiring diabetes with autosomal dominant inheritance and an age at onset of 25 years or younger. Patients are nonobese, and their hyperglycemia is due to impaired glucose-induced secretion of insulin. Six types of MODY have been described (Table 27–1). Except for MODY 2, in which a glucokinase gene is defective, all other types involve mutations of a nuclear transcription factor that regulates islet gene expression. Patients younger than 30 years with endogenous insulin production (urinary C-peptide/creatinine ratio of 0.2 nmol/mmol or higher) and negative autoantibodies are candidates for genetic screening for MODY. The enzyme glucokinase is a rate-limiting step in glycolysis and determines the rate of adenosine triphosphate (ATP) production from glucose and the insulin secretory response in the beta cell. MODY 2, due to glucokinase mutations, is usually quite mild, associated with only slight fasting hyperglycemia and few if any microvascular diabetic complications. MODY 3, due to mutations in hepatic nuclear factor 1 alpha is the most common form, accounting for two-thirds of all MODY cases. Initially, patients with MODY 3 are responsive to sulfonylurea therapy but the clinical course is of progressive beta cell failure and eventual need for insulin therapy. Mutations in both alleles of glucokinase present with more severe neonatal diabetes. Mutation in one allele of the pancreatic duodenal homeobox 1 (PDX1) causes diabetes usually at a later age (~ 35 years) than other forms of MODY; mutations in both alleles of PDX1 cause pancreatic agenesis.

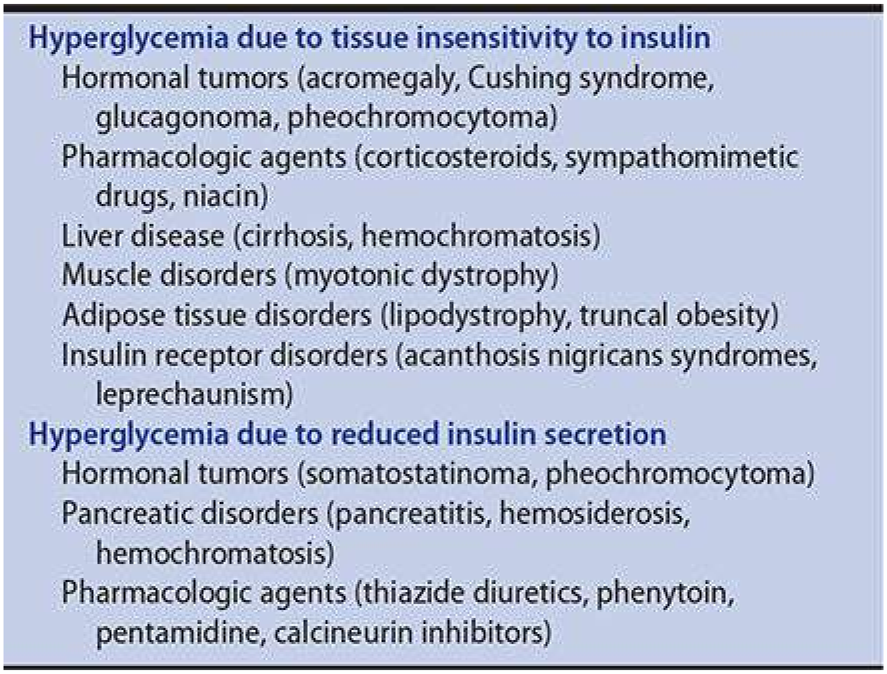
2. Diabetes mellitus associated with a mutation of mitochondrial DNA—Since sperm do not contain mitochondria, only the mother transmits mitochondrial genes to her offspring. Diabetes due to mutations of mitochondrial DNA occurs in less than 2% of patients with diabetes. The most common cause is the A3243G mutation in the gene coding for the tRNA (Leu, UUR). Diabetes usually develops in these patients in their late 30s, and characteristically, they also have hearing loss (maternally inherited diabetes and deafness [MIDD]).

3. Wolfram syndrome—Wolfram syndrome is an autosomal recessive neurodegenerative disorder first evident in childhood. It consists of diabetes insipidus, diabetes mellitus, optic atrophy, and deafness, hence the acronym DIDMOAD. It is due to mutations in a gene named WFS1, which encodes a 100.3 KDa transmembrane protein localized in the endoplasmic reticulum. Cranial diabetes insipidus and sensorineural deafness develop during the second decade in 60–75% of patients. Ureterohydronephrosis, neurogenic bladder, cerebellar ataxia, peripheral neuropathy, and psychiatric illness develop later in many patients.

4. Autosomal recessive syndromes—Homozygous mutations in a number of pancreatic transcription factors, NEUROG3, PTF1A, RFX6, and GLI-similar 3 (GLIS3), cause neonatal or childhood diabetes. Homozygous PTF1A mutations result in absent pancreas and cerebellar atrophy; NEUROG3 mutations cause severe malabsorption and diabetes before puberty. Homozygous mutations in RFX6 cause the Mitchell-Riley syndrome characterized by absence of all islet cell types apart from pancreatic polypeptide cells, hypoplasia of the pancreas and gallbladder, and intestinal atresia. GLIS3 gene plays a role in transcription of insulin gene, and homozygous mutations cause neonatal diabetes and congenital hypothyroidism. The gene EIF2AK3 encodes PKR-like ER kinase (PERK), which controls one of the pathways of the unfolded protein response. Absence of PERK leads to inadequate response to ER stress and accelerated beta cell apoptosis. Patients with mutation in this gene have neonatal diabetes, epiphyseal dysplasia, developmental delay, and liver and kidney dysfunction (Wolcott-Rallison syndrome).

5. Diabetes mellitus secondary to other causes—Endocrine tumors secreting growth hormone, glucocorticoids, catecholamines, glucagon, or somatostatin can cause glucose intolerance (Table 27–3). In the first four of these situations, peripheral responsiveness to insulin is impaired. With excess of glucocorticoids, catecholamines, or glucagon, increased hepatic output of glucose is a contributory factor; in the case of catecholamines, decreased insulin release is an additional factor in producing carbohydrate intolerance, and with somatostatin, inhibition of insulin secretion is the major factor. Diabetes mainly occurs in individuals with underlying defects in insulin secretion, and hyperglycemia typically resolves when the hormone excess is resolved.

Table 27–3. Secondary causes of hyperglycemia.



Hyperglycemia due to tissue insensitivity to insulin

- Hormonal tumors (acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma)
- Pharmacologic agents (corticosteroids, sympathomimetic drugs, niacin)
- Liver disease (cirrhosis, hemochromatosis)
- Muscle disorders (myotonic dystrophy)
- Adipose tissue disorders (lipodystrophy, truncal obesity)
- Insulin receptor disorders (acanthosis nigricans syndromes, leprechaunism)

Hyperglycemia due to reduced insulin secretion

- Hormonal tumors (somatostatinoma, pheochromocytoma)
- Pancreatic disorders (pancreatitis, hemosiderosis, hemochromatosis)
- Pharmacologic agents (thiazide diuretics, phenytoin, pentamidine, calcineurin inhibitors)

High-titer anti-insulin receptor antibodies that inhibit insulin binding cause a clinical syndrome characterized by severe insulin resistance, glucose intolerance or diabetes mellitus, and acanthosis nigricans. These patients usually have other autoimmune disorders. There are reports of spontaneous remission or remission with cytotoxic therapy.

Many medications are associated with carbohydrate intolerance or frank diabetes (Table 27–3). The medications act by decreasing insulin secretion or by increasing insulin resistance or both. Cyclosporine and tacrolimus impair insulin secretion; sirolimus principally increases insulin resistance. These agents contribute to the development of new-onset diabetes after transplantation. Corticosteroids increase insulin resistance but may also have an effect on beta cell function; in a case control study and a large population cohort study, oral corticosteroids doubled the risk for development of diabetes. Thiazide diuretics and beta-blockers modestly increase the risk for diabetes. Treating the hypokalemia due to thiazides may reverse the hyperglycemia. Atypical antipsychotics, particularly olanzapine and clozapine, are associated with increased risk of glucose intolerance. These medications cause weight gain and insulin resistance but may also impair beta cell function; an increase in rates of diabetic ketoacidosis (DKA) has been reported.

Chronic pancreatitis or subtotal pancreatectomy reduces the number of functioning B cells and can result in a metabolic derangement very similar to that of genetic type 1 diabetes except that a concomitant reduction in pancreatic A cells may reduce glucagon secretion so that relatively lower doses of insulin replacement are needed.

Insulin Resistance Syndrome (Metabolic Syndrome)

Twenty-five percent of the general nonobese, nondiabetic population has insulin resistance of a magnitude similar to that seen in type 2 diabetes. These insulin-resistant nondiabetic individuals are at much higher risk for developing type 2 diabetes than insulin-sensitive persons. These individuals also have a cluster of abnormalities termed **metabolic syndrome** that significantly increases their risk of atherosclerotic disease: elevated plasma triglycerides and small, dense, low-density lipoproteins (LDLs); lower high-density lipoproteins (HDLs); higher blood pressure; hyperuricemia; abdominal obesity; prothrombotic state with increased levels of plasminogen activator inhibitor type 1 (PAI-1); and proinflammatory state with increased levels of proinflammatory cytokines such as IL-6 and TNF-alpha.

It has been postulated that hyperinsulinemia and insulin resistance play a direct role in these metabolic abnormalities, but supportive evidence is inconclusive. The main value of grouping these disorders as a syndrome, however, is to remind clinicians that the therapeutic goals are not only to correct hyperglycemia but also to manage the elevated blood pressure and dyslipidemia that result in increased cerebrovascular and cardiac morbidity and mortality in these patients.

Clinical Findings

A. Symptoms and Signs

1. Type 1 diabetes—A characteristic symptom complex of hyperosmolality and hyperketonemia from the accumulation of circulating glucose and fatty acids typically presents in patients with type 1 diabetes. Increased urination and thirst are consequences of osmotic diuresis secondary to sustained hyperglycemia. The diuresis results in a loss of glucose as well as free water and electrolytes in the urine. Blurred vision often develops as the lenses are exposed to hyperosmolar fluids.

Weight loss despite normal or increased appetite is a common feature of type 1 when it develops subacutely. The weight loss is initially due to depletion of water, glycogen, and triglycerides; thereafter, reduced muscle mass occurs as amino acids are diverted to form glucose and ketone bodies. Loss of subcutaneous fat and muscle wasting are features of more slowly developing insulin deficiency. Lowered plasma volume produces symptoms of postural hypotension, which is a serious prognostic sign. Total body potassium loss and the general catabolism of muscle protein contribute to the weakness.

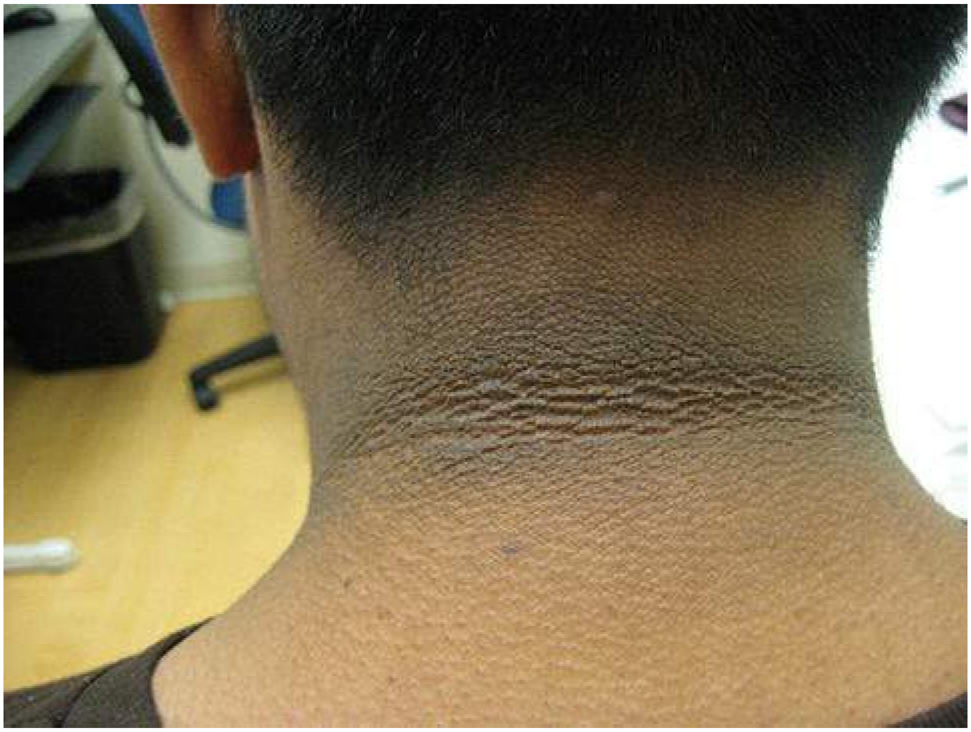
Paresthesias may be present at the time of diagnosis, particularly when the onset is subacute. They reflect a temporary dysfunction of peripheral sensory nerves, which clears as insulin replacement restores glycemic levels closer to normal, suggesting neurotoxicity from sustained hyperglycemia.

When absolute insulin deficiency is of acute onset, the above symptoms develop abruptly. Ketoacidosis exacerbates the dehydration and hyperosmolality by producing anorexia and nausea and vomiting, interfering with oral fluid replacement.

The patient’s level of consciousness can vary depending on the degree of hyperosmolality. When insulin deficiency develops relatively slowly and sufficient water intake is maintained, patients remain relatively alert and physical findings may be minimal. When vomiting occurs in response to worsening ketoacidosis, dehydration progresses and compensatory mechanisms become inadequate to keep serum osmolality below 320–330 mOsm/L. Under these circumstances, stupor or even coma may occur. The fruity breath odor of acetone further suggests the diagnosis of DKA.

2. Type 2 diabetes—While increased urination and thirst may be presenting symptoms in some patients with type 2 diabetes, many other patients have an insidious onset of hyperglycemia and are asymptomatic initially. This is particularly true in obese patients, whose diabetes may be detected only after glycosuria or hyperglycemia is noted during routine laboratory studies. Occasionally, when the disease has been occult for some time, patients with type 2 diabetes may have evidence of neuropathic or cardiovascular complications at the time of presentation. Chronic skin infections are common. Generalized pruritus and symptoms of vaginitis are frequently the initial complaints of women. Diabetes should be suspected in women with chronic candidal vulvovaginitis as well as in those who have delivered babies larger than 9 lb (4.1 kg) or have had polyhydramnios, preeclampsia, or unexplained fetal losses. Balanoposthitis (inflammation of the foreskin and glans in uncircumcised males) may occur.

Many patients with type 2 diabetes are overweight or obese. Even those who are not significantly obese often have characteristic localization of fat deposits on the upper segment of the body (particularly the abdomen, chest, neck, and face) and relatively less fat on the appendages, which may be quite muscular. This centripetal fat distribution is characterized by a high waist circumference; a waist circumference larger than 40 inches (102 cm) in men and 35 inches (88 cm) in women is associated with an increased risk of diabetes. Some patients may have acanthosis nigricans, which is associated with significant insulin resistance; the skin in the axilla, groin, and back of neck is hyperpigmented and hyperkeratotic (Figure 27–1). Mild hypertension is often present in obese patients with diabetes. Eruptive xanthomas on the flexor surface of the limbs and on the buttocks and lipemia retinalis due to hyperchylomicronemia can occur in patients with uncontrolled type 2 diabetes who also have a familial form of hypertriglyceridemia.



▲ **Figure 27–1. Acanthosis nigricans of the nape of the neck, with typical dark and velvety appearance.** (Used, with permission, from Umesh Masharani, MB, BS, MRCP [UK].)

Hyperglycemic hyperosmolar coma can also be present; in these cases, patients are profoundly dehydrated, hypotensive, lethargic, or comatose but without Kussmaul respirations.

B. Laboratory Findings

1. Urine glucose—A convenient method to detect glucosuria is the paper strip impregnated with glucose oxidase and a chromogen system (Clinistix, Diastix), which is sensitive to as little as 100 mg/dL (5.5 mmol) glucose in urine. A normal renal threshold for glucose as well as reliable bladder emptying is essential for interpretation.

Nondiabetic glycosuria (renal glycosuria) is a benign asymptomatic condition wherein glucose appears in the urine despite a normal amount of glucose in the blood, either basally or during a glucose tolerance test. Its cause may vary from mutations in the SGLT2 gene coding for sodium-glucose transporter 2 (familial renal glycosuria) to one associated with dysfunction of the proximal renal tubule (Fanconi syndrome, chronic kidney disease), or it may merely be a consequence of the increased load of glucose presented to the tubules by the elevated glomerular filtration rate (GFR) during pregnancy. As many as 50% of pregnant women normally have demonstrable sugar in the urine, especially during the third and fourth months. This sugar is practically always glucose except during the late weeks of pregnancy, when lactose may be present.

2. Urine and blood ketones—Qualitative detection of ketone bodies can be accomplished by nitroprusside tests (Acetest or Ketostix). Although these tests do not detect beta-hydroxybutyric acid, which lacks a ketone group, the semiquantitative estimation of ketonuria thus obtained is nonetheless usually adequate for clinical purposes. Many laboratories measure beta-hydroxybutyric acid, and there are meters available (Precision Xtra; Nova Max Plus) for patient use that measures beta-hydroxybutyric acid levels in capillary glucose samples. Beta-hydroxybutyrate levels greater than 0.6 mmol/L require evaluation. Patients with levels greater than 3.0 mmol/L, equivalent to very large urinary ketones, require hospitalization.

3. Plasma or serum glucose—The glucose concentration is 10–15% higher in plasma or serum than in whole blood because structural components of blood cells are absent. A plasma glucose level of 126 mg/dL (7 mmol/L) or higher on more than one occasion after at least 8 hours of fasting is diagnostic of diabetes mellitus (Table 27–4). Fasting plasma glucose levels of 100–125 mg/dL (5.6–6.9 mmol/L) are associated with increased risk of diabetes (impaired fasting glucose tolerance).

Table 27–4. Criteria for the diagnosis of diabetes.

	Normal Glucose Tolerance	Impaired Glucose Tolerance	Diabetes Mellitus[2]
Fasting plasma glucose mg/dL (mmol/L)	< 100 (5.6)	100–125 (5.6–6.9)	≥ 126 (7.0)
Two hours after glucose load[1] mg/dL (mmol/L)	< 140 (7.8)	≥ 140–199 (7.8–11.0)	≥ 200 (11.1)
HbA_{1c} (%)	< 5.7	5.7–6.4	≥ 6.5

[1] Give 75 g of glucose dissolved in 300 mL of water after an overnight fast in persons who have been receiving at least 150–200 g of carbohydrate daily for 3 days before the test.

[2] A fasting plasma glucose ≥ 126 mg/dL (7.0 mmol) or HbA_{1c} of ≥ 6.5% is diagnostic of diabetes if confirmed by repeat testing. A fasting plasma glucose ≥ 126 mg/dL (7.0 mmol) and HbA_{1c} ≥ 6.5% on the *same sample* is also diagnostic of diabetes.

4. Oral glucose tolerance test—If the fasting plasma glucose level is less than 126 mg/dL (7 mmol/L) when diabetes is nonetheless suspected, then a standardized oral glucose tolerance test may be done (Table 27–4). In order to optimize insulin secretion and effectiveness, especially when patients have been on a low-carbohydrate diet, a minimum of 150–200 g of carbohydrate per day should be included in the diet for 3 days preceding the test. The patient should eat nothing after midnight prior to the test day. On the morning of the test, patients are then given 75 g of glucose in 300 mL of water. The glucose load is consumed within 5 minutes. The test should be performed in the morning because there is some diurnal variation in oral glucose tolerance, and patients should not smoke or be active during the test.

Blood samples for plasma glucose are obtained at 0 and 120 minutes after ingestion of glucose. An oral glucose tolerance test is normal if the fasting venous plasma glucose value is less than 100 mg/dL (5.6 mmol/L) and the 2-hour value falls below 140 mg/dL (7.8 mmol/L). A fasting value of 126 mg/dL (7 mmol/L) or higher or a 2-hour value of greater than 200 mg/dL (11.1 mmol/L) is diagnostic of diabetes mellitus. Patients with 2-hour value of 140–199 mg/dL (7.8–11.1 mmol/L) have impaired glucose tolerance. False-positive results may occur in patients who are malnourished, bedridden, or afflicted with an infection or severe emotional stress.

5. Glycated hemoglobin (hemoglobin A1) measurements—Office-based immunoassays for HbA_{1c} using capillary blood give a result in about 9 minutes and this allows for nearly immediate feedback to the patients regarding their glycemic control.

Since HbA_{1c} circulates within red blood cells whose life span lasts up to 120 days, it generally reflects the state of glycemia over the preceding 8–12 weeks, thereby providing an improved method of assessing diabetic control. The HbA_{1c} value, however, is weighted to more recent glucose levels (previous month) and this explains why significant changes in HbA_{1c} are observed with short-term (1 month) changes in mean plasma glucose levels. Measurements should be made in patients with either type of diabetes mellitus at 3- to 4-month intervals. In patients monitoring their own blood glucose levels, HbA_{1c} values provide a valuable check on the accuracy of monitoring. In patients who do not monitor their own blood glucose levels, HbA_{1c} values are essential for adjusting therapy. The A_{1c} Derived Average Glucose Study reported that the relationship between average glucose in the previous 3 months and HbA_{1c} was $(28.7 \times HbA_{1c}) - 46.7$. There is, however, substantial individual variability; for HbA_{1c} values between 6.9% and 7.1%, the glucose levels range from 125 mg/dL to 205 mg/dL (6.9–11.4 mmol/L; 95% CIs). For HbA_{1c} of 6%, the mean glucose levels range from 100 mg/dL to 152 mg/dL (5.5–8.5 mmol/L); and for 8% they range from 147 mg/dL to 217 mg/dL (8.1–12.1 mmol/L). For this reason, caution should be exercised in estimating average glucose levels from measured HbA_{1c}.

The accuracy of HbA_{1c} values can be affected by hemoglobin variants or traits. In patients with high levels of hemoglobin F, immunoassays give falsely low values of HbA_{1c}. The National Glycohemoglobin Standardization Program website (www.ngsp.org) has information on the impact of frequently encountered hemoglobin variants and traits on the results obtained with the commonly used HbA_{1c} assays.

Any condition that shortens erythrocyte survival or decreases mean erythrocyte age (eg, recovery from acute blood loss, hemolytic anemia) will falsely lower HbA_{1c} irrespective of the assay method used. Intravenous iron and erythropoietin therapy for treatment of anemia in chronic kidney disease also falsely lower HbA_{1c} levels. Alternative methods such as fructosamine should be considered for these patients. Vitamins C and E are reported to falsely lower test results possibly by inhibiting glycation of hemoglobin. Conditions that increase erythrocyte survival such as splenectomy for hereditary spherocytosis will falsely raise HbA_{1c} levels. Iron deficiency anemia is also associated with higher HbA_{1c} levels.

HbA_{1c} is endorsed by the ADA as a diagnostic test for type 1 and type 2 diabetes (Table 27–4). A cutoff value of 6.5% (48 mmol/mol) was chosen because the risk for retinopathy increases substantially above this value. The advantages of using the HbA_{1c} to diagnose diabetes is that there is no need to fast; it has lower intraindividual variability than the fasting glucose test and the oral glucose tolerance test; and it provides an estimate of glucose control for the preceding 2–3 months. People with HbA_{1c} levels of 5.7–6.4% (39–46 mmol/mol) should be considered at high risk for developing diabetes (prediabetes). The diagnosis should be confirmed with a repeat HbA_{1c} test, unless the patient is symptomatic with plasma glucose levels greater than 200 mg/dL (11.1 mmol/L). This test is not appropriate to use in populations with high prevalence of hemoglobinopathies or in conditions with increased red cell turnover. Also, the testing is performed using a National Glycohemoglobin Standardization Program (NGSP) certified method and standardized to the Diabetes Control and Complication Trial assay. In the European Union, the tests are standardized to the International Federation of Clinical Chemistry (IFCC), which defines HbA_{1c} as mmol glycated hexapeptide per mol (glycated and nonglycated hexapeptides) and reported as mmol HbA_{1c}/mol Hb. The conversion factor for NGSP and IFCC results is NGSP (USA) result = (0.09148*IFCC result) + 2.152. There is worldwide consensus that HbA_{1c} should be reported in both NGSP (%) and IFCC (mmol/mol) units.

6. Serum fructosamine—Serum fructosamine is formed by nonenzymatic glycosylation of serum proteins (predominantly albumin). Since serum albumin has a much shorter half-life than hemoglobin, serum fructosamine generally reflects the state of glycemic control for only the preceding 1–2 weeks. Reductions in serum albumin (eg, nephrotic state, protein-losing enteropathy, or hepatic disease) will lower the serum fructosamine value. When abnormal hemoglobins or hemolytic states affect the interpretation of glycohemoglobin or when a narrower time frame is required, such as for ascertaining glycemic control at the time of conception in a diabetic woman who has recently become pregnant, serum fructosamine assays offer some advantage. Normal values vary in relation to the serum albumin concentration and are 200–285 mcmol/L when the serum albumin level is 5 g/dL. HbA_{1c} values and serum fructosamine are highly correlated. Serum fructosamine levels of 300, 367, and 430 mcmol/L approximate to HbA_{1c} values of 7%, 8%, and 9%, respectively. Substantial individual variability exists, though, when estimating the likely HbA_{1c} value from the fructosamine measurement.

7. Self-monitoring of blood glucose—Capillary blood glucose measurements performed by patients themselves, as outpatients, are extremely useful. In type 1 patients in whom “tight” metabolic control is attempted, they are indispensable. A large number of blood glucose meters are available. All are accurate, but they vary with regard to speed, convenience, size of blood samples required, reporting capability, and cost. Popular models include those manufactured by LifeScan (One Touch), Bayer Corporation (Breeze, Contour), Roche Diagnostics (Accu-Chek), and Abbott Laboratories (Precision, FreeStyle). These blood glucose meters are relatively inexpensive, ranging from $20 to $80 each. Test strips remain a major expense, costing about $.25 to $1.50 apiece. Each glucose meter also comes with a lancet device and disposable 26- to 33-gauge lancets. Most meters can store from 100 to 1000 glucose values in their memories and have capabilities to download the values into a computer or smartphone. Some meters are designed to communicate with a specific insulin pump. Contour Next Link meter, for example, communicates with the MiniMed Medtronic pump. The accuracy of data obtained by home glucose monitoring does require education of the patient in sampling and measuring procedures as well as in properly calibrating the instruments.

The clinician should be aware of the limitations of the self-monitoring glucose systems. The strips have limited lifespans and improper storage (high temperature; open vial) can affect their function. Patients should also be advised not to use expired strips. Increases or decreases in hematocrit can decrease or increase the measured glucose values. Meters and the test strips are calibrated over the glucose concentrations ranging from 60 mg/dL (3.3 mmol/L) to 160 mg/dL (8.9 mmol/L) and the accuracy is not as good for higher and lower glucose levels. When the glucose is less than 60 mg/dL (3.3 mmol/L), the difference between the meter and the laboratory value may be as much as 20%. Glucose oxidase–based amperometric systems underestimate glucose levels in the presence of high oxygen tension. This may be important in the critically ill who are receiving supplemental oxygen; under these circumstances, a glucose dehydrogenase–based system may be preferable. Glucose-dehydrogenase pyrroloquinoline quinone (GDH-PQQ) systems may report falsely high glucose levels in patients who are receiving parenteral products containing nonglucose sugars such as maltose, galactose, or xylose or their metabolites. Some meters have been approved for measuring glucose in blood samples obtained at alternative sites such as the forearm and thigh. There is, however, a 5- to 20-minute lag in the glucose response on the arm with respect to the glucose response on the finger. Forearm blood glucose measurements could therefore result in a delay in detection of rapidly developing hypoglycemia. Impaired circulation to the fingers (for example, in patients with Raynaud disease) will artificially lower fingerstick glucose measurements (pseudohypoglycemia).

8. Continuous glucose monitoring systems—Increasing number of patients, especially those with type 1 diabetes are using continuous glucose monitoring systems. These systems, manufactured by Medtronic MiniMed, DexCom systems, and Abbott Diagnostics, involve inserting a subcutaneous sensor (rather like an insulin pump cannula) that measures glucose concentrations continuously in the interstitial fluid for 7–14 days. The DexCom and MiniMed systems transmit glucose data wirelessly to smartphones or to the screens of insulin pumps. Directional arrows indicate rate and direction of change of glucose levels, and alerts can be set for dangerously low or high glucose values. The FreeStyle Libre (Abbott Diagnostics) sensor system requires the patient to hold a reading device or a smartphone close to the sensor patch for about a second to see the real time glucose value. The MiniMed system requires calibration with periodic fingerstick glucose levels, which is not necessary for the Dexcom and Freestyle Libre systems. A 6-month randomized controlled study of type 1 patients showed that adults (25 years and older) using these continuous glucose monitoring systems had improved glycemic control without an increase in the incidence of hypoglycemia. A randomized controlled study of continuous glucose monitoring during pregnancy showed improved glycemic control in the third trimester, lower birth weight, and reduced risk of macrosomia. The individual glucose values are not that critical—what matters is the direction and the rate at which the glucose is changing, allowing the user to take corrective action. The wearer also gains insight into the way particular foods and activities affect their glucose levels. The other main benefit is the low glucose alert warning. The MiniMed insulin pump can be programmed to automatically suspend insulin delivery for up to 2 hours when the glucose levels on its continuous glucose monitoring device falls to a preset level and the patient does not respond to the alert. This insulin suspension feature has been shown to reduce the amount of time patients are in the hypoglycemic range at night. Many of these systems are covered by insurance. The initial cost is about $800 to $1000, and the sensor, which has to be changed every 7 to 14 days, costs $35 to $60; the out-of-pocket expense is about $4000 annually.

9. Lipoprotein abnormalities in diabetes—Circulating lipoproteins are just as dependent on insulin as is the plasma glucose. In type 1 diabetes, moderately deficient control of hyperglycemia is associated with only a slight elevation of LDL cholesterol and serum triglycerides and little if any change in HDL cholesterol. Once the hyperglycemia is corrected, lipoprotein levels are generally normal. However, in patients with type 2 diabetes, a distinct “diabetic dyslipidemia” is characteristic of the insulin resistance syndrome. Its features are a high serum triglyceride level (300–400 mg/dL [3.4–4.5 mmol/L]), a low HDL cholesterol (less than 30 mg/dL [0.8 mmol/L]), and a qualitative change in LDL particles, producing a smaller dense particle whose membrane carries supranormal amounts of free cholesterol. These smaller dense LDL particles are more susceptible to oxidation, which renders them more atherogenic. Measures designed to correct the obesity and hyperglycemia, such as exercise, diet, and hypoglycemic therapy, are the treatment of choice for diabetic dyslipidemia, and in occasional patients in whom normal weight was achieved, all features of the lipoprotein abnormalities cleared. Since primary disorders of lipid metabolism may coexist with diabetes, persistence of lipid abnormalities after restoration of normal weight and blood glucose should prompt a diagnostic workup and possible pharmacotherapy of the lipid disorder. Chapter 28 discusses these matters in detail.

Selph S et al. Screening for type 2 diabetes mellitus: a systematic review for the U.S. Preventive Services Task Force. Ann Intern Med. 2015 Jun 2;162(11):765–76. [PMID: 25867111]

Clinical Trials in Diabetes

Findings of the Diabetes Control and Complications Trial and of the United Kingdom Prospective Diabetes Study have confirmed the beneficial effects of improved glycemic control in both type 1 and type 2 diabetes.

The Diabetes Control and Complications Trial (DCCT), a long-term therapeutic study involving 1441 patients with type 1 diabetes mellitus, reported that “near” normalization of blood glucose resulted in a delay in the onset and a major slowing of the progression of established microvascular and neuropathic complications of diabetes during a follow-up period of up to 10 years. Multiple insulin injections (66%) or insulin pumps (34%) were used in the intensively treated group, who were trained to modify their therapy in response to frequent glucose monitoring. The conventionally treated groups used no more than two insulin injections, and clinical well-being was the goal with no attempt to modify management based on HbA_{1c} determinations or the glucose results.

In half of the patients, a mean hemoglobin A_{1c} of 7.2% (normal: less than 6%) and a mean blood glucose of 155 mg/dL (8.6 mmol/L) were achieved using intensive therapy, while in the conventionally treated group HbA_{1c} averaged 8.9% with an average blood glucose of 225 mg/dL (12.5 mmol/L). Over the study period, which averaged 7 years, there was an approximately 60% reduction in risk between the two groups in regard to diabetic retinopathy, nephropathy, and neuropathy. The intensively treated group also had a nonsignificant reduction in the risk of macrovascular disease of 41% (95% CI, –10% to 68%). Intensively treated patients had a threefold greater risk of serious hypoglycemia as well as a greater tendency toward weight gain. However, there were no deaths definitely attributable to hypoglycemia in any persons in the DCCT study, and no evidence of posthypoglycemic cognitive damage was detected.

Subjects participating in the DCCT study were subsequently enrolled in a follow-up observational study, the Epidemiology of Diabetes Interventions and Complications (EDIC) study. Even though the between-group differences in mean HbA_{1c} narrowed over 4 years, the group assigned to intensive therapy had a lower risk of retinopathy at 4 years, microalbuminuria at 7 to 8 years, and impaired GFR (less than 60 mL/min/1.73 m^2) at 22 years of continued study follow-up. Moreover, by the end of the 11-year follow-up period, the intensive therapy group had significantly reduced their risk of any cardiovascular disease events by 42% (95% CI, 9% to 23%; P = 0.02). Thus, it seems that the benefits of good glucose control persist even if control deteriorates at a later date.

The general consensus of the ADA is that intensive insulin therapy associated with comprehensive self-management training should become standard therapy in patients with type 1 diabetes mellitus after the age of puberty. Exceptions include those with advanced chronic kidney disease and older adults since in these groups the detrimental risks of hypoglycemia outweigh the benefits of tight glycemic control.

The United Kingdom Prospective Diabetes Study (UKPDS), a multicenter study, was designed to establish, in type 2 diabetic patients, whether the risk of macrovascular or microvascular complications could be reduced by intensive blood glucose control with oral hypoglycemic agents or insulin and whether any particular therapy was of advantage.

Intensive treatment with either sulfonylureas, metformin, combinations of those two, or insulin achieved mean HbA_{1c} levels of 7%. This level of glycemic control decreased the risk of microvascular complications (retinopathy and nephropathy) in comparison with conventional therapy (mostly diet alone), which achieved mean levels of HbA_{1c} of 7.9%. Weight gain occurred in intensively treated patients except when metformin was used as monotherapy. No adverse cardiovascular outcomes were noted regardless of the therapeutic agent. In the overweight or obese subgroup, metformin therapy was more beneficial than diet alone in reducing the number of cases that progressed to diabetes as well as decreasing the number of patients who suffered myocardial infarctions and strokes. Hypoglycemic reactions occurred in the intensive treatment groups, but only one death from hypoglycemia was documented during 27,000 patient-years of intensive therapy.

Tight control of blood pressure (median value 144/82 mm Hg vs 154/87 mm Hg) substantially reduced the risk of microvascular disease and stroke but not myocardial infarction. In fact, reducing blood pressure by this amount had substantially greater impact on microvascular outcomes than that achieved by lowering HbA_{1c} from 7.9% to 7%. An epidemiologic analysis of the UKPDS data did show that every 10 mm Hg decrease in updated mean systolic blood pressure was associated with 11% reduction in risk for myocardial infarction. More than half of the patients needed two or more medications for adequate therapy of their hypertension, and there was no demonstrable advantage of angiotensin-converting enzyme (ACE) inhibitor therapy over therapy with beta-blockers with regard to diabetes end points. Use of a calcium channel blocker added to both treatment groups appeared to be safe over the long term in this diabetic population despite some controversy in the literature about its safety in patients with diabetes.

Like the DCCT trialists, the UKPDS researchers performed post-trial monitoring to determine whether there were long-term benefits of having been in the intensively treated glucose and blood pressure arms of the study. The intensively treated group had significantly reduced risk of myocardial infarction (15%, P = 0.01) and death from any cause (13%, P = 0.007) during the follow-up period. The subgroup of overweight or obese subjects who were initially randomized to metformin therapy showed sustained reduction in risk of myocardial infarction and death from any cause in the follow-up period. Unlike the sustained benefits seen with glucose control, there were no sustained benefits from having been in the more tightly controlled blood pressure group. Both blood pressure groups were at similar risk for microvascular events and diabetes-related end points during the follow-up period.

Thus, the follow-up of the UKPDS type 2 diabetes cohort showed that, as in type 1 diabetes, the benefits of good glucose control persist even if control deteriorates at a later date. Blood pressure benefits, however, last only as long as the blood pressure is well controlled.

Treatment Regimens

A. Diet

A well-balanced, nutritious diet remains a fundamental element of therapy. There is no specific recommendation on the percentage of calories that should come from carbohydrate, protein, and fat. The macronutrient proportions should be individualized based on the patient's eating patterns, preferences, and metabolic goals. In general, most patients with diabetes consume about 45% of their total daily calories in the form of carbohydrates, 25–35% in the form of fat, and 10–35% in the form of protein. In patients with type 2 diabetes, limiting the carbohydrate intake and substituting some of the calories with monounsaturated fats, such as olive oil, rapeseed (canola) oil, or the oils in nuts and avocados, can lower triglycerides and increase HDL cholesterol. A Mediterranean-style eating pattern (a diet supplemented with walnuts, almonds, hazelnuts, and olive oil) has been shown to improve glycemic control and lower combined endpoints for cardiovascular events and stroke. In those patients with obesity and type 2 diabetes, weight reduction by caloric restriction is an important goal of the diet (see Chapter 29). Patients with type 1 diabetes or type 2 diabetes who take insulin should be taught "carbohydrate counting," so they can administer their insulin bolus for each meal based on its carbohydrate content.

The current recommendations for saturated fats and dietary cholesterol intake for people with diabetes are the same as for the general population. Saturated fats should be limited to less than 10% of daily calories and dietary cholesterol intake should be less than 300 mg/day. For those patients with kidney disease, dietary protein should be maintained at the recommended daily allowance of 0.8 g/kg/day. Exchange lists for meal planning can be obtained from the American Diabetes Association and its affiliate associations or from the American Dietetic Association (http://www.eatright.org), 216 W. Jackson Blvd., Chicago, IL 60606 (312-899-0040).

1. Dietary fiber—Plant components such as cellulose, gum, and pectin are indigestible by humans and are termed dietary “fiber.” Insoluble fibers such as cellulose or hemicellulose, as found in bran, tend to increase intestinal transit and may have beneficial effects on colonic function. In contrast, soluble fibers such as gums and pectins, as found in beans, oatmeal, or apple skin, tend to retard nutrient absorption rates so that glucose absorption is slower and hyperglycemia may be slightly diminished. Although its recommendations do not include insoluble fiber supplements such as added bran, the ADA recommends food such as oatmeal, cereals, and beans with relatively high soluble fiber content as staple components of the diet in diabetics. High soluble fiber content in the diet may also have a favorable effect on blood cholesterol levels.

2. Glycemic index—The glycemic index of a carbohydrate containing food is determined by comparing the glucose excursions after consuming 50 g of test food with glucose excursions after consuming 50 g of reference food (white bread):

$$\text{Glycemic index} = \frac{\text{Blood glucose area under the curve (3h) for test food}}{\text{Blood glucose area under the curve (3h) for reference food}} \times 100$$

Eating low glycemic index foods results in lower glucose levels after meals. Low glycemic index foods have values of 55 or less and include many fruits, vegetables, grainy breads, pasta, and legumes. High glycemic index foods have values of 70 or greater and include baked potato, white bread, and white rice. Glycemic index is lowered by presence of fats and protein when food is consumed in a mixed meal. Even though it may not be possible to accurately predict the glycemic index of a particular food in the context of a meal, it is reasonable to choose foods with low glycemic index.

3. Artificial and other sweeteners—Saccharin (Sweet N Low), sucralose (Splenda), acesulfame potassium (Sweet One), and rebiana (Truvia) are “artificial” sweeteners that can be used in cooking and baking. Aspartame (NutraSweet) lacks heat stability, so it cannot be used in cooking. None of these sweeteners raise blood glucose levels.

Fructose represents a “natural” sugar substance that is a highly effective sweetener, induces only slight increases in plasma glucose levels, and does not require insulin for its metabolism. However, because of potential adverse effects of large amounts of fructose on raising serum cholesterol, triglycerides, and LDL cholesterol, it does not have any advantage as a sweetening agent in the diabetic diet. This does not preclude, however, ingestion of fructose-containing fruits and vegetables or fructose-sweetened foods in moderation.

Sugar alcohols, also known as polyols or polyalcohol, are commonly used as sweeteners and bulking agents. They occur naturally in a variety of fruits and vegetables but are also commercially made from sucrose, glucose, and starch. Examples are sorbitol, xylitol, mannitol, lactitol, isomalt, maltitol, and hydrogenated starch hydrolysates (HSH). They are not as easily absorbed as sugar, so they do not raise blood glucose levels as much. Therefore, sugar alcohols are often used in food products that are labeled as "sugar free," such as chewing gum, lozenges, hard candy, and sugar-free ice cream. However, if consumed in large quantities, they will raise blood glucose and can cause bloating and diarrhea.

B. Medications for Treating Hyperglycemia

The medications for treating type 2 diabetes are listed in Table 27–5.

Table 27–5. Drugs for treatment of type 2 diabetes mellitus.

Drug	Tablet Size	Daily Dose	Duration of Action
Sulfonylureas			
Acetohexamide (Dymelor) (not available in United States)	250 and 500 mg	0.25–1.5 g as single dose or in two divided doses	8–24 hours
Chlorpropamide (Diabinese)	100 and 250 mg	0.1–0.5 g as single dose	24–72 hours
Gliclazide (not available in United States)	80 mg	40–80 mg as single dose; 160–320 mg as divided dose	12 hours
Glimepiride (Amaryl)	1, 2, and 4 mg	1–4 mg once a day is usual dose; 8 mg once a day is maximal dose	Up to 24 hours
Glipizide			
(Glucotrol)	5 and 10 mg	2.5–40 mg as a single dose or in two divided doses 30 minutes before meals	6–12 hours
(Glucotrol XL)	2.5, 5, and 10 mg	2.5 to 10 mg once a day is usual dose; 20 mg once a day is maximal dose	Up to 24 hours
Glyburide			
(Dia Beta, Micronase)	1.25, 2.5, and 5 mg	1.25–20 mg as single dose or in two divided doses	Up to 24 hours
(Glynase)	1.5, 3, and 6 mg	1.5–12 mg as single dose or in two divided doses	Up to 24 hours
Tolazamide (Tolinase)	100, 250, and 500 mg	0.1–1 g as single dose or in two divided doses	Up to 24 hours
Tolbutamide (Orinase)	250 and 500 mg	0.5–2 g in two or three divided doses	6–24 hours
Meglitinide Analogs			
Mitiglinide (available in Japan)	5 and 10 mg	5 or 10 mg three times a day before meals	2 hours
Repaglinide (Prandin)	0.5, 1, and 2 mg	0.5 to 4 mg three times a day before meals	3 hours
D-Phenylalanine Derivative			
Nateglinide (Starlix)	60 and 120 mg	60 or 120 mg three times a day before meals	4 hours
Biguanides			
Metformin (Glucophage)	500, 850, and 1000 mg	1–2.5 g; 1 tablet with meals two or three times daily	4 hours
Metformin, extended release (Glucophage XR)	500, 750, and 1000 mg	500–2000 mg once a day	Up to 24 hours
Thiazolidinediones			
Pioglitazone (Actos)	15, 30, and 45 mg	15–45 mg daily	Up to 24 hours
Rosiglitazone (Avandia)	2, 4, and 8 mg	4–8 mg daily (can be divided)	Up to 24 hours
Alpha-Glucosidase Inhibitors			
Acarbose (Precose)	25, 50, and 100 mg	25–100 mg three times a day just before meals	4 hours
Miglitol (Glyset)	25, 50, and 100 mg	25–100 mg three times a day just before meals	4 hours
Voglibose (not available in United States)	0.2 and 0.3 mg	0.2–0.3 mg three times a day just before meals	4 hours
GLP-1 Receptor Agonists			
Dulaglutide (Trulicity)	0.75-, 1.5-mg single-dose pen or prefilled syringe	0.75 mg subcutaneously once weekly. Dose can be increased to 1.5 mg if necessary.	1 week
Exenatide (Byetta)	1.2 mL and 2.4 mL prefilled pens delivering 5 mcg and 10 mcg doses	5 mcg subcutaneously twice a day within 1 hour of breakfast and dinner. Increase to 10 mcg subcutaneously twice a day after about a month **AVOID** if CrCl < 30 mL/min	6 hours
Exenatide, long-acting release (Byetta LAR, Bydureon)	2 mg (powder)	Suspend in provided diluent and inject subcutaneously.	1 week
Liraglutide (Victoza)	Prefilled, multi-dose pen that delivers doses of 0.6 mg, 1.2 mg, or 1.8 mg	0.6 mg subcutaneously once a day (starting dose). Increase to 1.2 mg after a week if no adverse reactions. Dose can be further increased to 1.8 mg, if necessary.	24 hours

Lixisenatide (Adlyxin, Lyxumia)	3-mL prefilled pens delivering 10- or 20-mcg doses	10 mcg daily. Increase to 20 mcg daily after 2 weeks.	24 hours
Semaglutide (Ozempic)	Prefilled pens delivering 0.25 mg or 0.5 mg; and 1 mg	0.25 mg weekly for 1 month and increase to 0.5 mg weekly if no adverse reactions. Dose can be further increased to 1 mg weekly	1 week
DPP-4 Inhibitors			
Alogliptin (Nesina)	6.25, 12.5, and 25 mg	25 mg once daily; CrCl 30–59 mL/min: 12.5 mg daily; CrCl < 30 mL/min: 6.25 mg daily.	24 hours
Linagliptin (Tradjenta)	5 mg	5 mg daily	24 hours
Saxagliptin (Onglyza)	2.5 and 5 mg	2.5 mg or 5 mg once daily. CrCl ≤ 50 mL/min or if also taking drugs that are strong CYP3A4/5 inhibitors such as ketoconazole: 2.5 mg daily.	24 hours
Sitagliptin (Januvia)	25, 50, and 100 mg	100 mg once daily; CrCl 30–50 mL/min: 50 mg once daily; CrCl < 30 mL/min: 25 mg once daily	24 hours
Vildagliptin (Galvus) (not available in United States)	50 mg	50 mg once or twice daily. **AVOID** if CrCl ≤ 60 mL/min or AST/ALT three times upper limit of normal	24 hours
SGLT2 Inhibitors			
Canagliflozin (Invokana)	100 and 300 mg	100 mg daily is usual dose. 300-mg dose can be used if normal eGFR, resulting in lowering the HbA_{1c} an additional ~ 0.1–0.25%. **AVOID** if eGFR < 45 mL/min/1.72 m^2.	24 hours
Dapagliflozin (Farxiga)	5 and 10 mg	10 mg daily.	24 hours
Empagliflozin (Jardiance)	10 and 25 mg	10 mg daily. 25-mg dose can be used if necessary.	24 hours
Ertugliflozin (Steglatro)	5 and 15 mg	5 mg daily. 15 mg dose can be used if necessary	24 hours
Others			
Bromocriptine (Cycloset)	0.8 mg	0.8 mg daily. Increase weekly by 1 tablet until maximal tolerated dose of 1.6–4.8 mg daily.	24 hours
Colesevelam (Welchol)	625 mg	3 tablets twice a day	24 hours
Pramlintide (Symlin)	5-mL vial containing 0.6 mg/mL; also available as prefilled pens. Symlin pen 60 or Symlin pen 120 (subcutaneous injection)	For insulin-treated type 2 patients, start at 60-mcg dose three times a day (10 units on U100 insulin syringe). Increase to 120 mcg three times a day (20 units on U100 insulin syringe) if no nausea for 3–7 days. Give immediately before meal. For type 1 patients, start at 15 mcg three times a day (2.5 units on U100 insulin syringe) and increase by increments of 15 mcg to a maximum of 60 mcg three times a day, as tolerated. To avoid hypoglycemia, lower insulin dose by 50% on initiation of therapy.	2 hours

AST/ALT, aspartate aminotransferase/alanine aminotransferase; CrCl, creatinine clearance by estimated glomerular filtration rate.

1. Medications that primarily stimulate insulin secretion by binding to the sulfonylurea receptor on the beta cell—

A. SULFONYLUREAS—The primary mechanism of action of the sulfonylureas is to stimulate insulin release from pancreatic B cells.

Sulfonylureas are used in patients with type 2 but not type 1 diabetes, since these medications require functioning pancreatic B cells to produce their effect on blood glucose. Sulfonylureas are metabolized by the liver and apart from acetohexamide, whose metabolite is more active than the parent compound, the metabolites of all the other sulfonylureas are weakly active or inactive. The metabolites are excreted by the kidney and, in the case of the second-generation sulfonylureas, partly excreted in the bile.

Hypoglycemia is a common adverse reaction with the sulfonylureas. Weight gain is also common, especially in the first year of use. The mechanisms of the weight gain include improved glucose control and increased food intake in response to hypoglycemia.

Idiosyncratic reactions are rare, with skin rashes or hematologic toxicity (leukopenia, thrombocytopenia) occurring in less than 0.1% of users.

(1) First-generation oral sulfonylureas (tolbutamide, tolazamide, acetohexamide, chlorpropamide)—Tolbutamide is probably best administered in divided doses (eg, 500 mg before each meal and at bedtime); however, some patients require only one or two tablets daily with a maximum dose of 3000 mg/day. Tolbutamide has a relatively short duration of effect (about 6–10 hours). Because of its short duration of action, which is independent of kidney function, tolbutamide is relatively safe to use in kidney disease. Prolonged hypoglycemia has been reported rarely with tolbutamide, mostly in patients receiving antibacterial sulfonamides (sulfisoxazole), phenylbutazone for arthralgias, or the oral azole antifungal medications to treat candidiasis. These medications apparently compete with tolbutamide for oxidative enzyme systems in the liver, resulting in maintenance of high levels of unmetabolized, active sulfonylurea in the circulation.

Tolazamide, acetohexamide, and chlorpropamide are rarely used. Chlorpropamide has a prolonged biologic effect, and severe hypoglycemia can occur especially in older adults as their renal clearance declines with aging. Its other side effects include alcohol-induced flushing and hyponatremia due to its effect on vasopressin secretion and action.

(2) Second-generation sulfonylureas (glyburide, glipizide, gliclazide, glimepiride)—Glyburide, glipizide, gliclazide, and glimepiride are 100–200 times more potent than tolbutamide. These medications should be used with caution in patients with cardiovascular disease or in elderly patients, in whom prolonged hypoglycemia would be especially dangerous.

The usual starting dose of glyburide is 2.5 mg/day, and the average maintenance dose is 5–10 mg/day given as a single morning dose; maintenance doses higher than 20 mg/day are not recommended. Some reports suggest that 10 mg is a maximum daily therapeutic dose, with 15–20 mg having no additional benefit in poor responders and doses over 20 mg actually worsening hyperglycemia. A “Press Tab” formulation of “micronized” glyburide—easy to divide in half with slight pressure if necessary—is available. Glyburide is metabolized in the liver and the metabolic products of glyburide have hypoglycemic activity.

Glyburide has few adverse effects other than its potential for causing hypoglycemia, which at times can be prolonged. Flushing has rarely been reported after ethanol ingestion. It does not cause water retention, as chlorpropamide does, but rather slightly enhances free water clearance. Glyburide should not be used in patients with liver failure and chronic kidney disease because of the risk of hypoglycemia. Elderly patients are at particular risk for hypoglycemia even with relatively small daily doses.

The recommended starting dose of glipizide is 5 mg/day, with up to 15 mg/day given as a single daily dose before breakfast. When higher daily doses are required, they should be divided and given before meals. The maximum dose recommended by the manufacturer is 40 mg/d, although doses above 10–15 mg probably provide little additional benefit in poor responders and may even be less effective than smaller doses. For maximum effect in reducing postprandial hyperglycemia, glipizide should be ingested 30 minutes before meals, since rapid absorption is delayed when the medication is taken with food.

At least 90% of glipizide is metabolized in the liver to inactive products, and 10% is excreted unchanged in the urine. Glipizide therapy should therefore not be used in patients with liver failure. Because of its lower potency and shorter duration of action, it is preferable to glyburide in elderly patients and for those patients with kidney disease. Glucotrol-XL provides extended release of glipizide during transit through the gastrointestinal tract with greater effectiveness in lowering prebreakfast hyperglycemia than the shorter-duration immediate-release standard glipizide tablets. However, this formulation appears to have sacrificed its lower propensity for severe hypoglycemia compared with longer-acting glyburide without showing any demonstrable therapeutic advantages over glyburide.

Gliclazide (not available in the United States) is another intermediate duration sulfonylurea with a duration of action of about 12 hours. The recommended starting dose is 40–80 mg/day with a maximum dose of 320 mg. Doses of 160 mg and above are given as divided doses before breakfast and dinner. The medication is metabolized by the liver; the metabolites and conjugates have no hypoglycemic effect. An extended release preparation is available.

Glimepiride has a long duration of effect with a half-life of 5 hours allowing once or twice daily dosing. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound. A single daily dose of 1 mg/day has been shown to be effective, and the maximal recommended dose is 8 mg. It is completely metabolized by the liver to relatively inactive metabolic products.

B. MEGLITINIDE ANALOGS—Repaglinide is structurally similar to glyburide but lacks the sulfonic acid-urea moiety. It acts by binding to the sulfonylurea receptor and closing the adenosine triphosphate (ATP)-sensitive potassium channel. It is rapidly absorbed from the intestine and then undergoes complete metabolism in the liver to inactive biliary products, giving it a plasma half-life of less than 1 hour. The medication therefore causes a brief but rapid pulse of insulin. The starting dose is 0.5 mg three times a day 15 minutes before each meal. The dose can be titrated to a maximum daily dose of 16 mg. Like the sulfonylureas, repaglinide can be used in combination with metformin. Hypoglycemia is the main side effect. Like the sulfonylureas, repaglinide causes weight gain. Metabolism is by cytochrome P450 3A4 isoenzyme, and other medications that induce or inhibit this isoenzyme may increase or inhibit (respectively) the metabolism of repaglinide. The medication may be useful in patients with kidney impairment or in older adults.

Mitiglinide is a benzylsuccinic acid derivative that binds to the sulfonylurea receptor and is similar to repaglinide in its clinical effects. It is approved for use in Japan.

C. D-PHENYLALANINE DERIVATIVE—Nateglinide stimulates insulin secretion by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. It is rapidly absorbed from the intestine, reaching peak plasma levels within 1 hour. It is metabolized in the liver and has a plasma half-life of about 1.5 hours. Like repaglinide, it causes a brief rapid pulse of insulin, and when given before a meal it reduces the postprandial rise in blood glucose. For most patients, the recommended starting and maintenance dose is 120 mg three times a day before meals. Use 60 mg in patients who have mild elevations in HbA_{1c}. Like the other insulin secretagogues, its main side effects are hypoglycemia and weight gain.

2. Medications that primarily lower glucose levels by their actions on the liver, muscle, and adipose tissue—

A. METFORMIN—Metformin is the first-line therapy for patients with type 2 diabetes. It can be used alone or in conjunction with other oral agents or insulin in the treatment of patients with type 2 diabetes. It is ineffective in patients with type 1 diabetes.

Metformin's therapeutic effects primarily derive from the increasing hepatic adenosine monophosphate-activated protein kinase activity, which reduces hepatic gluconeogenesis and lipogenesis. Metformin has a half-life of 1.5–3 hours and is not bound to plasma proteins or metabolized, being excreted unchanged by the kidneys.

The current recommendation is to start metformin at diagnosis. A side benefit of metformin therapy is its tendency to improve both fasting and postprandial hyperglycemia and hypertriglyceridemia in obese patients with diabetes without the weight gain associated with insulin or sulfonylurea therapy. Patients with chronic kidney disease should not be given this medication because failure to excrete it would produce high blood and tissue levels of metformin that could stimulate lactic acid overproduction. In the United States, metformin use is not recommended at or above a serum creatinine level of 1.4 mg/dL in women and 1.5 mg/dL in men. In the United Kingdom, the recommendations are to review metformin use when the serum creatinine exceeds 130 mcmol/L (1.5 mg/dL) or the estimated glomerular filtration rate (eGFR) falls below 45 mL/min/1.73 m^2. The medication should be stopped if the serum creatinine exceeds 150 mcmol/L (1.7 mg/dL) or the eGFR is below 30 mL/min/1.73 m^2. Patients with liver failure or persons with excessive alcohol intake should not receive this medication because of the risk of lactic acidosis.

The maximum dosage of metformin is 2550 mg, although little benefit is seen above a total dose of 2000 mg. It is important to begin with a low dose and increase the dosage very gradually in divided doses—taken with meals—to reduce minor gastrointestinal upsets. A common schedule would be one 500-mg tablet three times a day with meals or one 850- or 1000-mg tablet twice daily at breakfast and dinner. Up to 2000 mg of the extended-release preparation can be given once a day. Lower doses should be used in patients with eGFRs between 30 and 45 mL/min/1.73 m^2. Lower doses should also be used in the elderly who have reduced renal functional reserve and are at higher risk for acute kidney injury.

The most frequent side effects of metformin are gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal discomfort, diarrhea), which occur in up to 20% of patients. These effects are dose-related, tend to occur at onset of therapy, and often are transient. However, in 3–5% of patients, therapy may have to be discontinued because of persistent diarrheal discomfort. Patients switching from immediate-release metformin to comparable dose of extended-release metformin may experience fewer gastrointestinal side effects.

Hypoglycemia does not occur with therapeutic doses of metformin, which permits its description as a “euglycemic” or “antihyperglycemic” medication rather than an oral hypoglycemic agent. Dermatologic or hematologic toxicity is rare. Metformin interferes with the calcium dependent absorption of vitamin B_{12}-intrinsic complex in the terminal ileum; vitamin B_{12} deficiency can occur after many years of metformin use. Periodic screening with vitamin B_{12} levels should be considered, especially in patients with peripheral neuropathy or if a macrocytic anemia develops. Increased intake of dietary calcium may prevent the metformin-induced B_{12} malaborption.

Lactic acidosis has been reported as a side effect but is uncommon with metformin in contrast to phenformin. Almost all reported cases have involved persons with associated risk factors that should have contraindicated its use (kidney, liver, or cardiorespiratory insufficiency and alcoholism). Acute kidney injury can occur rarely in certain patients receiving radiocontrast agents. Metformin therapy should therefore be temporarily halted on the day of radiocontrast administration and restarted a day or two later after confirmation that kidney function has not deteriorated.

B. THIAZOLIDINEDIONES—Two medications of this class, rosiglitazone and pioglitazone, are available for clinical use. These medications sensitize peripheral tissues to insulin. They bind the nuclear receptor peroxisome proliferator-activated receptor gamma (PPAR-gamma) and affect the expression of a number of genes. Like the biguanides, this class of medications does not cause hypoglycemia.

Both rosiglitazone and pioglitazone are effective as monotherapy and in combination with sulfonylureas or metformin or insulin, lowering HbA_{1c} by 1–2%. When used in combination with insulin, they can result in a 30–50% reduction in insulin dosage, and some patients can come off insulin completely. The dosage of rosiglitazone is 4–8 mg daily and of pioglitazone, 15–45 mg daily, and the medications do not have to be taken with food. Rosiglitazone is primarily metabolized by the CYP 2C8 isoenzyme and pioglitazone is metabolized by CYP 2C8 and CYP 3A4.

The combination of a thiazolidinedione and metformin has the advantage of not causing hypoglycemia. Patients inadequately managed on sulfonylureas can do well on a combination of sulfonylurea and rosiglitazone or pioglitazone.

These medications have some additional effects apart from glucose lowering. Rosiglitazone therapy is associated with increases in total cholesterol, LDL cholesterol (15%), and HDL cholesterol (10%). There is a reduction in free fatty acids of about 8–15%. The changes in triglycerides are generally not different from placebo. Pioglitazone in clinical trials lowered triglycerides (9%) and increased HDL cholesterol (15%) but did not cause a consistent change in total cholesterol and LDL cholesterol levels. A prospective randomized comparison of the metabolic effects of pioglitazone and rosiglitazone showed similar effects on HbA_{1c} and weight gain. Small prospective studies have demonstrated that treatment with these medications leads to improvements in the biochemical and histologic features of nonalcoholic fatty liver disease. The thiazolidinediones also may limit vascular smooth muscle proliferation after injury, and there are reports that pioglitazone can reduce neointimal proliferation after coronary stent placement. In one double-blind, placebo-controlled study, rosiglitazone was shown to be associated with a decrease in the ratio of urinary albumin to creatinine excretion.

Safety concerns and some troublesome side effects limit the use of this class of medication. Rosiglitazone use declined when a meta-analysis of 42 randomized clinical trials suggested that this medication increases the risk of angina pectoris or myocardial infarction; the European Medicines Agency suspended the use of rosiglitazone in Europe. In the United States, the FDA established a restricted distribution program. A subsequent large prospective clinical trial (the RECORD study) failed to confirm the meta-analysis finding and the restrictions were lifted in the United States.

Edema occurs in about 3–4% of patients receiving monotherapy with rosiglitazone or pioglitazone. The edema occurs more frequently (10–15%) in patients receiving concomitant insulin therapy and may result in heart failure. The medications are contraindicated in diabetic individuals with New York Heart Association class III and IV cardiac status. Thiazolidinediones have also been reported as being associated with new onset or worsening macular edema. Apparently, this is a rare side effect, and most of these patients also had peripheral edema. The macular edema resolved or improved once the medication was discontinued.

Troglitazone, the first medication in this class, was withdrawn from clinical use because of medication-associated fatal liver failure. Although rosiglitazone and pioglitazone have not been reported to cause liver injury, the FDA recommends that they should not be used in patients with clinical evidence of active liver disease or pretreatment elevation of the alanine aminotransferase (ALT) level that is 2.5 times greater than the upper limit of normal. Liver biochemical tests should be performed on all patients prior to initiation of treatment and periodically thereafter.

An increase in fracture risk in women (but not men) has been reported with both rosiglitazone and pioglitazone. The fracture risk is in the range of 1.9 per 100 patient-years with the thiazolidinedione compared to 1.1 per 100 patient-years on comparison treatment. In at least one study of rosiglitazone, the fracture risk was increased in premenopausal as well as postmenopausal women.

Other side effects include anemia, which occurs in 4% of patients treated with these medications; it may be due to a dilutional effect of increased plasma volume rather than a reduction in red cell mass. Weight gain occurs, especially when the medication is combined with a sulfonylurea or insulin. Some of the weight gain is fluid retention, but there is also an increase in total fat mass. Clinical studies have reported conflicting results regarding an association of bladder cancer with pioglitazone use. A 10-year observational cohort study of patients taking pioglitazone failed to find an association with bladder cancer. A large multipopulation pooled analysis (1.01 million persons over 5.9 million person-years) also failed to find an association between cumulative exposure of pioglitazone or rosiglitazone and incidence of bladder cancer. Another population-based study, however, generating 689,616 person-years of follow-up did find that pioglitazone but not rosiglitazone was associated with an increased risk of bladder cancer.

3. Medications that affect absorption of glucose—Alpha-glucosidase inhibitors competitively inhibit the alpha-glucosidase enzymes in the gut that digest dietary starch and sucrose. Two of these medications—acarbose and miglitol—are available for clinical use in the United States. Voglibose, another alpha-glucosidase inhibitor is available in Japan, Korea, and India. Acarbose and miglitol are potent inhibitors of glucoamylase, alpha-amylase, and sucrase but have less effect on isomaltase and hardly any on trehalase and lactase.

A. ACARBOSE—The recommended starting dose of acarbose is 50 mg twice daily, gradually increasing to 100 mg three times daily. For maximal benefit on postprandial hyperglycemia, acarbose should be given with the first mouthful of food ingested. In diabetic patients, it reduces postprandial hyperglycemia by 30–50%, and its overall effect is to lower the HbA_{1c} by 0.5–1%.

The principal adverse effect, seen in 20–30% of patients, is flatulence. This is caused by undigested carbohydrate reaching the lower bowel, where gases are produced by bacterial flora. In 3% of cases, troublesome diarrhea occurs. This gastrointestinal discomfort tends to discourage excessive carbohydrate consumption and promotes improved compliance of type 2 patients with their diet prescriptions. When acarbose is given alone, there is no risk of hypoglycemia. However, if combined with insulin or sulfonylureas, it might increase the risk of hypoglycemia from these agents. A slight rise in hepatic aminotransferases has been noted in clinical trials with acarbose (5% vs 2% in placebo controls, and particularly with doses greater than 300 mg/day). The levels generally return to normal on stopping the medication.

B. MIGLITOL—Miglitol is similar to acarbose in terms of its clinical effects. It is indicated for use in diet- or sulfonylurea-treated patients with type 2 diabetes. Therapy is initiated at the lowest effective dosage of 25 mg three times a day. The usual maintenance dose is 50 mg three times a day, although some patients may benefit from increasing the dose to 100 mg three times a day. Gastrointestinal side effects occur as with acarbose. The medication is not metabolized and is excreted unchanged by the kidney. Miglitol should not be used in end-stage chronic kidney disease, when its clearance would be impaired.

4. Incretins—Oral glucose provokes a threefold to fourfold higher insulin response than an equivalent dose of glucose given intravenously. This is because the oral glucose causes a release of gut hormones, principally glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP1), that amplify the glucose-induced insulin release. This "incretin effect" of GLP-1 secretion (but not GIP1 secretion) is reduced in patients with type 2 diabetes and when GLP-1 is infused in patients with type 2 diabetes, it stimulates insulin secretion and lowers glucose levels. GLP-1, unlike the sulfonylureas, has only a modest insulin stimulatory effect at normoglycemic concentrations. This means that GLP-1 has a lower risk for hypoglycemia than the sulfonylureas.

In addition to its insulin stimulatory effect, GLP-1 also has a number of other pancreatic and extrapancreatic effects. It suppresses glucagon secretion and so may ameliorate the hyperglucagonemia that is present in people with diabetes and improve postprandial hyperglycemia. GLP-1 acts on the stomach delaying gastric emptying; the importance of this effect on glucose lowering is illustrated by the observation that antagonizing the deceleration of gastric emptying markedly reduces the glucose lowering effect of GLP-1. GLP-1 receptors are present in the central nervous system and may play a role in the anorectic effect of the drugs. Type 2 diabetic patients undergoing GLP-1 infusion are less hungry; it is unclear whether this is mainly due to a deceleration of gastric emptying or whether there is a central nervous system effect as well.

A. GLP-1 RECEPTOR AGONISTS—GLP-1’s half-life is only 1–2 minutes. It is rapidly proteolyzed by dipeptidyl peptidase 4 (DPP-4) and by other enzymes, such as endopeptidase 24.11, and is also cleared quickly by the kidney. The native peptide, therefore, cannot be used therapeutically. Five GLP-1 receptor agonists with longer half-lives, exenatide, liraglutide, dulaglutide, lixisenatide, and semaglutide, are available for clinical use.

(1) Dosages and pharmacokinetics—Exenatide (Exendin 4) is a GLP-1 receptor agonist isolated from the saliva of the Gila monster (a venomous lizard) that is more resistant to DPP-4 action and cleared by the kidney. Its half-life is 2.4 hours, and its glucose lowering effect is about 6 hours. Exenatide is dispensed as two fixed-dose pens (5 mcg and 10 mcg). It is injected 60 minutes before breakfast and before dinner. Patients with type 2 diabetes should be prescribed the 5 mcg pen for the first month and, if tolerated, the dose can then be increased to 10 mcg twice a day. The medication is not recommended in patients with eGFR less than 30 mL/min. In clinical trials, adding exenatide therapy to patients with type 2 diabetes already taking metformin or a sulfonylurea, or both, further lowered the HbA_{1c} value by 0.4% to 0.6% over a 30-week period. These patients also experienced a weight loss of 3–6 pounds. Exenatide LAR is a once-weekly preparation that is dispensed as a powder (2 mg). It is suspended in the provided diluent just prior to injection. In comparative clinical trials, the long-acting drug lowers the HbA_{1c} level a little more than the twice daily drug. Low-titer antibodies against exenatide develop in over one-third (38%) of patients, but the clinical effects are not attenuated. High-titer antibodies develop in a subset of patients (~6%), and in about half of these cases, an attenuation of glycemic response has been seen.

Liraglutide is a soluble fatty acid acylated GLP-1 analog. The half-life is approximately 12 hours, allowing the medication to be injected once a day. The dosing is initiated at 0.6 mg daily, increased after 1 week to 1.2 mg daily. Some patients may benefit from increasing the dose to 1.8 mg. In clinical trials lasting 26 and 52 weeks, adding liraglutide to the therapeutic regimen (metformin, sulfonylurea, thiazolidinedione) of patients with type 2 diabetes further lowered the HbA_{1c} value. Depending on the dose and design of the study, the HbA_{1c} decline was in the range of 0.6% to 1.5%. The patients had sustained weight loss of 1–6 pounds. Liraglutide at a dose of 3 mg daily has been approved for weight loss.

In a postmarketing multinational study of 9340 patients with type 2 diabetes with known cardiovascular disease, the addition of liraglutide was associated with a lower primary composite outcome of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke (hazard ratio 0.87, $P = 0.01$). Patients taking liraglutide had lower HbA_{1c} levels, weight loss of 2.3 kg, lower systolic blood pressure, and fewer episodes of severe hypoglycemia.

Dulaglutide consists of two GLP-1 analog molecules covalently linked to an Fc fragment of human IgG_4. The GLP-1 molecule has amino acid substitutions that resist DPP-4 action. The half-life of dulaglutide is about 5 days. The usual dose is 0.75 mg weekly by subcutaneous injection. The maximum recommended dose is 1.5 mg weekly. Dulaglutide monotherapy and combination therapy lowers HbA_{1c} by about 0.7% to 1.6%. Weight loss ranged from 2 pounds to 7 pounds.

Lixisenatide is a synthetic analog of exendin 4 (deletion of a proline and addition of 6 lysines to the C-terminal region) with a half-life of 3 hours. It is dispensed as two fixed-dose pens (10 mcg and 20 mcg). The 10-mcg dose is injected once daily before breakfast for the first 2 weeks, and if tolerated, the dose is then increased to 20 mcg daily. Its clinical effect is about the same as exenatide with HbA_{1c} lowering in the 0.4–0.6% range. Weight loss ranges from 2 pounds to 6 pounds. Antibodies to lixisenatide occur frequently (70%) and ~ 2.4% with the highest antibody titers have attenuated glycemic response.

Semaglutide is a synthetic analog of GLP-1 with a drug half-life of about 1 week. It has an alpha-aminoisobutyric acid substitution at position 8 that makes the molecule resistant to DPP4 action and a C-18 fatty di-acid chain attached to lysine at position 26 that binds to albumin, which accounts for the drug’s long half-life. Semaglutide is dispensed as two pens: one pen delivers a 0.25-mg or 0.5-mg dose and the other pen delivers a 1-mg dose. The recommended dosing is 0.25 mg weekly for 4 weeks and if tolerated the dose is then increased to 0.5 mg per week. The 1-mg per week dose can provide additional glucose lowering effect. Semaglutide monotherapy and combination therapy lowers HbA_{1c} from 1.5% to 1.8%. An increase in diabetic retinopathy was observed in the semaglutide treated group in one of the clinical trials. It is thought that this might have been secondary to the rapid glucose lowering with the drug.

(2) Adverse effects of GLP-1 receptor agonists—The most frequent adverse reactions of the GLP-1 receptor agonists are nausea (11–40%), vomiting (4–13%), and diarrhea (9–17%). The reactions are more frequent at the higher doses. In clinical trials about 1–5% of participants withdrew from the studies because of the gastrointestinal symptoms.

The GLP-1 receptor agonists have been associated with increased risk of pancreatitis. The pancreatitis was severe (hemorrhagic or necrotizing) in 6 instances, and 2 of these patients died. In the liraglutide and dulaglutide clinical trials, there were 13 and 5 cases of pancreatitis in the drug-treated groups versus 1 and 1 case in the comparator groups, respectively. This translates to about 1.4–2.2 vs 0.6–0.9 cases of pancreatitis per 1000 patient-years. Patients taking GLP-1 receptor agonists should be advised to seek immediate medical care if they experience unexplained persistent severe abdominal pain.

There have been rare reports of acute kidney injury in patients taking exenatide. Some of these patients had preexisting kidney disease, and others had one or more risk factors for kidney disease. A number of the patients reported nausea, vomiting, and diarrhea, and it is possible that these side effects caused volume depletion and contributed to the development of the kidney injury. For this reason, the GLP-1 receptors agonists should be prescribed cautiously in patients with kidney impairment.

GLP-1 receptor agonists stimulate C-cell neoplasia and cause medullary thyroid carcinoma in rats. Human C-cells express very few GLP-1 receptors, and the relevance to human therapy is unclear. The medications, however, should not be used in patients with personal or family history of medullary thyroid carcinoma or multiple endocrine neoplasia (MEN) syndrome type 2.

B. DPP-4 INHIBITORS—An alternate approach to the use of GLP-1 receptor agonists is to inhibit the enzyme DPP-4 and prolong the action of endogenously released GLP-1 and GIP. Four oral DPP-4 inhibitors, sitagliptin, saxagliptin, linagliptin, and alogliptin, are available in the United States for the treatment of type 2 diabetes. An additional DPP-4 inhibitor, vildagliptin, is available in Europe. Other DPP-4 inhibitors—gemigliptin, anagliptin, teneligliptin, trelagliptin, omarigliptin, evogliptin, and gosogliptin—have been approved outside the United States and European Union (Korea, India, Thailand, Japan, Russia, and several South American countries).

Sitagliptin, when used alone or in combination with other diabetes medications, lowers HbA_{1c} by approximately 0.5%. The usual dose of sitagliptin is 100 mg once daily, but the dose is reduced to 50 mg daily if the calculated creatinine clearance is 30–50 mL/min and to 25 mg for clearances less than 30 mL/min. Unlike exenatide, sitagliptin does not cause nausea or vomiting. It also does not result in weight loss. Saxagliptin, when added to the therapeutic regimen (metformin, sulfonylurea, thiazolidinedione) of patients with type 2 diabetes, further lowered the HbA_{1c} value by about 0.7–0.9%. The dose is 2.5 mg or 5 mg orally once a day. The 2.5-mg dose should be used in patients with calculated creatinine clearance less than 50 mL/min. The medication is weight neutral.

Alogliptin lowers HbA_{1c} by about 0.5–0.6% when added to metformin, sulfonylurea, or pioglitazone. The usual dose is 25 mg orally daily. The 12.5-mg dose is used in patients with calculated creatinine clearance of 30 to 60 mLs/min; and 6.25 mg for clearance less than 30 mL/min. Linagliptin lowers HbA_{1c} by about 0.4–0.6% when added to metformin, sulfonylurea, or pioglitazone. The dose is 5 mg orally daily, and, since it is primarily excreted unmetabolized via the bile, no dose adjustment is needed in patients with kidney disease. Vildagliptin lowers HbA_{1c} by about 0.5–1% when added to the therapeutic regimen of patients with type 2 diabetes. The dose is 50 mg once or twice daily.

5. Sodium-glucose co-transporter 2 inhibitors—Glucose is freely filtered by the kidney glomeruli and is reabsorbed in the proximal tubules by the action of sodium-glucose co-transporters (SGLT). Sodium-glucose co-transporter 2 (SGLT2) accounts for about 90% of glucose reabsorption and its inhibition causes glycosuria in people with diabetes, lowering plasma glucose levels. The SGLT2 inhibitors canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin are approved for clinical use in the United States. These agents reduce the threshold for glycosuria from a plasma glucose threshold of about a 180 mg/dL to about 40 mg/dL; and lower HbA_{1c} by 0.5–1% when used alone or in combination with other oral agents or insulin. The efficacy is higher at higher HbA_{1c} levels when more glucose is excreted as a result of SGLT2 inhibition. The loss of calories results in modest weight loss of 2–5 kg.

The usual dose of canagliflozin is 100 mg daily but up to 300 mg daily can be used in patients with normal kidney function. The dose of dapagliflozin is 10 mg daily but 5 mg daily is the recommended initial dose in patients with hepatic failure. The usual dosage of empagliflozin is 10 mg daily but a higher dose of 25 mg daily can be used. The recommended starting dose of ertugliflozin is 5 mg, but the dose can be increased to 15 mg daily if additional glucose lowering is needed.

In a postmarketing multinational study of 7020 patients with type 2 diabetes with known cardiovascular disease, the addition of empagliflozin was associated with a lower primary composite outcome of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke (hazard ratio 0.86, $P = 0.04$). The mechanisms regarding the benefit remain unclear. Weight loss, lower blood pressure, and diuresis may have played a role since there were fewer deaths from heart failure in the treated group whereas the rates of myocardial infarction were unaltered. A similar multinational study was performed with the addition of canagliflozin. This was a study of 10,142 patients with type 2 diabetes with known or at increased risk for cardiovascular disease. The canagliflozin treated group had a lower primary composite outcome of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke (hazard ratio 0.86, $P = 0.02$). Both empagliflozin and canagliflozin showed benefit in terms of progression of albuminuria and kidney injury, possibly by lowering glomerular hyperfiltration. In type 2 diabetes patients with diabetic kidney disease (eGFR 30 to less than 90 mL/min/1.73 m^2 and urine albumin excretion more than 300 mg/g creatinine), canagliflozin has been shown to prevent progression to end-stage renal disease.

As might be expected, the efficacy of the SGLT2 inhibitors is reduced in chronic kidney disease. They can also increase creatinine and decrease eGFR, especially in patients with kidney impairment. Canagliflozin is contraindicated in patients with eGFR less than 45 mL/min/1.73 m^2. The main side effects are increased incidence of genital mycotic infections and urinary tract infections affecting ~8–9% of patients. There have also been reports of cases of pyelonephritis and septicemia requiring hospitalization. The glycosuria can cause intravascular volume contraction and hypotension.

The multinational study with canagliflozin showed an increased risk of amputations, especially of the toes (hazard ratio 1.97, 95 % CI 1.41–2.75). It is not known if this is a class effect or an adverse effect specific to this agent.

Canagliflozin has been reported to cause a decrease in bone mineral density at the lumbar spine and the hip. In a pooled analysis of eight clinical trials (mean duration 68 weeks), a 30% increase in fractures was observed in patients taking canagliflozin. It is likely that the effect on the bones is a class effect and not restricted to canagliflozin. All the SGLT2 inhibitors cause a modest increase in LDL cholesterol levels (3–8%). Also, in clinical trials, patients taking dapagliflozin had higher rates of breast cancer (nine cases vs none in comparator arms) and bladder cancer (10 cases vs 1 in placebo arm). These cancer rates exceeded the expected rates in age-matched reference diabetes population.

Cases of DKA have been reported with off-label use of SGLT2 inhibitors in patients with type 1 diabetes. Type 1 patients are taught to give less insulin if their glucose levels are not elevated. SGLT2 inhibitors lower glucose levels by changing the renal threshold and not by insulin action. Type 1 patients taking an SGLT2 inhibitor, because the glucose levels are not elevated, may either withhold or reduce their insulin doses to such a degree as to induce ketoacidosis. SGLT2 inhibitors should not be used in patients with type 1 diabetes and in those patients labeled as having type 2 diabetes but who are very insulin deficient and ketosis-prone.

6. Others—Pramlintide is a synthetic analog of islet amyloid polypeptide (IAPP or amylin). When given subcutaneously, it delays gastric emptying, suppresses glucagon secretion, and decreases appetite. It is approved for use both in type 1 diabetes and in insulin-treated type 2 diabetes. In 6-month clinical studies with type 1 and insulin-treated type 2 patients, those taking the medication had an approximately 0.4% reduction in HbA_{1c} and about 1.7 kg weight loss compared with placebo. The HbA_{1c} reduction was sustained for 2 years but some of the weight was regained. The medication is given by injection immediately before the meal. Hypoglycemia can occur, and it is recommended that the short-acting or premixed insulin doses be reduced by 50% when the medication is started. Since the medication slows gastric emptying, recovery from hypoglycemia can be a problem because of delay in absorption of fast-acting carbohydrates. Nausea was the other main side effect, affecting 30–50% of persons, but tended to improve with time. In patients with type 1 diabetes, the initial dose of pramlintide is 15 mcg before each meal and titrated up by 15-mcg increments to a maintenance dose of 30 mcg or 60 mcg before each meal. In patients with type 2 diabetes, the starting dose is 60 mcg premeals increased to 120 mcg in 3 to 7 days if no significant nausea occurs.

Bromocriptine, a dopamine 2 receptor agonist, has been shown to modestly lower HbA_{1c} by 0.1–0.5% when compared to baseline and 0.4–0.5% compared to placebo. The tablet dose is 0.8 mg and the daily dose is 2 (1.6 g) to 6 (4.8 mg) tablets as tolerated. Common side effects are nausea, vomiting, dizziness, and headache.

Colesevelam, the bile acid sequestrant, when added to metformin or sulfonylurea or insulin, lowered HbA_{1c} 0.3– 0.4% when compared to baseline and 0.5–0.6% compared to placebo. HbA_{1c} lowering, however, was not observed in a single monotherapy clinical trial comparing colesevelam to placebo. Colesevelam use is associated with ~20% increase in triglyceride levels. Other adverse effects include constipation and dyspepsia.

With their modest glucose lowering and significant side effects, using bromocriptine or colesevelam to treat diabetes is not recommended.

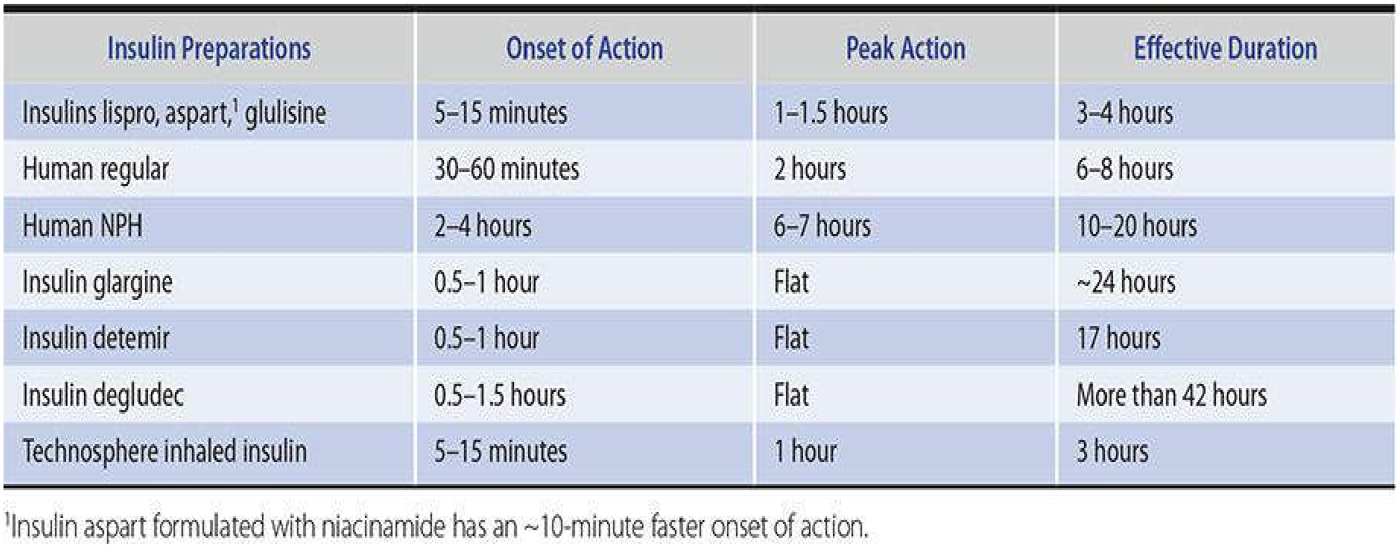
7. Medication combinations—Several medication combinations are available in different dose sizes, including glyburide and metformin (Glucovance); glipizide and metformin (Metaglip); repaglinide and metformin (Prandi-Met); rosiglitazone and metformin (Avandamet); pioglitazone and metformin (ACTOplusMet); rosiglitazone and glimepiride (Avandaryl); pioglitazone and glimepiride (Duetact); sitagliptin and metformin (Janumet); saxagliptin and metformin XR (Kombiglyze XR); linagliptin and metformin (Jentadueto); alogliptin and metformin (Kazano); alogliptin and pioglitazone (Oseni); dapagliflozin and metformin (Xigduo); canagliflozin and metformin (Invokamet); empagliflozin and metformin (Synjardy); empagliflozin and linagliptin (Glyxambi); ertugliflozin and metformin (Segluormet); ertugliflozin and sitagliptin (Steglujan); insulin degludec and liraglutide (Xultophy); and insulin glargine and lixisenatide (Soliqua). These medication combinations, however, limit the clinician’s ability to optimally adjust dosage of the individual medications and for that reason are not recommended.

C. Insulin

Insulin is indicated for type 1 diabetes as well as for type 2 diabetic patients with insulinopenia whose hyperglycemia does not respond to diet therapy either alone or combined with other hypoglycemic medications.

1. Characteristics of available insulin preparations—Human insulin is dispensed as either regular (R) or NPH (N) formulations. Six analogs of human insulin—three rapidly acting (insulin lispro, insulin aspart, insulin glulisine) and three long-acting (insulin glargine, insulin detemir, and insulin degludec)—are approved by the FDA for clinical use. Commercial insulin preparations differ with respect to the time of onset and duration of their biologic action (Table 27–6). All currently available insulins contain less than 10 ppm of proinsulin and are labeled as “purified.” These purified insulins preserve their potency, so that refrigeration is recommended but not crucial. During travel, reserve supplies of insulin can be readily transported for weeks without losing potency if protected from extremes of heat or cold. All the insulins in the United States are available in a concentration of 100 units/mL (U100) and dispensed in 10-mL vials or 0.3-mL cartridges or prefilled disposable pens. Several insulins are available at higher concentrations: insulin glargine, 300 units/mL (U300); insulin degludec, 200 units/mL (U200); insulin lispro, 200 units/mL (U200); and regular insulin, 500 units/mL (U500).

Table 27–6. Summary of bioavailability characteristics of the insulins.

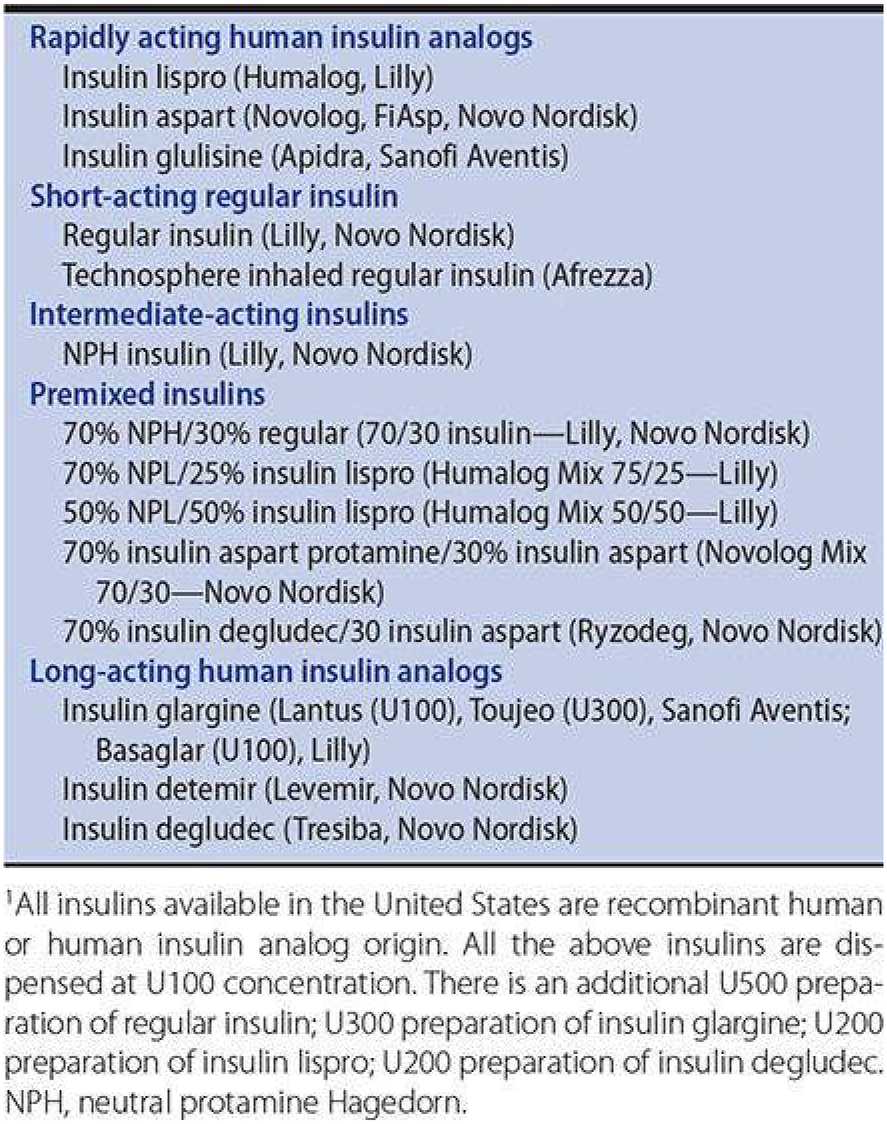


Insulin Preparations	Onset of Action	Peak Action	Effective Duration
Insulins lispro, aspart,[1] glulisine	5–15 minutes	1–1.5 hours	3–4 hours
Human regular	30–60 minutes	2 hours	6–8 hours
Human NPH	2–4 hours	6–7 hours	10–20 hours
Insulin glargine	0.5–1 hour	Flat	~24 hours
Insulin detemir	0.5–1 hour	Flat	17 hours
Insulin degludec	0.5–1.5 hours	Flat	More than 42 hours
Technosphere inhaled insulin	5–15 minutes	1 hour	3 hours

[1] Insulin aspart formulated with niacinamide has an ~10-minute faster onset of action.

2. Insulin preparations—See Table 27–7. The rapidly acting insulin analogs and the long-acting insulins are designed for subcutaneous administration, while regular insulin can also be given intravenously.

Table 27–7. Insulin preparations available in the United States.[1]



Rapidly acting human insulin analogs
- Insulin lispro (Humalog, Lilly)
- Insulin aspart (Novolog, FiAsp, Novo Nordisk)
- Insulin glulisine (Apidra, Sanofi Aventis)

Short-acting regular insulin
- Regular insulin (Lilly, Novo Nordisk)
- Technosphere inhaled regular insulin (Afrezza)

Intermediate-acting insulins
- NPH insulin (Lilly, Novo Nordisk)

Premixed insulins
- 70% NPH/30% regular (70/30 insulin—Lilly, Novo Nordisk)
- 70% NPL/25% insulin lispro (Humalog Mix 75/25—Lilly)
- 50% NPL/50% insulin lispro (Humalog Mix 50/50—Lilly)
- 70% insulin aspart protamine/30% insulin aspart (Novolog Mix 70/30—Novo Nordisk)
- 70% insulin degludec/30 insulin aspart (Ryzodeg, Novo Nordisk)

Long-acting human insulin analogs
- Insulin glargine (Lantus (U100), Toujeo (U300), Sanofi Aventis; Basaglar (U100), Lilly)
- Insulin detemir (Levemir, Novo Nordisk)
- Insulin degludec (Tresiba, Novo Nordisk)

[1] All insulins available in the United States are recombinant human or human insulin analog origin. All the above insulins are dispensed at U100 concentration. There is an additional U500 preparation of regular insulin; U300 preparation of insulin glargine; U200 preparation of insulin lispro; U200 preparation of insulin degludec. NPH, neutral protamine Hagedorn.

A. SHORT-ACTING INSULIN PREPARATIONS—

(1) Regular insulin—Regular insulin is a short-acting soluble crystalline zinc insulin whose effect appears within 30 minutes after subcutaneous injection and lasts 5–7 hours when usual quantities are administered. Intravenous infusions of regular insulin are particularly useful in the treatment of DKA and during the perioperative management of patients with diabetes who require insulin. For markedly insulin-resistant persons who would otherwise require large volumes of insulin solution, a U500 preparation of human regular insulin is available both in a vial form and a disposable pen. A U500 insulin syringe should be used if the vial form is dispensed. U500 regular insulin is much more expensive than the U100 concentration and is rarely needed. There is a U300 preparation of insulin glargine, a U200 preparation of insulin lispro, and a U200 preparation of insulin degludec.

(2) Rapidly acting insulin analogs—Insulin lispro (Humalog) is an insulin analog where the proline at position B28 is reversed with the lysine at B29. Insulin aspart (Novolog) is a single substitution of proline by aspartic acid at position B28. In insulin glulisine (Apidra) the asparagine at position B3 is replaced by lysine and the lysine in position B29 by glutamic acid. These three analogs have less of a tendency to form hexamers, in contrast to human insulin. When injected subcutaneously, the analogs quickly dissociate into monomers and are absorbed very rapidly, reaching peak serum values in as soon as 1 hour—in contrast to regular human insulin, whose hexamers require considerably more time to dissociate and become absorbed. The amino acid changes in these analogs do not interfere with their binding to the insulin receptor, with the circulating half-life, or with their immunogenicity, which are all identical with those of human regular insulin. An insulin aspart formulation (FiAsp) that contains niacinamide (vitamin B_3) has a more rapid initial absorption and its onset of action is about 10 minutes faster than the standard insulin aspart formulation. Because of this more rapid onset of action, the 1-hour (but not 2-hour) postprandial glucose excursions are lower compared to the standard formulation.

Clinical trials have demonstrated that the optimal times of preprandial subcutaneous injection of comparable doses of the rapidly acting insulin analogs and of regular human insulin are 20 minutes and 60 minutes, respectively, before the meal. While this more rapid onset of action has been welcomed as a great convenience by diabetic patients who object to waiting as long as 60 minutes after injecting regular human insulin before they can begin their meal, patients must be taught to ingest adequate absorbable carbohydrate early in the meal to avoid hypoglycemia during the meal. Another desirable feature of rapidly acting insulin analogs is that their duration of action remains at about 4 hours irrespective of dosage. This contrasts with regular insulin, whose duration of action is prolonged when larger doses are used.

The rapidly acting analogs are also commonly used in pumps. In a double-blind crossover study comparing insulin lispro with regular insulin in insulin pumps, persons using insulin lispro had lower HbA_{1c} values and improved postprandial glucose control with the same frequency of hypoglycemia. In the event of pump failure, however, users of the rapidly acting insulin analogs will have more rapid onset of hyperglycemia and ketosis.

While insulin aspart has been approved for intravenous use (eg, in hyperglycemic emergencies), there is no advantage in using insulin aspart over regular insulin by this route. A U200 concentration of insulin lispro is available in a disposable prefilled pen. The only advantage of the U200 over the U100 insulin lispro preparation is that it delivers the same dose in half the volume.

B. LONG-ACTING INSULIN PREPARATIONS—

(1) NPH (neutral protamine Hagedorn or isophane) insulin—NPH is an intermediate-acting insulin whose onset of action is delayed to 2–4 hours, and its peak response is generally reached in about 6–7 hours. The onset of action is delayed by combining 2 parts soluble crystalline zinc insulin with 1 part protamine zinc insulin. This produces equivalent amounts of insulin and protamine, so that neither is present in an uncomplexed form ("isophane"). Because its duration of action is often less than 24 hours (with a range of 10–20 hours), most patients require at least two injections daily to maintain a sustained insulin effect. Occasional vials of NPH insulin have tended to show unusual clumping of their contents or "frosting" of the container, with considerable loss of bioactivity. This instability is rare and occurs less frequently if NPH human insulin is refrigerated when not in use and if bottles are discarded after 1 month of use.

(2) Insulin glargine—In this insulin, the asparagine at position 21 of the insulin A chain is replaced by glycine and two arginines are added to the carboxyl terminal of the B chain. The arginines raise the isoelectric point of the molecule closer to neutral making it more soluble in an acidic environment. In contrast, human insulin has an isoelectric point of pH 5.4. Insulin glargine is a clear insulin, which, when injected into the neutral pH environment of the subcutaneous tissue, forms microprecipitates that slowly release the insulin into the circulation. This insulin lasts for about 24 hours without any pronounced peaks and is given once a day to provide basal coverage. This insulin cannot be mixed with the other human insulins because of its acidic pH. When this insulin was given as a single injection at bedtime to type 1 patients in clinical trials, fasting hyperglycemia was better controlled with less nocturnal hypoglycemia when compared to NPH insulin.

A more concentrated form of insulin glargine (U300) is available as an insulin pen. In pharmacodynamic studies in type 1 patients, the U300 compared to the U100 preparation had approximately 5 hours longer duration of action. In clinical trials in type 1 patients, U300 use did not result in better control or reduce the rates of hypoglycemia. Although limited clinical data suggest that insulin glargine is safe in pregnancy, it is not approved for this use.

(3) Insulin detemir—In this insulin analog, the threonine at position B30 has been removed and a 14-C fatty acid chain (tetradecanoic acid) is attached to the lysine at position 29 by acylation. Its prolonged action is due to dihexamerization and binding of hexamers and dimers to albumin at the injection site as well as binding of the monomer via its fatty acid side chain to albumin in the circulation. The affinity of insulin detemir is fourfold to fivefold lower than that of human soluble insulin and therefore the U100 formulation of insulin detemir has an insulin concentration of 2400 nmol/mL compared with 600 nmol/mL for NPH. The duration of action for insulin detemir is about 17 hours at therapeutically relevant doses. It is recommended that the insulin be injected once or twice a day to achieve a stable basal coverage. It has been approved for use during pregnancy.

(4) Insulin degludec—In this insulin analog, the threonine at position B30 has been removed, and the lysine at position B29 is conjugated to hexdecanoic acid via a gamma-L-glutamyl spacer. In the vial, in the presence of phenol and zinc, the insulin is in the form of dihexamers but when injected subcutaneously, it self associates into large multihexameric chains consisting of thousands of dihexamers. The chains slowly dissolve in the subcutaneous tissue and insulin monomers are steadily released into the systemic circulation. The half-life of insulin degludec is 25 hours. Its onset of action is in 30–90 minutes and its duration of action is more than 42 hours. It is recommended that the insulin be injected once or twice a day to achieve a stable basal coverage. Insulin degludec is available in two concentrations, U100 and U200, and dispensed in prefilled disposable pens.

C. MIXED INSULIN PREPARATIONS—Patients with type 2 diabetes can sometimes achieve reasonable glucose control with just prebreakfast and predinner injections of mixtures of short acting and NPH insulins. The regular insulin or rapidly acting insulin analog is withdrawn first, then the NPH insulin and then injected immediately. Stable premixed insulins (70% NPH and 30% regular) are available as a convenience to patients who have difficulty mixing insulin because of visual problems or impairment of manual dexterity (Table 27–7). Premixed preparations of insulin lispro and NPH insulins are unstable; stability is achieved by replacing the NPH insulin with NPL (neutral protamine lispro). This insulin has the same duration of action as NPH insulin. Premixed combinations of NPL and insulin lispro (75% NPL/25% insulin lispro mixture [Humalog Mix 75/25] and 50% NPL/50% insulin lispro mixture [Humalog Mix 50/50]) are available for clinical use. Similarly, a 70% insulin aspart protamine/30% insulin aspart (NovoLog Mix 70/30) is available. The main advantages of these mixtures are that they can be given within 15 minutes of starting a meal and they are superior in controlling the postprandial glucose rise after a carbohydrate rich meal. These benefits have not translated into improvements in HbA_{1c} levels when compared with the usual 70% NPH/30% regular mixture. The longer-acting insulin analogs, insulin glargine and insulin detemir, cannot be mixed with either regular insulin or the rapidly acting insulin analogs. Insulin degludec, however, can be mixed and is available as 70% insulin degludec/30% insulin aspart and is injected once or twice a day.

3. Methods of insulin administration—

A. INSULIN SYRINGES AND NEEDLES—Plastic disposable syringes are available in 1-mL, 0.5-mL, and 0.3-mL sizes. The “low-dose” 0.3-mL syringes are popular because many patients with diabetes do not take more than 30 units of insulin in a single injection except in rare instances of extreme insulin resistance. Three lengths of needles are available: 6 mm, 8 mm, and 12.7 mm. Long needles are preferable in obese patients to reduce variability of insulin absorption. The needles are of 28, 30, and 31 gauges. The 31-gauge needles are almost painless. “Disposable” syringes may be reused until blunting of the needle occurs (usually after three to five injections). Sterility adequate to avoid infection with reuse appears to be maintained by recapping syringes between uses. Cleansing the needle with alcohol may not be desirable since it can dissolve the silicone coating and can increase the pain of skin puncturing.

B. SITES OF INJECTION—Any part of the body covered by loose skin can be used, such as the abdomen, thighs, upper arms, flanks, and upper buttocks. Preparation with alcohol is not required prior to injection as long as the skin is clean. Rotation of sites is recommended to avoid delayed absorption when fibrosis or lipohypertrophy occurs from repeated use of a single site. Regular insulin is absorbed more rapidly when injected in the deltoid or abdomen compared to thighs and buttocks. Exercise can increase absorption when the injection site is adjacent to the exercise muscle. For most patients, the abdomen is the recommend region for injection because it provides adequate area in which to rotate sites. The effect of anatomic regions appears to be much less pronounced with the analog insulins.

C. INSULIN PEN INJECTOR DEVICES—Insulin pens eliminate the need for carrying insulin vials and syringes. Cartridges of insulin lispro and insulin aspart are available for reusable pens (Novo Nordisk, and Owen Mumford). Disposable prefilled pens are also available for regular insulin (U100 and U500), insulin lispro, insulin aspart, insulin glulisine, insulin detemir, insulin glargine, insulin degludec, NPH, 70% NPH/30% regular, 75% NPL/25% insulin lispro, 50% NPL/50% insulin lispro, 70% insulin aspart protamine/30% insulin aspart, and 70% insulin degludec/30% insulin aspart. Pen needles are available in 29, 31, and 32 gauges and 4-, 5-, 6-, 8-, and 12.7-mm lengths (Novofine; BD).

D. INSULIN PUMPS—In the United States, Medtronic Mini-Med, Insulet, and Tandem make battery operated continuous subcutaneous insulin infusion (CSII) pumps. These pumps are small (about the size of a pager) and easy to program. They offer many features, including the ability to set a number of different basal rates throughout the 24 hours and to adjust the time over which bolus doses are given. They also are able to detect pressure build-up if the catheter is kinked. The catheter connecting the insulin reservoir to the subcutaneous cannula can be disconnected, allowing the patient to remove the pump temporarily (eg, for bathing). Ominpod (Insulet Corporation) is an insulin infusion system in which the insulin reservoir and infusion set are integrated into one unit (pod), so there is no catheter (electronic patch pump). The pod, placed on the skin, delivers subcutaneous basal and bolus insulin based on wirelessly transmitted instructions from a personal digital assistant. The great advantage of continuous subcutaneous insulin infusion (CSII) is that it allows for establishment of a basal profile tailored to the patient allowing for better overnight and between meals glucose control. The ability to adjust the basal insulin infusion makes it easier for the patient to manage glycemic excursions that occur with exercise. The pumps have software that can assist the patient to calculate boluses based on glucose reading and carbohydrates to be consumed. They keep track of the time elapsed since last insulin bolus and the patient is reminded of this when he or she attempts to give additional correction bolus before the effect of the previous bolus has worn off ("insulin on board" feature). This feature reduces the risk of overcorrecting and subsequent hypoglycemia.

CSII therapy is appropriate for patients with type 1 diabetes who are motivated, mechanically inclined, educated about diabetes (diet, insulin action, treatment of hypoglycemia and hyperglycemia), and willing to monitor their blood glucose four to six times a day. Known complications of CSII include ketoacidosis, which can occur when insulin delivery is interrupted, and skin infections. Another disadvantage is its cost and the time demanded of the clinician and staff in initiating therapy. Almost all patients use rapid-acting insulin analogs in their pumps.

V-go (Valeritas) is a mechanical patch pump designed specifically for people with type 2 diabetes who use a basal/bolus insulin regimen. The device is preset to deliver one of three fixed and flat basal rates (20, 30, or 40 units) for 24 hours (at which point it must be replaced) and there is a button that delivers two units per press to help cover meals.

E. CLOSED LOOP SYSTEMS—Algorithms have been devised to use glucose data from the continuous glucose monitoring systems to automatically deliver insulin by continuous subcutaneous insulin infusion pump. These closed loop systems (artificial pancreas) have been shown in short-term clinical studies to improve nighttime glucose control and reduce the risk of nocturnal hypoglycemia. The FDA-approved MiniMed 670 G closed loop system uses glucose data from a sensor to automatically adjust basal insulin doses every 5 minutes, targeting a sensor glucose level of 120 mg/dL (6.7 mmol/L). Insulin delivery is suspended when the sensor glucose level falls below or is predicted to fall below target level. The glucose target can be adjusted up to 150 mg/dL (8.3 mmol/L) for physical activity. The patient is still responsible for bolusing insulin for meals and snacks. Successful use of this closed loop system requires the patient to be proficient at using both the insulin pump and continuous glucose monitor.

F. INHALED INSULIN—Technosphere insulin (Afrezza) is a dry-powder formulation of recombinant human regular insulin that can be inhaled. It consists of 2- to 2.5-mcm crystals of the excipient fumaryl diketopiperazine that provide large surface area for adsorption of proteins like insulin. The technosphere insulin is rapidly absorbed with peak insulin levels reached in 12–15 minutes and declining to baseline in 3 hours; the median time to maximum effect with inhaled insulin is approximately 1 hour and declines to baseline by about 3 hours. In contrast, the median time to maximum effect with subcutaneous insulin lispro is about 2 hours and declines to baseline by 4 hours. In clinical trials, technosphere insulin combined with basal insulin was as effective in glucose lowering as rapid-acting insulin analogs combined with basal insulin. It is formulated as a single-use, color-coded cartridge delivering 4, 8, or 12 units immediately before the meal. The manufacturer provides a dose conversion table; patients injecting up to 4 units of rapid-acting insulin analog should use the 4-unit cartridge. Those injecting 5 to 8 units should use the 8-unit cartridge. If the dose is 9–12 units of rapid-acting insulin premeal then one 4-unit cartridge and one 8-unit cartridge or one 12-unit cartridge should be used. The inhaler is about the size of a referee's whistle.

The most common adverse reaction of the inhaled insulin is a cough, affecting about 27% of patients. A small decrease in pulmonary function (forced expiratory volume in 1 second [FEV_1]) is seen in the first 3 months of use, which persists over 2 years of follow-up. Inhaled insulin is contraindicated in smokers and patients with chronic lung disease, such as asthma and chronic obstructive pulmonary disease. Spirometry should be performed to identify potential lung disease prior to initiating therapy. During clinical trials, there were two cases of lung cancer in patients who were taking inhaled insulin and none in the comparator-treated patients. All the patients in whom lung cancer developed had a history of prior cigarette smoking. There were also two cases of squamous cell carcinoma of the lung in nonsmokers exposed to inhaled insulin; these cases occurred after completion of the clinical trials. Cases of lung cancer were also reported in cigarette smokers using a previously available inhaled insulin preparation (Exubera). The incidence rate in the Exubera treated group was 0.13 per 1000 patient-years and 0.03 per 1000 patient-years in the comparator-treated group.

D. Transplantation

1. Pancreas transplantation—All patients with end-stage kidney disease and type 1 diabetes who are candidates for a kidney transplant should be considered potential candidates for a pancreas transplant. Eligibility criteria include age younger than 55 and minimal cardiovascular risk. Contraindications include noncorrectable coronary artery disease, extensive peripheral vascular disease, and significant obesity (weight greater than 100 kg). The pancreas transplant may occur at the same time as kidney transplant or after kidney transplant. Patients undergoing simultaneous pancreas and kidney transplantation have an 83% chance of pancreatic graft survival at 1 year and 69% at 5 years. Solitary pancreatic transplantation in the absence of a need for kidney transplantation is considered only in those rare patients who do not respond to all other insulin therapeutic approaches and who have frequent severe hypoglycemia, or who have life-threatening complications related to their lack of metabolic control. Solitary pancreas transplant graft survival is 78% at 1 year and 54% at 5 years.

2. Islet transplantation—Total pancreatectomy is curative for severe pain syndrome associated with chronic pancreatitis. The pancreatectomy, however, results in surgical diabetes. Harvesting islets from the removed pancreas and autotransplanting them into the liver (via portal vein) can prevent the development of diabetes or result in “mild” diabetes (partial islet function) that is easier to manage. Since the islets are autologous no immunosuppression is required. The number of islets transplanted is the main predictor of insulin independence.

People with type 1 diabetes can become insulin independent after receiving islets isolated from a donor pancreas (alloislet transplant). The islets are infused into the portal vein using a percutaneous transhepatic approach, and they lodge in the liver releasing insulin in response to physiologic stimuli. Long-term immunosuppression is necessary to prevent allograft rejection and to suppress the autoimmune process that led to the disease in the first place. Insulin independence for more than 5 years has been demonstrated in patients who got anti-CD3 antibody or anti-thymocyte globulin induction immunosuppression and calcineurin inhibitors, mTor inhibitors, and mycophenolate mofetil as maintenance immunosuppression. One major limitation is the need for more than one islet infusion to achieve insulin independence. This is because of significant loss of islets during isolation and the period prior to engraftment. Widespread alloislet transplantation will depend on improving insulin independence rates with one infusion and also demonstrating that the long-term outcomes are as good as those of pancreas transplant alone.

Steps in the Management of the Diabetic Patient

A. Diagnostic Examination

An attempt should be made to characterize the diabetes as type 1 or type 2 or other specific types such as MODY, based on the clinical features present and on whether or not ketonuria accompanies the glycosuria. Features that suggest end-organ insulin insensitivity to insulin, such as visceral obesity, acanthosis nigricans, or both, must be identified. The family history should document not only the incidence of diabetes in other members of the family but also the age at onset, association with obesity, the need for insulin, and whether there were complications. For the occasional patient, measurement of GAD65, IAA, ICA 512, and zinc transporter 8 antibodies can help distinguish between type 1 and type 2 diabetes (Table 27–2). Many patients with newly diagnosed type 1 diabetes still have significant endogenous insulin production, and C peptide levels do not reliably distinguish between type 1 and type 2 diabetes. Other factors that increase cardiac risk, such as smoking history, presence of hypertension or hyperlipidemia, or oral contraceptive pill use, should be recorded.

Laboratory diagnosis of diabetes should document fasting plasma glucose levels above 126 mg/dL (7 mmol/L) or postprandial values consistently above 200 mg/dL (11.1 mmol/L) or HbA_{1c} of at least 6.5% and whether ketonuria accompanies the glycosuria. An HbA_{1c} measurement is also useful for assessing the effectiveness of future therapy. Baseline values include fasting plasma triglycerides, total cholesterol and HDL cholesterol, electrocardiography, kidney function studies, peripheral pulses, and neurologic, podiatric, and ophthalmologic examinations to help guide future assessments.

B. Patient Education (Self-Management Training)

Since diabetes is a lifelong disorder, education of the patient and the family is probably the most important obligation of the clinician who provides care. The best persons to manage a disease that is affected so markedly by daily fluctuations in environmental stress, exercise, diet, and infections are the patients themselves and their families. The “teaching curriculum” should include explanations by the clinician or nurse of the nature of diabetes and its potential acute and chronic hazards and how they can be recognized early and prevented or treated. Self-monitoring of blood glucose should be emphasized, especially in insulin-requiring diabetic patients, and instructions must be given on proper testing and recording of data.

Patients taking insulin should have an understanding of the actions of basal and bolus insulins. They should be taught to determine whether the basal dose is appropriate and how to adjust the rapidly acting insulin dose for the carbohydrate content of a meal. Patients and their families and friends should be taught to recognize signs and symptoms of hypoglycemia and how to treat low glucose reactions. Strenuous exercise can precipitate hypoglycemia, and patients must therefore be taught to reduce their insulin dosage in anticipation of strenuous activity or to take supplemental carbohydrate.

Injection of insulin into a site farthest away from the muscles most involved in the exercise may help ameliorate exercise-induced hypoglycemia, since insulin injected in the proximity of exercising muscle may be more rapidly mobilized. Exercise training also increases the effectiveness of insulin, and insulin doses should be adjusted accordingly. Infections can cause insulin resistance, and patients should be instructed on how to manage the hyperglycemia with supplemental rapidly acting insulin.

Advice on personal hygiene, including detailed instructions on foot and dental care, should be provided. All infections (especially pyogenic ones) provoke the release of high levels of insulin antagonists, such as catecholamines or glucagon, and thus bring about a marked increase in insulin requirements. Patients who are taking oral agents may decompensate and temporarily require insulin. Patients should be told about community agencies, such as Diabetes Association chapters, that can serve as a continuing source of instruction.

Finally, vigorous efforts should be made to persuade patients with newly diagnosed diabetes who smoke to give up the habit, since large vessel peripheral vascular disease and debilitating retinopathy are less common in nonsmoking diabetic patients.

C. Therapy

Treatment must be individualized on the basis of the type of diabetes and specific needs of each patient. However, certain general principles of management can be outlined for hyperglycemic states of different types.

1. Type 1 diabetes—Traditional once- or twice-daily insulin regimens are usually ineffective in type 1 patients without residual endogenous insulin. In these patients, information and counseling based on the findings of the DCCT, which showed that near normalization of blood glucose in patients with type 1 diabetes resulted in a delay in the onset and a major slowing of the progression of established microvascular and neuropathic complications of diabetes, should be provided about the advantages of taking multiple injections of insulin in conjunction with self–blood glucose monitoring. If near-normalization of blood glucose is attempted, at least four measurements of capillary blood glucose and three or four insulin injections are necessary.

A combination of rapidly acting insulin analogs and long-acting insulin analogs allows for more physiologic insulin replacement. The rapidly acting insulin analogs have been advocated as a safer and much more convenient alternative to regular human insulin for preprandial use. However, because of their relatively short duration (no more than 3–4 hours), the rapidly acting insulin analogs need to be combined with longer-acting insulins to provide basal coverage and avoid hyperglycemia prior to the next meal. In addition to carbohydrate content of the meal, the effect of simultaneous fat ingestion must also be considered a factor in determining the rapidly acting insulin analog dosage required to control the glycemic increment during and just after the meal. With low-carbohydrate content and high-fat intake, there is an increased risk of hypoglycemia from insulin lispro within 2 hours after the meal. Table 27–8 illustrates a regimen with a rapidly acting insulin analog and insulin detemir or insulin glargine that might be appropriate for a 70-kg person with type 1 diabetes eating meals providing standard carbohydrate intake and moderate to low fat content.

Table 27–8. Examples of intensive insulin regimens using rapidly acting insulin analogs (insulin lispro, aspart, or glulisine) and insulin detemir, or insulin glargine or degludec in a 70-kg man with type 1 diabetes.[1–3]

	Pre-breakfast	Pre-lunch	Pre-dinner	At Bedtime
Rapidly acting insulin analog	5 units	4 units	6 units	
Insulin detemir[3]	6–7 units			8–9 units
OR				
Rapidly acting insulin analog	5 units	4 units	6 units	—
Insulin glargine or degludec[3]		—		15–16 units

[1] Assumes that patient is consuming approximately 75 g carbohydrate at breakfast, 60 g at lunch, and 90 g at dinner.

[2] The dose of rapidly acting insulin can be raised by 1 or 2 units if extra carbohydrate (15–30 g) is ingested or if premeal blood glucose is > 170 mg/dL (9.4 mmol/L).

[3] Insulin glargine or insulin detemir must be given as a separate injection.

Insulin glargine or insulin degludec is usually given once in the evening to provide 24-hour coverage. There are occasional patients in whom insulin glargine does not seem to last for 24 hours, and in such cases it needs to be given twice a day. Insulin detemir may also need to be given twice a day to get adequate 24-hour basal coverage. Alternatively, small doses of NPH (~3–4 units) can be given with each meal to provide daytime basal coverage with a larger dose at night. Unlike the long-acting insulin analogs, NPH can be mixed in the same syringe as the insulin lispro, insulin aspart, and insulin glulisine.

CSII by portable battery-operated “open loop” devices currently provides the most flexible approach, allowing the setting of different basal rates throughout the 24 hours and permitting bolus dose adjustments by as little as 0.05-unit increments. The 24-hour basal dosage is usually based on age and body weight. An adolescent might need as much as 0.4 unit/kg/day; young adult (less than 25 years), 0.35 unit per/kg/day; and older adults, 0.25 unit/kg/day. For example, a 70-kg, 30-year-old man may require a basal rate of 0.7 unit per hour throughout the 24 hours with the exception of 3 AM to 8 AM, when 0.8 unit per hour might be appropriate (given the "**dawn phenomenon**"—reduced tissue sensitivity to insulin between 5 AM and 8 AM). The meal bolus varies based on the time of day and the person's age. Adolescents and young adults usually require 1 unit for about 10 g of carbohydrate. Older adults usually require about 1 unit for 15 g of carbohydrate. The correction factor—how much insulin is needed to lower glucose levels by 50 mg/dL—can be calculated from the insulin-to-carbohydrate ratios. For example, if 1 unit is required for 15 g of carbohydrate, then 1 unit will lower glucose levels by 50 mg/dL. If 1.5 units of insulin are required for 15 g of carbohydrate (that is, 1 unit for 10 g carbohydrate), then 1.5 units of insulin will lower glucose levels by 50 mg/dL (that is, 1 unit will lower glucose level by 33 mg/dL). For a 70-kg 30-year-old man, bolus ratios of 1 unit for 12–15 g of carbohydrate plus 1 unit for 50 mg/dL of blood glucose over a target value of 120 mg/dL would be reasonable starting point. Further adjustments to basal and bolus dosages would depend on the results of blood glucose monitoring. One of the more difficult therapeutic problems in managing patients with type 1 diabetes is determining the proper adjustment of insulin dose when the prebreakfast blood glucose level is high. Occasionally, the prebreakfast hyperglycemia is due to the **Somogyi effect,** in which nocturnal hypoglycemia leads to a surge of counterregulatory hormones to produce high blood glucose levels by 7 AM. However, a more common cause for prebreakfast hyperglycemia is the waning of circulating insulin levels by the morning.

The diagnosis of the cause of prebreakfast hyperglycemia can be facilitated by self-monitoring of blood glucose at 3 AM in addition to the usual bedtime and 7 AM measurements (Table 27–9). This is required for only a few nights, and when a particular pattern emerges from monitoring blood glucose levels overnight, appropriate therapeutic measures can be taken. The Somogyi effect can be treated by eliminating the dose of intermediate insulin at dinnertime and giving it at a lower dosage at bedtime or by supplying more food at bedtime. When a waning insulin level is the cause, then either increasing the evening dose or shifting it from dinnertime to bedtime (or both) can be effective. A bedtime dose either of insulin glargine or insulin detemir provides more sustained overnight insulin levels than human NPH and may be effective in managing refractory prebreakfast hyperglycemia. If this fails, insulin pump therapy may be required.

Table 27–9. Prebreakfast hyperglycemia: classification by blood glucose and insulin

levels.

	Blood Glucose (mg/dL [mmol/L])			Free Immunoreactive Insulin (microunit/mL)		
	10:00 PM	3:00 AM	7:00 AM	10:00 PM	3:00 AM	7:00 AM
Somogyi effect	90 [5]	40 [2.2]	200 [11.1]	High	Slightly high	Normal
Dawn phenomenon	110 [6.1]	110 [6.1]	150 [8.3]	Normal	Normal	Normal
Waning of insulin dose plus dawn phenomenon	110 [6.1]	190 [10.6]	220 [12.2]	Normal	Low	Low
Waning of insulin dose plus dawn phenomenon plus Somogyi effect	110 [6.1]	40 [2.2]	380 [21.1]	High	Normal	Low

2. Type 2 diabetes—Therapeutic recommendations are based on the relative contributions of beta cell insufficiency and insulin insensitivity in individual patients. The possibility that the individual patient has a specific etiologic cause for their diabetes should always be considered, especially when the patient does not have a family history of type 2 diabetes or does not have any evidence of central obesity or insulin resistance. Such patients should be evaluated for other types of diabetes such as LADA or MODY (Table 27–1). Patients with LADA should be prescribed insulin when the disease is diagnosed and treated like patients with type 1 diabetes. It is also important to note that many patients with type 2 diabetes mellitus have a progressive loss of beta cell function and will require additional therapeutic interventions with time.

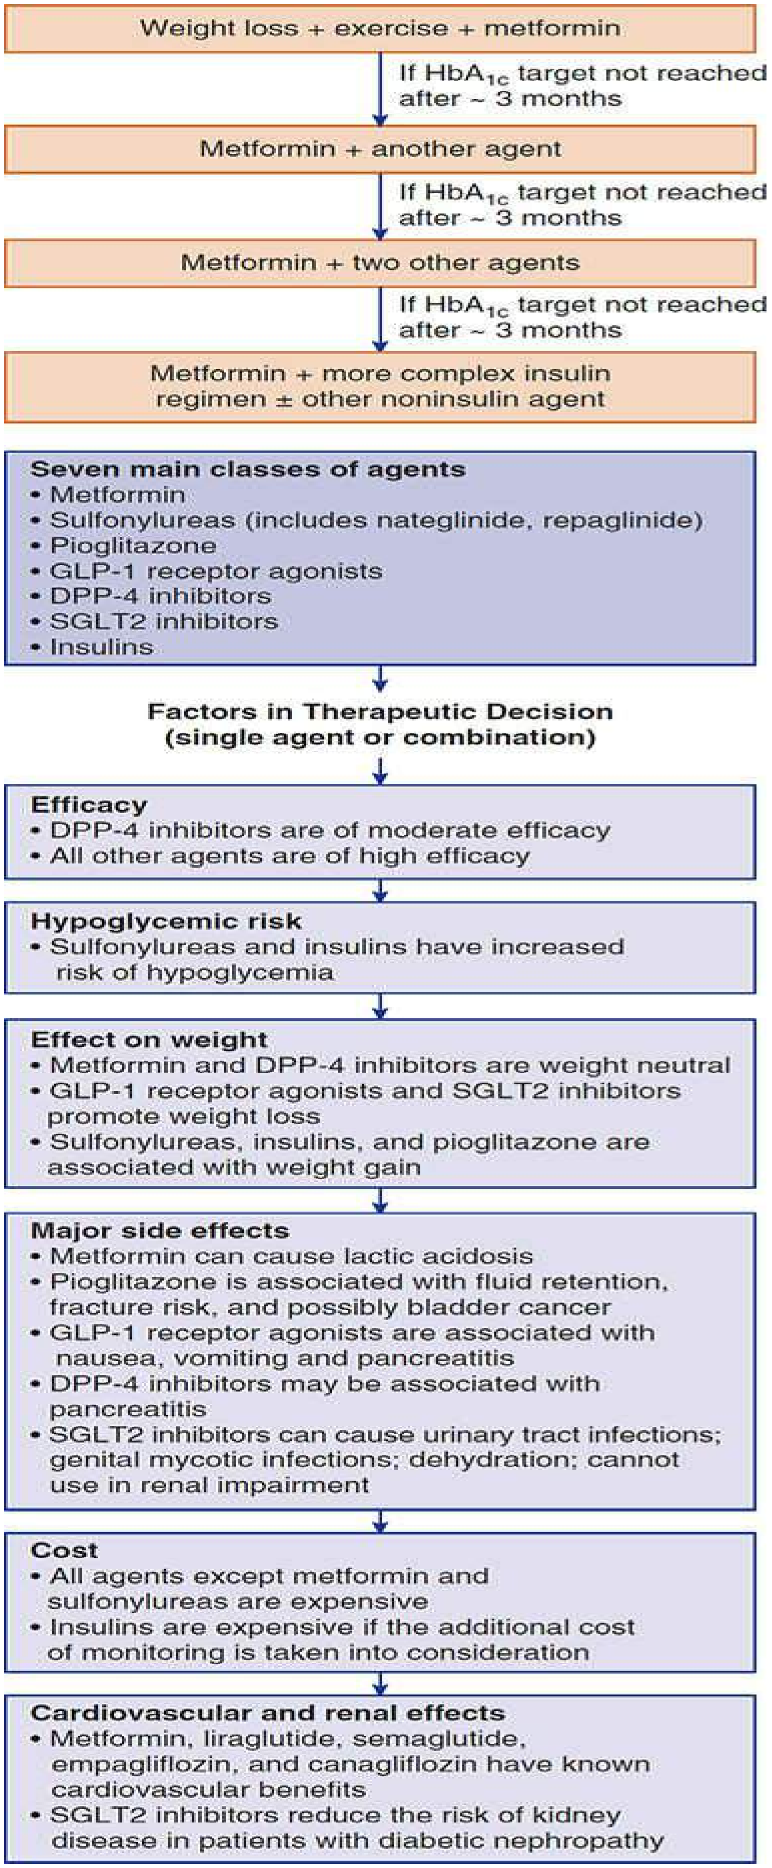
A. WEIGHT REDUCTION—One of the primary modes of therapy in the obese patient with type 2 diabetes is weight reduction. Normalization of glycemia can be achieved by weight loss and improvement in tissue sensitivity to insulin. A combination of caloric restriction, increased exercise, and behavior modification is required if a weight reduction program is to be successful. Understanding the risks associated with the diagnosis of diabetes may motivate the patient to lose weight.

For selected patients, medical or surgical options for weight loss should be considered. Orlistat, phentermine/topiramate, lorcaserin, naltrexone/extended-release bupropion, and high-dose liraglutide (3 mg daily) are weight loss medications approved for use in combination with diet and exercise (see Chapter 29).

Bariatric surgery (Roux-en-Y, gastric banding, gastric sleeve, biliopancreatic diversion/duodenal switch) typically results in substantial weight loss and improvement in glucose levels. A meta-analysis examining the impact of bariatric surgery on patients with diabetes and BMI of 40 kg/m^2 or greater noted that 82% of patients had resolution of clinical and laboratory manifestations of diabetes in the first 2 years after surgery and 62% remained free of diabetes more than 2 years after surgery. The improvement was most marked in the procedure that caused the greatest weight loss (biliopancreatic diversion/duodenal switch). There was, however, a high attrition of patients available for follow-up, and there was little information about different ethnic types. Weight regain does occur after bariatric surgery, and it can be expected that 20–25% of the lost weight will be regained over 10 years. The impact of this weight gain on diabetes recurrence depends principally on the degree of beta cell dysfunction.

Nonobese patients with type 2 diabetes frequently have increased visceral adiposity—the so-called metabolically obese normal weight patient. There is less emphasis on weight loss, but exercise remains an important aspect of treatment.

B. GLUCOSE-LOWERING AGENTS—Figure 27–2 outlines the treatment approach based on the consensus algorithm proposed by the American Diabetes Association and the European Association for the Study of Diabetes. The current recommendation is to start metformin therapy at diagnosis and not wait to see whether the patient can achieve target glycemic control with weight management and exercise. See discussion of the individual medications, above.



Weight loss + exercise + metformin
If HbA_{1c} target not reached after ~ 3 months
Metformin + another agent
If HbA_{1c} target not reached after ~ 3 months
Metformin + two other agents
If HbA_{1c} target not reached after ~ 3 months
Metformin + more complex insulin regimen ± other noninsulin agent

Seven main classes of agents
- Metformin
- Sulfonylureas (includes nateglinide, repaglinide)
- Pioglitazone
- GLP-1 receptor agonists
- DPP-4 inhibitors
- SGLT2 inhibitors
- Insulins

Factors in Therapeutic Decision (single agent or combination)

Efficacy
- DPP-4 inhibitors are of moderate efficacy
- All other agents are of high efficacy

Hypoglycemic risk
- Sulfonylureas and insulins have increased risk of hypoglycemia

Effect on weight
- Metformin and DPP-4 inhibitors are weight neutral
- GLP-1 receptor agonists and SGLT2 inhibitors promote weight loss
- Sulfonylureas, insulins, and pioglitazone are associated with weight gain

Major side effects
- Metformin can cause lactic acidosis
- Pioglitazone is associated with fluid retention, fracture risk, and possibly bladder cancer
- GLP-1 receptor agonists are associated with nausea, vomiting and pancreatitis
- DPP-4 inhibitors may be associated with pancreatitis
- SGLT2 inhibitors can cause urinary tract infections; genital mycotic infections; dehydration; cannot use in renal impairment

Cost
- All agents except metformin and sulfonylureas are expensive
- Insulins are expensive if the additional cost of monitoring is taken into consideration

Cardiovascular and renal effects
- Metformin, liraglutide, semaglutide, empagliflozin, and canagliflozin have known cardiovascular benefits
- SGLT2 inhibitors reduce the risk of kidney disease in patients with diabetic nephropathy

▲ **Figure 27–2. Algorithm for the treatment of type 2 diabetes based on the 2018 recommendations of the consensus panel of the American Diabetes Association/European Association for the Study of Diabetes.**

When diabetes is not well controlled with initial therapy (usually metformin), then a second agent should be added. Sulfonylureas have been available for many years and their use in combination with metformin is well established. They do, however, have the propensity of causing hypoglycemia and weight gain. In patients who experience hyperglycemia after a carbohydrate-rich meal (such as dinner), a short-acting secretagogue (repaglinide or nateglinide) before meals may suffice to get the glucose levels into the target range. Patients with severe insulin resistance may be candidates for pioglitazone. Patients who are very concerned about weight gain may benefit from a trial of GLP-1 receptor agonist or DPP-4 inhibitor or SGLT2 inhibitor. Presence of cardiovascular disease should be considered; liraglutide, empagliflozin, and canagliflozin have been shown to have improved cardiovascular outcomes. If two agents are inadequate, then a third agent is added, although data regarding efficacy of such combined therapy are limited.

When the combination of oral agents (and injectable GLP-1 receptor agonists) fails to achieve euglycemia in patients with type 2 diabetes, then insulin treatment should be instituted. Various insulin regimens may be effective. One proposed regimen is to continue the oral combination therapy and then simply add a bedtime dose of NPH or long-acting insulin analog (insulin glargine or insulin detemir) to reduce excessive nocturnal hepatic glucose output and improve fasting glucose levels. If the patient does not achieve target glucose levels during the day, then daytime insulin treatment can be initiated. A convenient insulin regimen under these circumstances is a split dose of 70/30 NPH/regular mixture (or Humalog Mix 75/25 or NovoLogMix 70/30) before breakfast and before dinner. If this regimen fails to achieve satisfactory glycemic goals or is associated with unacceptable frequency of hypoglycemic episodes, then a more intensive regimen of multiple insulin injections can be instituted as in patients with type 1 diabetes. Metformin principally reduces hepatic glucose output, and it is reasonable to continue with this medication when insulin therapy is instituted. Pioglitazone, which improves peripheral insulin sensitivity, can be used together with insulin but this combination is associated with more weight gain and peripheral edema. The sulfonylureas, the GLP-1 receptor agonists, and the DPP-4 inhibitors also have been shown to be of continued benefit. Weight-reducing interventions should continue even after initiation of insulin therapy and may allow for simplification of the therapeutic regimen in the future.

D. Acceptable Levels of Glycemic Control

A reasonable aim of therapy is to approach normal glycemic excursions without provoking severe or frequent hypoglycemia. Table 27–10 summarizes blood glucose and HbA_{1c} goals for different patient groups. The UKPDS study demonstrated that blood pressure control was as significant or more significant than glycemic control in patients with type 2 diabetes regarding the prevention of microvascular as well as macrovascular complications.

Table 27–10. Glycemic targets for different groups of patients with diabetes.

	Blood Glucose Targets (mg/dL [mmol/L])	HbA_{1c} Target (% [mmol/mol])
Nonpregnant healthy adults	Premeal glucose 90–130 (5–7.2) 1-hour peak < 180 (10) 2-hour peak < 150 (8.3)	< 7 (53). Aim for < 6.5 (48) if it can be achieved without significant hypoglycemia or polypharmacy
Pregnancy	Premeal glucose ≤ 95 (5.3) 1-hour peak ≤ 140 (7.8) 2-hour peak ≤ 120 (6.7)	6–6.5 (42–48). Aim for < 6 (42) if possible without significant hypoglycemia
Older adults		
Healthy	Premeal 90–130 (5–7.2) Bedtime 90–150 (5–8.3)	< 7.5 (58)
Frail with limited life expectancy	Premeal 100–180 (5.6–10) Bedtime 110–200 (6.1–11.1)	< 8.5 (69)
History of severe hypoglycemia	Premeal 90–150 (5–8.3) Bedtime 100–180 (5.6–10)	< 8 (64)
Hospitalized patient	140–180 (7.8–10)	—
CKD	Glycemic targets in CKD are the same as those without CKD. HbA_{1c} and fructosamine values may not be accurate in end-stage renal disease and greater reliance should be placed on the home glucose measurements	
Children and adolescents	Premeal glucose 90–130 (5–7.2) Bedtime/overnight 90–150 (5–8.3)	< 7.5 (58)

CKD, chronic kidney disease.

E. Complications of Insulin Therapy

1. Hypoglycemia—Hypoglycemic reactions are the most common complications that occur in patients with diabetes who are treated with insulin. The signs and symptoms of hypoglycemia may be divided into those resulting from stimulation of the autonomic nervous system and those from neuroglycopenia (insufficient glucose for normal central nervous system function). When the blood glucose falls to around 54 mg/dL (3 mmol/L), the patient starts to experience both sympathetic (tachycardia, palpitations, sweating, tremulousness) and parasympathetic (nausea, hunger) nervous system symptoms. If these autonomic symptoms are ignored and the glucose levels fall further (to around 50 mg/dL [2.8 mmol/L]), then neuroglycopenic symptoms appear, including irritability, confusion, blurred vision, tiredness, headache, and difficulty speaking. A further decline in glucose can then lead to loss of consciousness or even a seizure. With repeated episodes of hypoglycemia, there is adaptation, and autonomic symptoms do not occur until the blood glucose levels are much lower and so the first symptoms are often due to neuroglycopenia. This condition is referred to as “hypoglycemic unawareness.” It has been shown that hypoglycemic unawareness can be reversed by keeping glucose levels high for a period of several weeks. Except for sweating, most of the sympathetic symptoms of hypoglycemia are blunted in patients receiving beta-blocking agents. Though not absolutely contraindicated, these medications must be used with caution in patients with diabetes who require insulin, and beta-1-selective blocking agents are preferred.

Hypoglycemia can occur in a patient taking sulfonylureas, repaglinide, and nateglinide, particularly if the patient is elderly, has kidney or liver disease, or is taking certain other medications that alter metabolism of the sulfonylureas (eg, phenylbutazone, sulfonamides, or warfarin). It occurs more frequently with the use of long-acting sulfonylureas than when shorter-acting agents are used. Otherwise, hypoglycemia in insulin-treated patients with diabetes occurs as a consequence of three factors: behavioral issues, impaired counterregulatory systems, and complications of diabetes.

Behavioral issues include injecting too much insulin for the amount of carbohydrates ingested. Drinking alcohol in excess, especially on an empty stomach, can also cause hypoglycemia. In patients with type 1 diabetes, hypoglycemia can occur during or even several hours after exercise, and so glucose levels need to be monitored and food and insulin adjusted. Some patients do not like their glucose levels to be high, and they treat every high glucose level aggressively. These individuals who "stack" their insulin—that is, give another dose of insulin before the first injection has had its full action—can develop hypoglycemia.

Counterregulatory issues resulting in hypoglycemia include impaired glucagon response, sympatho-adrenal responses, and cortisol deficiency. Patients with diabetes of greater than 5 years in duration lose their glucagon response to hypoglycemia. As a result, they are at a significant disadvantage in protecting themselves against falling glucose levels. Once the glucagon response is lost, their sympatho-adrenal responses take on added importance. Unfortunately, aging, autonomic neuropathy, or hypoglycemic unawareness due to repeated low glucose levels further blunts the sympatho-adrenal responses. Occasionally, Addison disease develops in persons with type 1 diabetes mellitus; when this happens, insulin requirements fall significantly, and unless insulin dose is reduced, recurrent hypoglycemia will develop.

Complications of diabetes that increase the risk for hypoglycemia include autonomic neuropathy, gastroparesis, and end-stage chronic kidney disease. The sympathetic nervous system is an important system alerting the individual that the glucose level is falling by causing symptoms of tachycardia, palpitations, sweating, and tremulousness. Failure of the sympatho-adrenal responses increases the risk of hypoglycemia. In addition, in patients with gastroparesis, if insulin is given before a meal, the peak of insulin action may occur before the food is absorbed causing the glucose levels to fall. Finally, in end-stage chronic kidney disease, hypoglycemia can occur presumably because of decreased insulin clearance as well as loss of renal contribution to gluconeogenesis in the postabsorptive state.

To prevent and treat insulin-induced hypoglycemia, the diabetic patient should carry glucose tablets or juice at all times. For most episodes, ingestion of 15 grams of carbohydrate is sufficient to reverse the hypoglycemia. The patient should be instructed to check the blood glucose in 15 minutes and treat again if the glucose level is still low. A parenteral glucagon emergency kit (1 mg) should be provided to every patient with diabetes who is receiving insulin therapy. Family or friends should be instructed how to inject it subcutaneously or intramuscularly into the buttock, arm, or thigh in the event that the patient is unconscious or refuses food. The medication can occasionally cause vomiting, and the unconscious patient should be turned on his or her side to protect the airway. The glucagon mobilizes glycogen from the liver, raising the blood glucose by about 36 mg/dL (2 mmol/L) in about 15 minutes. After the patient recovers consciousness, additional oral carbohydrate should be given. People with diabetes receiving hypoglycemic medication therapy should also wear an identification MedicAlert bracelet or necklace or carry a card in his or her wallet (1-800-ID-ALERT, www.medicalert.org).

Medical personnel treating severe hypoglycemia can give 50 mL of 50% glucose solution by rapid intravenous infusion. If intravenous access is not available, 1 mg of glucagon can be injected intramuscularly.

2. Immunopathology of insulin therapy—At least five molecular classes of insulin antibodies are produced during the course of insulin therapy in diabetes, including IgA, IgD, IgE, IgG, and IgM. With the switch to human and purified pork insulin, the various immunopathologic syndromes such as insulin allergy, immune insulin resistance, and lipoatrophy have become quite rare since the titers and avidity of these induced antibodies are generally quite low.

A. INSULIN ALLERGY—Insulin allergy, or immediate-type hypersensitivity, is a rare condition in which local or systemic urticaria is due to histamine release from tissue mast cells sensitized by adherence of anti-insulin IgE antibodies. In severe cases, anaphylaxis results. When only human insulin has been used from the onset of insulin therapy, insulin allergy is exceedingly rare. Antihistamines, corticosteroids, and even desensitization may be required, especially for systemic hypersensitivity. There have been case reports of successful use of insulin lispro in those rare patients who have a generalized allergy to human insulin or insulin resistance due to a high titer of insulin antibodies.

B. IMMUNE INSULIN RESISTANCE—A low titer of circulating IgG anti-insulin antibodies that neutralize the action of insulin to a small extent develops in most insulin-treated patients. With the old animal insulins, a high titer of circulating antibodies sometimes developed, resulting in extremely high insulin requirements—often more than 200 units daily. This is now rarely seen with the switch to human or highly purified pork insulins and has not been reported with the analogs.

C. LIPODYSTROPHY—Atrophy of subcutaneous fatty tissue leading to disfiguring excavations and depressed areas may rarely occur at the site of injection. This complication results from an immune reaction, and it has become rarer with the development of human and highly purified insulin preparations. Lipohypertrophy, on the other hand, is a consequence of the pharmacologic effects of insulin being deposited in the same location repeatedly. It can occur with purified insulins as well. Rotation of injection sites will prevent lipohypertrophy.

Chronic Complications of Diabetes

Late clinical manifestations of diabetes mellitus include a number of pathologic changes that involve small and large blood vessels, cranial and peripheral nerves, the skin, and the lens of the eye. These lesions lead to hypertension, end-stage chronic kidney disease, blindness, autonomic and peripheral neuropathy, amputations of the lower extremities, myocardial infarction, and cerebrovascular accidents. These late manifestations correlate with the duration of the diabetic state subsequent to the onset of puberty. In type 1 diabetes, end-stage chronic kidney disease develops in up to 40% of patients, compared with less than 20% of patients with type 2 diabetes. Proliferative retinopathy ultimately develops in both types of diabetes but has a slightly higher prevalence in type 1 patients (25% after 15 years' duration). In patients with type 1 diabetes, complications from end-stage chronic kidney disease are a major cause of death, whereas patients with type 2 diabetes are more likely to have macrovascular diseases leading to myocardial infarction and stroke as the main causes of death. Cigarette use adds significantly to the risk of both microvascular and macrovascular complications in diabetic patients.

A. Ocular Complications

1. Diabetic cataracts—Premature cataracts occur in diabetic patients and seem to correlate with both the duration of diabetes and the severity of chronic hyperglycemia. Nonenzymatic glycosylation of lens protein is twice as high in diabetic patients as in age-matched nondiabetic persons and may contribute to the premature occurrence of cataracts.

2. Diabetic retinopathy—There are two main categories of diabetic retinopathy: nonproliferative and proliferative (see Chapter 7). Diabetic macular edema can occur at any stage. **Nonproliferative ("background") retinopathy** represents the earliest stage of retinal involvement by diabetes and is characterized by such changes as microaneurysms, dot hemorrhages, exudates, and retinal edema. The prevalence of nonproliferative retinopathy in patients with type 2 diabetes is 60% after 16 years.

Proliferative retinopathy involves the growth of new capillaries and fibrous tissue within the retina and into the vitreous chamber. It is a consequence of small vessel occlusion, which causes retinal hypoxia; this in turn stimulates new vessel growth. New vessel formation may occur at the optic disk or elsewhere on the retina. Prior to proliferation of new capillaries, a preproliferative phase often occurs in which arteriolar ischemia is manifested as cotton-wool spots (small infarcted areas of retina). Vision is usually normal until vitreous hemorrhage or retinal detachment occurs.

Proliferative retinopathy can occur in both types of diabetes but is more common in type 1, developing about 7–10 years after onset of symptoms, with a prevalence of 25% after 15 years' duration. Vision-threatening retinopathy virtually never appears in type 1 patients in the first 3–5 years of diabetes or before puberty. Up to 20% of patients with type 2 diabetes have retinopathy at the time of diagnosis, because many were probably diabetic for an extensive period of time before diagnosis. Annual consultation with an ophthalmologist should be arranged for patients who have had type 1 diabetes for more than 3–5 years and for all patients with type 2 diabetes. Chapter 7 describes the treatment of retinopathy and macular edema. There is no contraindication to using aspirin in patients with proliferative retinopathy.

3. Glaucoma—Glaucoma occurs in approximately 6% of persons with diabetes. It is responsive to the usual therapy for open-angle disease. Neovascularization of the iris in patients with diabetes can predispose to closed-angle glaucoma, but this is relatively uncommon except after cataract extraction, when growth of new vessels has been known to progress rapidly, involving the angle of the iris and obstructing outflow.

B. Diabetic Nephropathy

Diabetic nephropathy is initially manifested by albuminuria; subsequently, as kidney function declines, urea and creatinine accumulate in the blood (see Chapter 22). Conventional 24-hour urine collections, in addition to being inconvenient for patients, also show wide variability of albumin excretion, since several factors such as sustained erect posture, dietary protein, and exercise tend to increase albumin excretion rates. For these reasons, an albumin-creatinine ratio in an early morning spot urine collected upon awakening is preferable. In the early morning spot urine, a ratio of albumin (mcg/L) to creatinine (mg/L) of less than 30 mcg/mg creatinine is normal, and a ratio of 30–300 mcg/mg creatinine suggests abnormal microalbuminuria. At least two early morning spot urine collections over a 3- to 6-month period should be abnormal before a diagnosis of microalbuminuria is justified. Short-term hyperglycemia, exercise, urinary tract infections, heart failure, and acute febrile illness can cause transient albuminuria and so testing for microalbuminuria should be postponed until resolution of these problems.

Subsequent end-stage chronic kidney disease can be predicted by persistent urinary albumin excretion rates exceeding 30 mcg/mg creatinine. Glycemic control as well as a protein diet of ~0.8 g/kg/day may reduce both the hyperfiltration and the elevated microalbuminuria in patients in the early stages of diabetes and those with incipient diabetic nephropathy. Antihypertensive therapy also decreases microalbuminuria.

Evidence from some studies supports a specific role for ACE inhibitors in reducing intraglomerular pressure in addition to their lowering of systemic hypertension. An ACE inhibitor (captopril, 50 mg twice daily) in normotensive diabetic patients impedes progression to proteinuria and prevents the increase in albumin excretion rate. Since microalbuminuria has been shown to correlate with elevated nocturnal systolic blood pressure, it is possible that "normotensive" diabetic patients with microalbuminuria have slightly elevated systolic blood pressure during sleep, which is lowered during antihypertensive therapy. This action may contribute to the reported efficacy of ACE inhibitors in reducing microalbuminuria in "normotensive" patients.

If treatment is inadequate, then the disease progresses with proteinuria of varying severity occasionally leading to nephrotic syndrome with hypoalbuminemia, edema, and an increase in circulating LDL cholesterol, as well as progressive azotemia. In contrast to all other kidney disorders, the proteinuria associated with diabetic nephropathy does not diminish with progressive end-stage chronic kidney disease (patients continue to excrete 10–11 g daily as creatinine clearance diminishes). As end-stage chronic kidney disease progresses, there is an elevation in the renal threshold at which glycosuria appears.

Diabetic patients with normal kidney function do not appear to be at increased risk for contrast nephropathy. If a contrast study is considered essential, patients with a serum creatinine of 1.5–2.5 mg/dL should be adequately hydrated before the procedure. Hydration with saline has been the cornerstone of contrast nephropathy prevention: intravenous saline 1 mL/kg/h is started 12 hours before the procedure and continued for 12 hours afterward. Radiographic contrast material should not be given to a patient with a serum creatinine greater than 3 mg/dL unless the potential benefit outweighs the high risk of acute kidney injury.

C. Diabetic Neuropathy

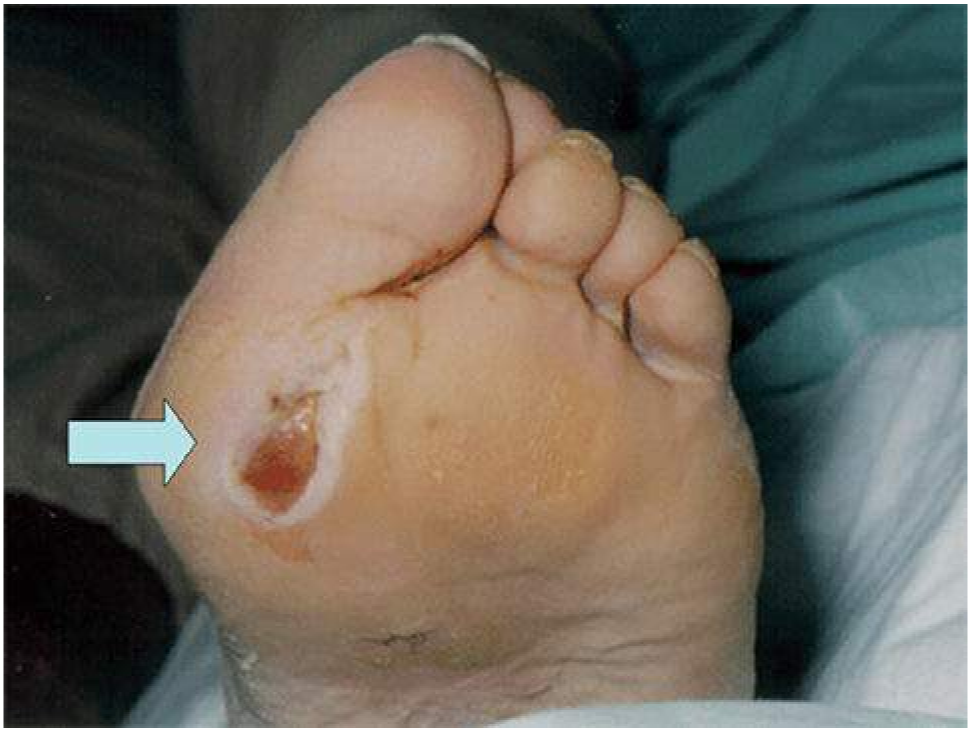
Diabetic neuropathies are the most common complications of diabetes, affecting up to 50% of older patients with type 2 diabetes.

1. Peripheral neuropathy—

A. DISTAL SYMMETRIC POLYNEUROPATHY—This is the most common form of diabetic peripheral neuropathy where loss of function appears in a stocking-glove pattern and is due to an axonal neuropathic process. Longer nerves are especially vulnerable, hence the impact on the foot. Both motor and sensory nerve conduction is delayed in the peripheral nerves, and ankle jerks may be absent.

Sensory involvement usually occurs first and is generally bilateral, symmetric, and associated with dulled perception of vibration, pain, and temperature. The pain can range from mild discomfort to severe incapacitating symptoms. The sensory deficit may eventually be of sufficient degree to prevent patients from feeling pain. Patients who have a sensory neuropathy should therefore be examined with a 5.07 Semmes-Weinstein filament and those who cannot feel the filament must be considered at risk for unperceived neuropathic injury.

The denervation of the small muscles of the foot results in clawing of the toes and displacement of the submetatarsal fat pads anteriorly. These changes, together with the joint and connective tissue changes, alter the biomechanics of the foot and increase plantar pressures. This combination of decreased pain threshold, abnormally high foot pressures, and repetitive stress (such as from walking) can lead to calluses and ulcerations in the high-pressure areas such as over the metatarsal heads (Figure 27–3). Peripheral neuropathy, autonomic neuropathy, and trauma also predisposes to the development of Charcot arthropathy. An acute case of Charcot foot arthropathy presents with pain and swelling, and if left untreated, leads to a “rocker bottom” deformity and ulceration. The early radiologic changes show joint subluxation and periarticular fractures. As the process progresses, there is frank osteoclastic destruction leading to deranged and unstable joints particularly in the midfoot. Not surprisingly, the key issue for the healing of neuropathic ulcers in a foot with good vascular supply is mechanical unloading. In addition, any infection should be treated with debridement and appropriate antibiotics; healing duration of 8–10 weeks is typical. Occasionally, when healing appears refractory, platelet-derived growth factor (becaplermin [Regranex]) should be considered for local application. A post-marketing epidemiologic study showed increased cancer deaths in patients who had used three or more tubes of becaplermin on their leg or feet ulcers, resulting in a “black box” warning on the medication label. Once ulcers are healed, therapeutic footwear is key to preventing recurrences. Custom molded shoes are reserved for patients with significant foot deformities. Other patients with neuropathy may require accommodative insoles that distribute the load over as wide an area as possible. Patients with foot deformities and loss of their protective threshold should get regular care from a podiatrist. Patients should be educated on appropriate footwear and those with loss of their protective threshold should be instructed to inspect their feet daily for reddened areas, blisters, abrasions, or lacerations.



▲ **Figure 27–3. Diabetic foot ulcer over head of first metatarsal (arrow).** (Used, with permission, from Dean SM, Satiani B, Abraham WT. Color Atlas and Synopsis of Vascular Diseases. McGraw-Hill, 2014.)

In some patients, hypersensitivity to light touch and occasionally severe "burning" pain, particularly at night, can become physically and emotionally disabling. Nortriptyline or desipramine in doses of 25–150 mg/day orally may provide dramatic relief for pain from diabetic neuropathy, often within 48–72 hours. This rapid response is in contrast to the 2 or 3 weeks required for an antidepressive effect. Patients often attribute the benefit to having a full night's sleep. Mild to moderate morning drowsiness is a side effect that generally improves with time or can be lessened by giving the medication several hours before bedtime. This medication should not be continued if improvement has not occurred after 5 days of therapy. Amitriptyline, 25–75 mg orally at bedtime, can also be used but has more anticholinergic effects. Tricyclic antidepressants, in combination with fluphenazine (3 mg daily in three divided doses) have been shown in two studies to be efficacious in painful neuropathy, with benefits unrelated to relief of depression. Gabapentin (900–1800 mg orally daily in three divided doses) has also been shown to be effective in the treatment of painful neuropathy and should be tried if the tricyclic medications prove ineffective. Pregabalin, a congener of gabapentin, has been shown in an 8-week study to be more effective than placebo in treating painful diabetic peripheral neuropathy. However, this medication was not compared with an active control. Also, because of its abuse potential, it has been categorized as a schedule V controlled substance. Duloxetine (60–120 mg), a serotonin and norepinephrine reuptake inhibitor, is approved for the treatment of painful diabetic neuropathy. Capsaicin, a topical irritant, is effective in reducing local nerve pain; it is dispensed as a cream (Zostrix 0.025%, Zostrix-HP 0.075%) to be rubbed into the skin over the painful region two to four times daily. Gloves should be used for application since hand contamination could result in discomfort if the cream comes in contact with eyes or sensitive areas such as the genitalia. Application of a 5% lidocaine patch over an area of maximal pain has been reported to be of benefit. It is approved for treatment of postherpetic neuralgia.

Diabetic neuropathic cachexia is a syndrome characterized by a symmetric peripheral neuropathy associated with profound weight loss (up to 60% of total body weight) and painful dysesthesias affecting the proximal lower limbs, the hands, or the lower trunk. Treatment is usually with insulin and analgesics. The prognosis is generally good, and patients typically recover their baseline weight with resolution of the painful sensory symptoms within 1 year.

B. ISOLATED PERIPHERAL NEUROPATHY—Involvement of the distribution of only one nerve (“mononeuropathy”) or of several nerves (“mononeuropathy multiplex”) is characterized by sudden onset with subsequent recovery of all or most of the function. This neuropathology has been attributed to vascular ischemia or traumatic damage. Cranial and femoral nerves are commonly involved, and motor abnormalities predominate. The patient with cranial nerve involvement usually has diplopia and single third, fourth, or sixth nerve weakness on examination but the pupil is spared. A full recovery of function occurs in 6–12 weeks. Diabetic amyotrophy presents with onset of severe pain in the front of the thigh. Within a few days or weeks of the onset of pain, weakness and wasting of the quadriceps develops. As the weakness appears, the pain tends to improve. Management includes analgesia and improved diabetes control. The symptoms improve over 6–18 months.

2. Autonomic neuropathy—Neuropathy of the autonomic system occurs principally in patients with diabetes of long duration. It affects many diverse visceral functions including blood pressure and pulse, gastrointestinal activity, bladder function, and erectile dysfunction. Treatment is directed specifically at each abnormality.

Involvement of the gastrointestinal system may be manifested by nausea, vomiting, postprandial fullness, reflux or dysphagia, constipation or diarrhea (or both), and fecal incontinence. Gastroparesis should be considered in type 1 diabetic patients in whom unexpected fluctuations and variability in their blood glucose levels develops after meals. Metoclopramide has been of some help in treating diabetic gastroparesis. It is given in a dose of 10 mg orally three or four times a day, 30 minutes before meals and at bedtime. Drowsiness, restlessness, fatigue, and lassitude are common adverse effects. Tardive dyskinesia and extrapyramidal effects can occur, especially when used for longer than 3 months, and the FDA has cautioned against the long-term use of metoclopramide.

Erythromycin appears to bind to motilin receptors in the stomach and has been found to improve gastric emptying over the short term in doses of 250 mg three times daily, but its effectiveness seems to diminish over time. In selected patients, injections of botulinum toxin into the pylorus can reduce pylorus sphincter resistance and enhance gastric emptying. Gastric electrical stimulation has been reported to improve symptoms and quality of life indices in patients with gastroparesis refractory to pharmacologic therapy.

Diarrhea associated with autonomic neuropathy has occasionally responded to broad-spectrum antibiotic therapy (such as rifaximin, metronidazole, amoxicillin/clavulanate, ciprofloxacin, or doxycycline), although it often undergoes spontaneous remission. Refractory diabetic diarrhea is often associated with impaired sphincter control and fecal incontinence. Therapy with loperamide, 4–8 mg daily, or diphenoxylate with atropine, two tablets up to four times a day, may provide relief. In more severe cases, tincture of paregoric or codeine (60-mg tablets) may be required to reduce the frequency of diarrhea and improve the consistency of the stools. Clonidine has been reported to lessen diabetic diarrhea; however, its usefulness is limited by its tendency to lower blood pressure in these patients who already have autonomic neuropathy, resulting in orthostatic hypotension. Constipation usually responds to stimulant laxatives such as senna.

Incomplete emptying of the bladder can sometimes occur. Bethanechol in doses of 10–50 mg orally three times a day has occasionally improved emptying of the atonic urinary bladder. Catheter decompression of the distended bladder has been reported to improve its function, and considerable benefit has been reported after surgical severing of the internal vesicle sphincter.

Use of Jobst fitted stockings, tilting the head of the bed, and arising slowly from the supine position can be helpful in treating symptoms of orthostatic hypotension. When such measures are inadequate, then treatment with fludrocortisone 0.1–0.2 mg orally daily can be considered. This medication, however, can result in supine hypertension and hypokalemia. Midodrine (10 mg orally three times a day), an alpha-agonist, can also be used.

Erectile dysfunction can result from neurologic, psychological, or vascular causes, or a combination of these causes. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) have been shown in placebo-controlled clinical trials to improve erections in response to sexual stimulation. The recommended dose of sildenafil for most patients is one 50-mg tablet taken approximately 1 hour before sexual activity. The peak effect is at 1.5–2 hours, with some effect persisting for 4 hours. Patients with diabetes mellitus using sildenafil reported 50–60% improvement in erectile function. The maximum recommended dose is 100 mg. The recommended dose of both vardenafil and tadalafil is 10 mg. The doses may be increased to 20 mg or decreased to 5 mg based on efficacy and side effects. Tadalafil has been shown to improve erectile function for up to 36 hours after dosing. Low doses are available for daily use. In clinical trials, only a few adverse effects have been reported—transient mild headache, flushing, dyspepsia, and some altered color vision. Priapism can occur with these medications, and patients should be advised to seek immediate medical attention if an erection persists for longer than 4 hours. These phosphodiesterase type 5 (PDE5) inhibitors potentiate the hypotensive effects of nitrates and their use is contraindicated in patients who are concurrently using organic nitrates in any form. Caution is advised for men who have suffered a heart attack, stroke, or life-threatening arrhythmia within the previous 6 months; men who have resting hypotension or hypertension; and men who have a history of heart failure or have unstable angina. Rarely, a decrease in vision or permanent visual loss has been reported after PDE5 inhibitor use.

Intracorporeal injection of vasoactive medications causes penile engorgement and erection. Medications most commonly used include papaverine alone, papaverine with phentolamine, and alprostadil (prostaglandin E_1). Alprostadil injections are relatively painless, but careful instruction is essential to prevent local trauma, priapism, and fibrosis. Intraurethral pellets of alprostadil avoid the problem of injection of the medication.

External vacuum therapy (Erec-Aid System) is a nonsurgical treatment consisting of a suction chamber operated by a hand pump that creates a vacuum around the penis. This draws blood into the penis to produce an erection that is maintained by a specially designed tension ring inserted around the base of the penis and which can be kept in place for up to 20–30 minutes. While this method is generally effective, its cumbersome nature limits its appeal.

Surgical implants of penile prostheses remain an option for those patients in whom the nonsurgical approaches are ineffective.

D. Cardiovascular Complications

1. Heart disease—Microangiopathy occurs in the heart and may explain the etiology of congestive cardiomyopathies in diabetic patients who do not have demonstrable coronary artery disease. More commonly, however, heart disease in patients with diabetes is due to coronary atherosclerosis. Myocardial infarction is three to five times more common in diabetic patients and is the leading cause of death in patients with type 2 diabetes. Cardiovascular disease risk is increased in patients with type 1 diabetes as well, although the absolute risk is lower than in patients with type 2 diabetes. Premenopausal women who normally have lower rates of coronary artery disease lose this protection once diabetes develops. The increased risk in patients with type 2 diabetes reflects the combination of hyperglycemia, hyperlipidemia, abnormalities of platelet adhesiveness, coagulation factors, hypertension, oxidative stress, and inflammation. Large intervention studies of risk factor reduction in diabetes are lacking, but it is reasonable to assume that reducing these risk factors would have a beneficial effect. Lowering LDL cholesterol reduces first events in patients without known coronary disease and secondary events in patients with known coronary disease. These intervention studies included some patients with diabetes, and the benefits of LDL cholesterol lowering was apparent in this group. The National Cholesterol Education Program clinical practice guidelines have designated diabetes as a coronary risk equivalent and have recommended that patients with diabetes should have an LDL cholesterol goal of less than 100 mg/dL (2.6 mmol/L). Lowering LDL cholesterol to 70 mg/dL (1.8 mmol/L) may have additional benefit and is a reasonable target for most patients with type 2 diabetes who have multiple risk factors for cardiovascular disease.

Aspirin at a dose of 81–325 mg daily is effective in reducing cardiovascular morbidity and mortality in patients who have a history of myocardial infarction or stroke (secondary prevention). For primary prevention, a 2018 randomized study of 15,480 persons with diabetes but no evident cardiovascular disease observed that 100 mg aspirin reduced the first vascular event of myocardial infarction, stroke or transient ischemic attack or death from vascular event (excluding intracranial hemorrhage) (rate ratio 0.88; 95% confidence interval 0.79 to 0.97). There were, however, more major bleeding events, especially gastrointestinal, in the aspirin group (rate ratio 1.29; 95% confidence interval 1.09 to 1.52). Thus, for primary prevention, the use of aspirin should only be considered for patients with high cardiovascular risk and low bleeding risk and generally not for adults older than 70 years. Based on the Early Treatment Diabetic Retinopathy Study (ETDRS), there does not appear to be a contraindication to aspirin use to achieve cardiovascular benefit in diabetic patients who have proliferative retinopathy. Aspirin also does not seem to affect the severity of vitreous/preretinal hemorrhages or their resolution.

2. Hypertension—The ADA also recommends lowering systolic blood pressure to less than 140 mm Hg and diastolic pressure to less than 90 mm Hg in patients with diabetes. The systolic target of 130 mm Hg or less and diastolic target of 80 mm Hg or less are recommended for the younger patient if they can be achieved without undue treatment burden. The Systolic Blood Pressure Intervention Trial (SPRINT) reported that treating to a systolic blood pressure of less than 120 mm Hg reduced cardiovascular events by 25% and death from cardiovascular causes by 43% during 3.26 years of follow-up. People with diabetes, however, were excluded from this study, and it is unclear if the results are applicable to this population. Patients with type 2 diabetes who already have cardiovascular disease or microalbuminuria should be considered for treatment with an ACE inhibitor. More clinical studies are needed to address the question of whether patients with type 2 diabetes who do not have cardiovascular disease or microalbuminuria would specifically benefit from ACE inhibitor treatment.

3. Peripheral vascular disease—Atherosclerosis is markedly accelerated in the larger arteries. It is often diffuse, with localized enhancement in certain areas of turbulent blood flow, such as at the bifurcation of the aorta or other large vessels. Clinical manifestations of peripheral vascular disease include ischemia of the lower extremities, erectile dysfunction, and intestinal angina.

The incidence of **gangrene of the feet** in patients with diabetes is 30 times that in age-matched controls. The factors responsible for its development, in addition to peripheral vascular disease, are small vessel disease, peripheral neuropathy with loss of both pain sensation and neurogenic inflammatory responses, and secondary infection. In two-thirds of patients with ischemic gangrene, pedal pulses are not palpable. In the remaining one-third who have palpable pulses, reduced blood flow through these vessels can be demonstrated by plethysmographic or Doppler ultrasound examination. Prevention of foot injury is imperative. Agents that reduce peripheral blood flow such as tobacco should be avoided. Control of other risk factors such as hypertension is essential. Beta-blockers are relatively contraindicated because of presumed negative peripheral hemodynamic consequences but data that support this are lacking. Cholesterol-lowering agents are useful as adjunctive therapy when early ischemic signs are detected and when dyslipidemia is present. Patients should be advised to seek immediate medical care if a diabetic foot ulcer develops. Improvement in peripheral blood flow with endarterectomy and bypass operations is possible in certain patients.

E. Skin and Mucous Membrane Complications

Chronic pyogenic infections of the skin may occur, especially in poorly controlled diabetic patients. Candidal infection can produce erythema and edema of intertriginous areas below the breasts, in the axillas, and between the fingers. It causes vulvovaginitis in women with chronically uncontrolled diabetes who have persistent glucosuria and is a frequent cause of pruritus. While antifungal creams containing miconazole or clotrimazole offer immediate relief of vulvovaginitis, recurrence is frequent unless glucosuria is reduced.

In some patients with type 2 diabetes, poor glycemic control can cause a severe hypertriglycemia, which can present as eruptive cutaneous xanthomas and pancreatitis. The skin lesions appear as yellow morbilliform eruptions 2–5 mm in diameter with erythematous areolae. They occur on extensor surfaces (elbows, knees, buttocks) and disappear after triglyceride levels are reduced.

Necrobiosis lipoidica diabeticorum is usually located over the anterior surfaces of the legs or the dorsal surfaces of the ankles. They are oval or irregularly shaped plaques with demarcated borders and a glistening yellow surface and occur in women two to four times more frequently than in men. Pathologically, the lesions show degeneration of collagen, granulomatous inflammation of subcutaneous tissues and blood vessels, capillary basement membrane thickening and obliteration of vessel lumina. The condition is associated with type 1 diabetes, although it can occur in patients with type 2 diabetes, and also in patients without diabetes. First-line therapy includes topical and subcutaneous corticosteroids. Improving glycemic control may help the condition.

“Shin spots” are not uncommon in adults with diabetes. They are brownish, rounded, painless atrophic lesions of the skin in the pretibial area.

F. Bone and Joint Complications

Long-standing diabetes can cause progressive stiffness of the hand secondary to contracture and tightening of skin over the joints (diabetic cheiroarthropathy), frozen shoulder (adhesive capsulitis), carpal tunnel syndrome, and Dupuytren contractures. These complications are believed to be due to glycosylation of collagen and perhaps other proteins in connective tissue. There may also be an inflammatory component.

Data on bone mineral density and fracture risk in people with diabetes are contradictory. Patients with type 2 diabetes do appear to be at increased risk for nonvertebral fractures. Women with type 1 diabetes have an increased risk of fracture when compared with women without diabetes. Other factors, such as duration of diabetes, and diabetes complications, such as neuropathy and kidney disease, likely affect both the bone mineral density and fracture risk.

Diffuse idiopathic skeletal hyperostosis (DISH) is characterized by ossification of the anterior longitudinal ligaments of the spine and various extraspinal ligaments. It causes stiffness and decreased range of spinal motion. The peripheral joints most commonly affected are the metacarpophalangeal joints, elbows, and shoulders. Diabetes, obesity, hypertension, and dyslipidemia are risk factors for this condition.

Hyperuricemia and acute and tophaceous gout are more common in type 2 diabetes.

Bursitis, particularly of the shoulders and hips, occurs more frequently than expected in patients with diabetes.

Special Situations

A. Diabetes Management in the Hospital

Most patients with diabetes are hospitalized for reasons other than their diabetes. Indeed, up to 10–15% of all hospitalized patients have diabetes. It is challenging using outpatient oral therapies or insulin regimens in the hospital because patients are not eating as usual; they are often fasting for procedures; clinical events increase adverse reactions associated with diabetes medicines, eg, thiazolidinediones can cause fluid retention and worsen heart failure; metformin should not be used in patients with significant chronic kidney or liver disease, or those getting contrast for radiographic studies. Subcutaneous or intravenous insulin therapy is frequently substituted for other diabetes medicines because the insulin dose can be adjusted to match changing inpatient needs and it is safe to use insulin in patients with heart, kidney, and liver disease.

Surgery represents a stress situation during which most of the insulin antagonists (eg, catecholamines, growth hormone, and corticosteroids) are mobilized. In the diabetic patient, this can lead to a worsening of hyperglycemia and perhaps even ketoacidosis. The aim of medical management of people with diabetes during the perioperative period is to minimize these stress-induced changes. Recommendations for management depend both on the patient’s usual diabetic regimen and on the type of surgery (major or minor) to be done (see also Chapter 3).

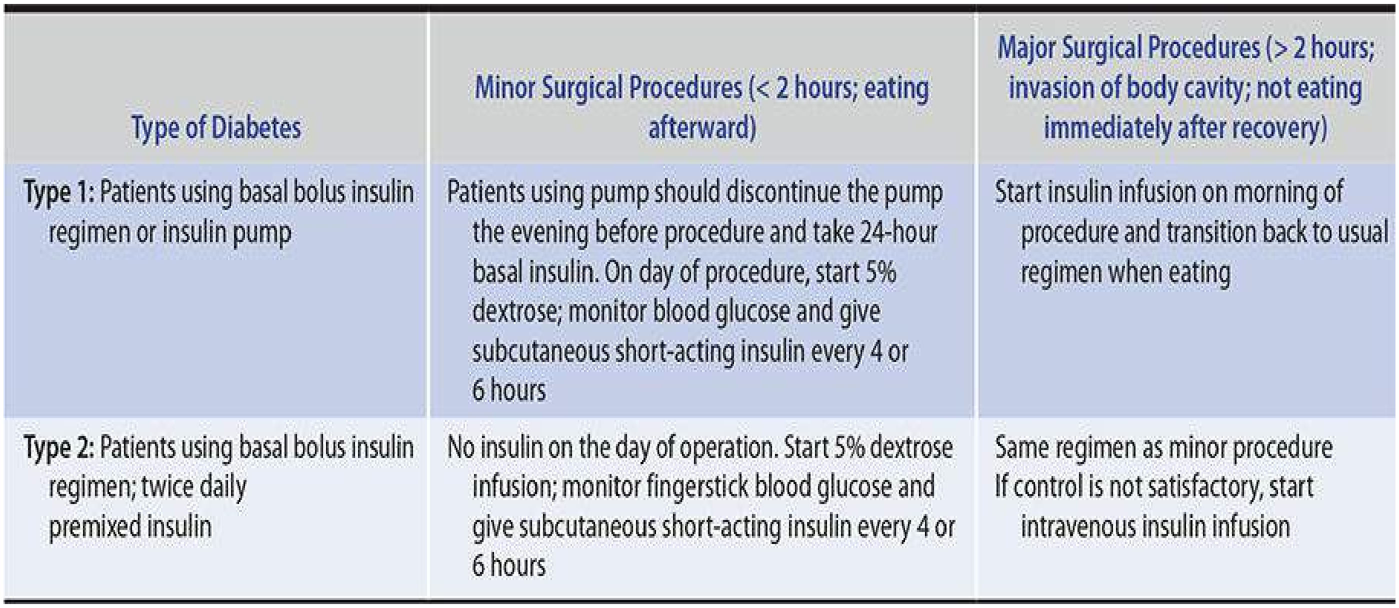
For people with diabetes controlled with diet alone, no special precautions must be taken unless diabetic control is markedly disturbed by the procedure. If this occurs, small doses of short-acting insulin as needed will correct the hyperglycemia.

Patients taking oral agents should not take them on the day of surgery. If there is significant hyperglycemia, small doses of short-acting insulin are given as needed. If this approach does not provide adequate control, an insulin infusion should be started in the manner indicated below. The oral agents can be restarted once the patient is eating normally after the operation. It is important to order a postoperative serum creatinine level to ensure adequate kidney function prior to restarting metformin therapy.

Patients taking insulin represent the only serious challenge to management of diabetes when surgery is necessary. However, with careful attention to changes in the clinical or laboratory picture, glucose control can be managed successfully. The protocol used to control the glucose depends on the kind of diabetes (type 1 or type 2);

whether it is minor surgery (lasting less than 2 hours and patient eating afterwards) or major surgery (lasting more than 2 hours, with invasion of a body cavity, and patient not eating afterwards); and the preoperative insulin regimen (basal bolus or premixed insulin twice a day or premeal bolus only or regular insulin before meals and NPH at bedtime). Patients with type 1 diabetes must be receiving some insulin to prevent the development of DKA. Many patients with type 2 diabetes who are taking insulin do well perioperatively without insulin for a few hours. Ideally, patients with diabetes should undergo surgery early in the morning. Table 27–11 summarizes the approach for these patients.

Table 27–11. Recommendations for management of insulin-treated diabetes during surgery.



Type of Diabetes	Minor Surgical Procedures (< 2 hours; eating afterward)	Major Surgical Procedures (> 2 hours; invasion of body cavity; not eating immediately after recovery)
Type 1: Patients using basal bolus insulin regimen or insulin pump	Patients using pump should discontinue the pump the evening before procedure and take 24-hour basal insulin. On day of procedure, start 5% dextrose; monitor blood glucose and give subcutaneous short-acting insulin every 4 or 6 hours	Start insulin infusion on morning of procedure and transition back to usual regimen when eating
Type 2: Patients using basal bolus insulin regimen; twice daily premixed insulin	No insulin on the day of operation. Start 5% dextrose infusion; monitor fingerstick blood glucose and give subcutaneous short-acting insulin every 4 or 6 hours	Same regimen as minor procedure If control is not satisfactory, start intravenous insulin infusion

One insulin infusion method adds 10 units of regular insulin to 1 L of 5% dextrose in 0.45% saline, and this is infused intravenously at a rate of 100–180 mL/h. This gives the patient 1–1.8 units of insulin per hour which, except in the most severe cases, generally keeps the blood glucose within the range of 100–250 mg/dL (5.5–13.9 mmol/L). The infusion may be continued for several days, if necessary. Perioperatively, plasma glucose or blood glucose should be determined every 2–4 hours to be sure metabolic control is adequate. If it is not, adjustments in the ratio of insulin to dextrose in the intravenous solution can be made.

An alternative method consists of separate infusions of insulin and glucose delivered by pumps to permit independent adjustments of each infusion rate, depending on hourly variation of blood glucose values. There are a number of different algorithms available for insulin infusions (see http://www.hospitalmedicine.org).

After surgery, when the patient has resumed an adequate oral intake, subcutaneous administration of insulin can be resumed and intravenous administration of insulin and dextrose can be stopped 30 minutes after the first subcutaneous dose. Insulin needs may vary in the first several days after surgery because of continuing postoperative stresses and because of variable caloric intake. In this situation, multiple doses of short-acting insulin plus some long-acting basal insulin, guided by blood glucose determinations, can keep the patient in acceptable metabolic control.

In the **intensive care units (ICUs),** glucose levels are controlled most frequently using insulin infusions. Patients receiving total parenteral nutrition can have insulin added to the bag. Standard total parenteral nutrition contains 25% dextrose so an infusion rate of 50 mL/h delivers 12.5 g of dextrose per hour.

Based on the evidence available, ICU patients with diabetes and new-onset hyperglycemia with blood glucose levels above 180 mg/dL (10 mmol/L) should be treated with insulin, aiming for target glucose levels between 140 mg/dL (7.8 mmol/L) and 180 mg/dL (10 mmol/L). In the ICU setting, aiming for blood glucose levels close to 100 mg/dL (5.6 mmol/L) is not beneficial and may even be harmful. When patients leave the ICU, target glucose values between 100 mg/dL (5.6 mmol/L) and 180 mg/dL (10 mmol/L) may be appropriate, although this view is based on clinical observations rather than conclusive evidence.

On the **general surgical and medical inpatient services,** most patients are treated with subcutaneous insulin regimens. Limited cross-sectional and prospective studies suggest that the best glucose control is achieved on a combination of basal and bolus regimen with 50% of daily insulin needs provided by intermediate- or long-acting insulins. Standardized order sets can reduce errors, and they often include algorithms for recognition and treatment of hypoglycemia (see http://ucsfinpatientdiabetes.pbworks.com for examples).

The morbidity and mortality in diabetic patients are twice those of nondiabetic patients. Those with new-onset hyperglycemia (ie, those without a preadmission diagnosis of diabetes) have even higher mortality—almost eightfold that of nondiabetic patients in one study. These observations have led to the question of whether tight glycemic control in the hospital improves outcomes.

Kansagara D et al. Intensive insulin therapy in hospitalized patients: a systematic review. Ann Intern Med. 2011 Feb 15;154(4):268–82. [PMID: 21320942]

B. Pregnancy and the Diabetic Patient

See Chapter 19. Tight glycemic control with normal HbA_{1c} levels is very important during pregnancy. Early in pregnancy, poor control increases the risk of spontaneous abortion and congenital malformations. Late in pregnancy, poor control can result in polyhydramnios, preterm labor, stillbirth, and fetal macrosomia with its associated problems. Diabetes complications can impact both maternal and fetal health. Diabetic retinopathy can first develop during pregnancy or retinopathy that is already present can worsen. Diabetic women with microalbuminuria can have worsening albuminuria during pregnancy and are at higher risk for preeclampsia. Aspirin can reduce the risk of preeclampsia and should be prescribed after 12 weeks of gestation. Patients who have preexisting kidney failure (prepregnancy creatinine clearance less than 80 mL/min) are at high risk for further decline in kidney function during the pregnancy, and this may not reverse after delivery. Diabetic gastroparesis can severely exacerbate the nausea and vomiting of pregnancy and some patients may require fluid and nutritional support.

Although there is evidence that glyburide is safe during pregnancy, the current practice is to control diabetes with insulin therapy. Every effort should be made, utilizing multiple injections of insulin or a continuous infusion of insulin by pump, to maintain near-normalization of fasting and preprandial blood glucose values while avoiding hypoglycemia.

Regular and NPH insulin and the insulin analogs lispro, aspart, and detemir are labeled pregnancy category B. Insulin glargine, glulisine, and degludec are labeled category C because of lack of clinical safety data. A small study using insulin glargine in 32 pregnancies did not reveal any problems.

Unless there are fetal or maternal complications, diabetic women should be able to carry the pregnancy to full-term, delivering at 38 to 41 weeks. Induction of labor before 39 weeks may be considered if there is concern about increasing fetal weight. See Chapter 19 for further details.

Prognosis

The DCCT showed that the previously poor prognosis for as many as 40% of patients with type 1 diabetes is markedly improved by optimal care. DCCT participants were generally young and highly motivated and were cared for in academic centers by skilled diabetes educators and endocrinologists who were able to provide more attention and services than are usually available. Improved training of primary care providers may be beneficial.

For type 2 diabetes, the UKPDS documented a reduction in microvascular disease with glycemic control, although this was not apparent in the obese subgroup.

Cardiovascular outcomes were not improved by glycemic control, although antihypertensive therapy showed benefit in reducing the number of adverse cardiovascular complications as well as in reducing the occurrence of microvascular disease among hypertensive patients. In patients with visceral obesity, successful management of type 2 diabetes remains a major challenge in the attempt to achieve appropriate control of hyperglycemia, hypertension, and dyslipidemia. Once safe and effective methods are devised to prevent or manage obesity, the prognosis of type 2 diabetes with its high cardiovascular risks should improve considerably.

In addition to poorly understood genetic factors relating to differences in individual susceptibility to development of long-term complications of hyperglycemia, it is clear that in both types of diabetes, the diabetic patient's intelligence, motivation, and awareness of the potential complications of the disease contribute significantly to the ultimate outcome.

When to Refer

- All patients should receive self-management education when diabetes is diagnosed and at intervals thereafter. The instructional team should include a registered dietitian and registered nurse; they must be Certified Diabetes Educators (CDEs).
- Patients with type 1 diabetes should be comanaged by an endocrinologist and a primary care provider.
- Patients with type 2 diabetes should be referred to an endocrinologist if treatment goals are not met or if the patient requires an increasingly complex regimen to maintain glycemic control.
- Patients with type 2 diabetes should be referred to an ophthalmologist or optometrist for a dilated eye examination when the diabetes is diagnosed, and patients with type 1 diabetes should be referred 5 years after the diagnosis is made.
- Patients with peripheral neuropathy, especially those with loss of protective threshold (unable to detect 5.07 Semmes-Weinstein filament) or structural foot problems, should be referred to a podiatrist.
- Referrals to other specialists may be required for management of chronic complications of diabetes.

DIABETIC COMA

Coma may be due to a variety of causes not directly related to diabetes. Certain causes directly related to diabetes require differentiation: (1) Hypoglycemic coma resulting from excessive doses of insulin or oral hypoglycemic agents. (2) Hyperglycemic coma associated with either severe insulin deficiency (DKA) or mild to moderate insulin deficiency (hyperglycemic hyperosmolar state). (3) Lactic acidosis associated with diabetes, particularly in patients with diabetes stricken with severe infections or with cardiovascular collapse.

DIABETIC KETOACIDOSIS

ESSENTIALS OF DIAGNOSIS

- Hyperglycemia greater than 250 mg/dL (13.9 mmol/L).
- Metabolic acidosis with blood pH < 7.3; serum bicarbonate less than 15 mEq/L.
- Serum positive for ketones.

General Considerations

Diabetic ketoacidosis (DKA) may be the initial manifestation of type 1 diabetes or may result from increased insulin requirements in type 1 diabetes patients during the course of infection, trauma, myocardial infarction, or surgery. It is a life-threatening medical emergency with a mortality rate just under 5% in individuals under 40 years of age, but with a more serious prognosis in older adults, who have mortality rates over 20%. The National Data Group reports an annual incidence of five to eight episodes of DKA per 1000 diabetic persons. Ketoacidosis may develop in patients with type 2 diabetes when severe stress such as sepsis or trauma is present. DKA is one of the more common serious complications of insulin pump therapy, occurring in approximately 1 per 80 patient-months of treatment. Many patients who monitor capillary blood glucose regularly ignore urine ketone measurements, which signals the possibility of insulin leakage or pump failure before serious illness develops. Poor compliance, either for psychological reasons or because of inadequate education, is one of the most common causes of recurrent DKA.

Clinical Findings

A. Symptoms and Signs

The appearance of DKA is usually preceded by a day or more of polyuria and polydipsia associated with marked fatigue, nausea, and vomiting. If untreated, mental stupor ensues that can progress to coma. Drowsiness is fairly common, but frank coma only occurs in about 10% of patients. On physical examination, evidence of dehydration in a stuporous patient with rapid deep breathing and a “fruity” breath odor of acetone strongly suggests the diagnosis. Hypotension with tachycardia indicates profound fluid and electrolyte depletion, and mild hypothermia is usually present. Abdominal pain and even tenderness may be present in the absence of abdominal disease. Conversely, cholecystitis or pancreatitis may occur with minimal symptoms and signs.

B. Laboratory Findings

Typically, the patient with moderately severe DKA has a plasma glucose of 350–900 mg/dL (19.4–50 mmol/L), serum ketones at a dilution of 1:8 or greater or beta-hydroxybutyrate more than 4 nmol/L, hyperkalemia (serum potassium level of 5–8 mEq/L), slight hyponatremia (serum sodium of approximately 130 mEq/L), hyperphosphatemia (serum phosphate level of 6–7 mg/dL [1.9–2.3 mmol/L]), and elevated blood urea nitrogen and serum creatinine levels (Table 27–12). Acidosis may be severe (pH ranging from 6.9 to 7.2 and serum bicarbonate ranging from 5 mEq/L to 15 mEq/L); PCO_2 is low (15–20 mm Hg) related to compensatory hyperventilation. Fluid depletion is marked, typically about 100 mL/kg.

Table 27–12. Laboratory diagnosis of coma in diabetic patients.

	Urine Glucose	Urine Ketones	Plasma Glucose	Plasma Bicarbonate	Plasma Ketones
Related to Diabetes					
Hypoglycemia	0[1]	0 or +	Low	Normal	0
Diabetic ketoacidosis	++++	++++	High	Low	++++
Hyperglycemic hyperosmolar state coma	++++	0	High	Normal or slightly low	0
Lactic acidosis	0 or +	0 or +	Normal or low or high	Low	0 or +
Unrelated to Diabetes					
Alcohol or other toxic drugs	0 or +	0 or +	May be low	Normal or low[2]	0 or +
Cerebrovascular accident or head trauma	+ or 0	0	Often high	Normal	0
Uremia	0 or +	0	High or normal	Low	0 or +

[1] Leftover urine in bladder might still contain glucose from earlier hyperglycemia.

[2] Alcohol can elevate plasma lactate as well as keto acids to reduce pH.

The difference between venous and arterial pH is 0.02 to 0.15 pH units and venous and arterial bicarbonate is 1.88 mEq/L. These small differences will not affect either the diagnosis or the management of DKA, and there is no need to collect arterial blood for measuring the acid-base status.

The hyperkalemia occurs despite total body potassium depletion because of the shift of potassium from the intracellular to extracellular spaces that occurs in systemic acidosis. The average total body potassium deficit resulting from osmotic diuresis, acidosis, and gastrointestinal losses is about 3–5 mEq/kg. Similarly, despite the elevated serum phosphate, total body phosphate is generally depleted. Serum sodium is generally reduced due to loss of sodium ions (7–10 mEq/kg) by polyuria and vomiting and because severe hyperglycemia shifts intracellular water into the interstitial compartment. For every 100 mg/dL of plasma glucose, serum sodium decreases by 1.6 mEq/L (5.56 mmol/L). The decrease in serum sodium may be greater when patients have more severe hyperglycemia (greater than 400 mg/dL, 22.2 mmol/L) and a correction factor of 2.4 mEq/L may be used. Hypertriglyceridemia should be considered if the corrected sodium is very low. Serum osmolality can be directly measured by standard tests of freezing point depression or can be estimated by calculating the molarity of sodium, chloride, and glucose in the serum. A convenient method of estimating effective serum osmolality is as follows (normal values in humans are 280–300 mOsm/kg):

$$\text{mOsm/kg} = 2\,[\text{measured Na}^+] + \frac{\text{Glucose (mg/dL)}}{18}$$

These calculated estimates are usually 10–20 mOsm/kg lower than values measured by standard cryoscopic techniques. Central nervous system depression or coma occurs when the effective serum osmolality exceeds 320–330 mOsm/L. Coma in a diabetic patient with a lower osmolality should prompt a search for cause of coma other than hyperosmolality (see Table 27–12 and Chapter 24).

Ketoacidemia represents the effect of insulin lack at multiple enzyme loci. Insulin lack associated with elevated levels of growth hormone, catecholamines, and glucagon contributes to increases in lipolysis from adipose tissue and in hepatic ketogenesis. In addition, reduced ketolysis by insulin-deficient peripheral tissues contributes to the ketoacidemia. The only true “keto” acid present is acetoacetic acid which, along with its by-product acetone, is measured by nitroprusside reagents (Acetest and Ketostix). The sensitivity for acetone, however, is poor, requiring over 10 mmol/L, which is seldom reached in the plasma of ketoacidotic patients—although this detectable concentration is readily achieved in urine. Thus, in the plasma of ketotic patients, only acetoacetate is measured by these reagents. The more prevalent beta-hydroxybutyric acid has no ketone group and is therefore not detected by conventional nitroprusside tests. This takes on special importance in the presence of circulatory collapse during DKA, wherein an increase in lactic acid can shift the redox state to increase beta-hydroxybutyric acid at the expense of the readily detectable acetoacetic acid. Bedside diagnostic reagents are then unreliable, suggesting no ketonemia in cases where beta-hydroxybutyric acid is a major factor in producing the acidosis. Combined glucose and ketone meters (Precision Xtra, Nova Max Plus) that measure blood beta-hydroxybutyrate concentration on capillary blood are available. Many clinical laboratories also offer direct blood beta-hydroxybutyrate measurement.

Nonspecific elevations of serum amylase and lipase occurs in about 16–25% of cases of DKA, and an imaging study may be necessary if the diagnosis of acute pancreatitis is being seriously considered. Leukocytosis as high as 25,000/mcL with a left shift may occur with or without associated infection. The presence of an elevated or even a normal temperature can suggest the presence of an infection, since patients with DKA are generally hypothermic if uninfected.

Treatment

Patients with mild DKA are alert and have pH levels between 7.25 and 7.30 and beta-hydroxybutyrate levels of 3–4 mmol/L; those with moderate ketoacidosis are either alert or little drowsy and have pH levels between 7.0 and 7.24 and beta-hydroxybutyrate levels of 4–8 mmol/L; and those with severe ketoacidosis are stuporose and have a pH < 7.0 and beta-hydroxybutyrate levels of greater than 8 mmol/L. Those with mild ketoacidosis can be treated in the emergency department, but those with moderate or severe ketoacidosis require admission to the ICU or step-down unit. Therapeutic goals are to restore plasma volume and tissue perfusion, reduce blood glucose and osmolality toward normal, correct acidosis, replenish electrolyte losses, and identify and treat precipitating factors. Gastric intubation is recommended in the comatose patient to prevent vomiting and aspiration that may occur as a result of gastric atony, a common complication of DKA. An indwelling catheter may also be necessary. In patients with preexisting heart or kidney failure or those in severe cardiovascular collapse, a central venous pressure catheter should be inserted to evaluate the degree of hypovolemia and to monitor subsequent fluid administration.

A comprehensive flow sheet that includes vital signs, serial laboratory data, and therapeutic interventions (eg, fluids, insulin) should be meticulously maintained by the clinician responsible for the patient's care. Plasma glucose should be recorded hourly and electrolytes and pH at least every 2–3 hours during the initial treatment period. Bedside glucose meters should be used to titrate the insulin therapy. The patient should not receive sedatives or opioids in order to avoid masking signs and symptoms of impeding cerebral edema.

A. Fluid Replacement

In most patients, the fluid deficit is 4–5 L. Initially, 0.9% saline solution is the solution of choice to help reexpand the contracted vascular volume and should be started in the emergency department as soon as the diagnosis is established. The saline should be infused rapidly to provide 1 L/h over the first 1–2 hours. After the first 2 L of fluid have been given, the intravenous infusion should be at the rate of 300–400 mL/h. Use 0.9% ("normal") saline unless the serum sodium is greater than 150 mEq/L, when 0.45% ("half normal") saline solution should be used. The volume status should be very carefully monitored. Failure to give enough volume replacement (at least 3–4 L in 8 hours) to restore normal perfusion is one of the most serious therapeutic shortcomings adversely influencing satisfactory recovery. Excessive fluid replacement (more than 5 L in 8 hours) may contribute to acute respiratory distress syndrome or cerebral edema. When blood glucose falls to approximately 250 mg/dL (13.9 mmol/L), the fluids should be changed to a 5% glucose-containing solution to maintain serum glucose in the range of 250–300 mg/dL (13.9–16.7 mmol/L). This will prevent the development of hypoglycemia and will also reduce the likelihood of cerebral edema, which could result from too rapid decline of blood glucose.

B. Insulin Replacement

Immediately after initiation of fluid replacement, regular insulin can be given intravenously in a loading dose of 0.1 unit/kg as a bolus to prime the tissue insulin receptors. Following the initial bolus, intravenous doses of insulin as low as 0.1 unit/kg/h are continuously infused or given hourly as an intramuscular injection; this is sufficient to replace the insulin deficit in most patients. A prospective randomized study showed that a bolus dose is not required if patients are given hourly insulin infusion at 0.14 unit/kg. Replacement of insulin deficiency helps correct the acidosis by reducing the flux of fatty acids to the liver, reducing ketone production by the liver, and also improving removal of ketones from the blood. Insulin treatment reduces the hyperosmolality by reducing the hyperglycemia. It accomplishes this by increasing removal of glucose through peripheral utilization as well as by decreasing production of glucose by the liver. This latter effect is accomplished by direct inhibition of gluconeogenesis and glycogenolysis as well as by lowered amino acid flux from muscle to liver and reduced hyperglucagonemia.

The insulin infusion should be “piggy-backed” into the fluid line so the rate of fluid replacement can be changed without altering the insulin delivery rate. If the plasma glucose level fails to fall at least 10% in the first hour, a repeat loading dose (0.1 or 0.14 unit/kg) is recommended. Rarely, a patient with immune insulin resistance is encountered, and this requires doubling the insulin dose every 2–4 hours if hyperglycemia does not improve after the first two doses of insulin. The insulin dose should be adjusted to lower the glucose concentration by about 50–70 mg/dL/h (2.8–3.9 mmol/L). If clinical circumstances prevent use of insulin infusion, then the insulin can be given intramuscularly. An initial 0.15 unit/kg of regular insulin is given intravenously, and at the same time, the same size dose is given intramuscularly. Subsequently, regular insulin is given intramuscularly hourly at a dose of 0.1 unit/kg until the blood glucose falls to around 250 mg/dL, when the insulin can be given subcutaneously. Patients who normally take insulin glargine or insulin detemir can be given their usual maintenance doses during initial treatment of their DKA. The continuation of their subcutaneous basal insulins means that lower doses of intravenous insulin will be needed, and there will be a smoother transition from intravenous insulin infusion to the subcutaneous regimen.

C. Potassium

Total body potassium loss from polyuria and vomiting may be as high as 200 mEq. However, because of shifts of potassium from cells into the extracellular space as a consequence of acidosis, serum potassium is usually normal to slightly elevated prior to institution of treatment. As the acidosis is corrected, potassium flows back into the cells, and hypokalemia can develop if potassium replacement is not instituted. If the patient is not uremic and has an adequate urinary output, potassium chloride in doses of 10–30 mEq/h should be infused during the second and third hours after beginning therapy as soon as the acidosis starts to resolve. Replacement should be started sooner if the initial serum potassium is inappropriately normal or low and should be delayed if serum potassium fails to respond to initial therapy and remains above 5 mEq/L, as in cases of chronic kidney disease. Occasionally, a patient may present with a serum potassium level less than 3.5 mEq/L, in which case insulin therapy should be delayed until the potassium level is corrected to greater than 3.5 mEq/L. An ECG can be of help in monitoring the patient's potassium status: High peaked T waves are a sign of hyperkalemia, and flattened T waves with U waves are a sign of hypokalemia. Foods high in potassium content should be prescribed when the patient has recovered sufficiently to take food orally. Tomato juice has 14 mEq of potassium per 240 mL, and a medium-sized banana provides about 10 mEq.

D. Sodium Bicarbonate

The use of sodium bicarbonate in management of DKA has been questioned since clinical benefit was not demonstrated in one prospective randomized trial and because of the following potentially harmful consequences: (1) development of hypokalemia from rapid shift of potassium into cells if the acidosis is overcorrected; (2) tissue anoxia from reduced dissociation of oxygen from hemoglobin when acidosis is rapidly reversed (leftward shift of the oxygen dissociation curve); and (3) cerebral acidosis resulting from lowering of cerebrospinal fluid pH. It must be emphasized, however, that these considerations are less important when very severe acidosis exists. Therefore, it is recommended that bicarbonate be administered in DKA if the arterial blood pH is 7.0 or less, with careful monitoring to prevent overcorrection. One or two ampules of sodium bicarbonate (one ampule contains 44 mEq/50 mL) should be added to 1 L of 0.45% saline with 20 mEq KCl or to 400 mL of sterile water with 20 mEq KCl and infused over 1 to 2 hours. (**Note:** Addition of sodium bicarbonate to 0.9% saline would produce a markedly hypertonic solution that could aggravate the hyperosmolar state already present.) It can be repeated until the arterial pH reaches 7.1, but it should not be given if the pH is 7.1 or greater since additional bicarbonate would increase the risk of rebound metabolic alkalosis as ketones are metabolized. Alkalosis shifts potassium from serum into cells, which could precipitate a fatal cardiac arrhythmia.

E. Phosphate

Phosphate replacement is seldom required in treating DKA. However, if severe hypophosphatemia of less than 1 mg/dL (0.32 mmol/L) develops during insulin therapy, a small amount of phosphate can be replaced per hour as the potassium salt. Three randomized studies, though, in which phosphate was replaced in patients with DKA did not show any apparent clinical benefit from phosphate administration. Moreover, attempts to use potassium phosphate as the sole means of replacing potassium have led to a number of reported cases of severe hypocalcemia with tetany. To minimize the risk of inducing tetany from too-rapid replacement of phosphate, the average deficit of 40–50 mmol of phosphate should be replaced intravenously at a rate no greater than 3–4 mmol/h in a 60- to 70-kg person. A stock solution (Abbott) provides a mixture of 1.12 g KH_2PO_4 and 1.18 g K_2HPO_4 in a 5-mL single-dose vial (this equals 22 mmol of potassium and 15 mmol of phosphate). One-half of this vial (2.5 mL) should be added to 1 L of either 0.45% saline or 5% dextrose in water. Two liters of this solution, infused at a rate of 400 mL/h, will correct the phosphate deficit at the optimal rate of 3 mmol/h while providing 4.4 mEq of potassium per hour. (Additional potassium should be administered as potassium chloride to provide a total of 10–30 mEq of potassium per hour, as noted above.) If the serum phosphate remains below 2.5 mg/dL (0.8 mmol/L) after this infusion, a repeat 5-hour infusion can be given.

F. Hyperchloremic Acidosis During Therapy

Because of the considerable loss of keto acids in the urine during the initial phase of therapy, substrate for subsequent regeneration of bicarbonate is lost and correction of the total bicarbonate deficit is hampered. A portion of the bicarbonate deficit is replaced with chloride ions infused in large amounts as saline to correct the dehydration. In most patients, as the ketoacidosis clears during insulin replacement, a hyperchloremic, low-bicarbonate pattern emerges with a normal anion gap. This is a relatively benign condition that reverses itself over the subsequent 12–24 hours once intravenous saline is no longer being administered. Using a balanced electrolyte solution with a pH of 7.4 and 98 mEq/L chloride instead of normal saline (pH ~ 5.5; chloride 154 mEq/L) similar to serum in chloride concentration and pH during resuscitation instead of normal saline has been reported to prevent the hyperchloremic acidosis.

G. Treatment of Associated Infection

Antibiotics are prescribed as indicated (Table 30–5). Cholecystitis and pyelonephritis may be particularly severe in these patients.

H. Transition to Subcutaneous Insulin Regimen

Once the DKA is controlled and the patient is awake and able to eat, subcutaneous insulin therapy can be initiated. The patient with type 1 diabetes may have persistent significant tissue insulin resistance and may require a total daily insulin dose of approximately 0.6 unit/kg. The amount of insulin required in the previous 8 hours can also be helpful in estimating the initial insulin doses. Half the total daily dose can be given as a long-acting basal insulin and the other half as short-acting insulin premeals. The patient should receive subcutaneous basal insulin and rapid-acting insulin analog with the first meal and the insulin infusion discontinued an hour later. The overlap of the subcutaneous insulin action and insulin infusion is necessary to prevent relapse of the

DKA. In patients with preexisting diabetes, giving their basal insulin by subcutaneous injection at initiation of treatment simplifies the transition from intravenous to subcutaneous regimen. The increased insulin resistance is only present for a few days, and it is important to reduce both the basal and bolus insulins to avoid hypoglycemia. A patient with new-onset type 1 diabetes usually still has significant beta cell function and may not need any basal insulin and only very low doses of rapid-acting insulin before meals after recovery from the ketoacidosis. Patients with type 2 diabetes and DKA due to severe illness may initially require insulin therapy but can often transition back to oral agents during outpatient follow-up.

Prognosis

Low-dose insulin infusion and fluid and electrolyte replacement combined with careful monitoring of patients' clinical and laboratory responses to therapy have dramatically reduced the mortality rates of DKA to less than 5%. However, this complication remains a significant risk in the aged who have mortality rates greater than 20% and in patients in profound coma in whom treatment has been delayed. Acute myocardial infarction and infarction of the bowel following prolonged hypotension worsen the outlook. A serious prognostic sign is end-stage chronic kidney disease, and prior kidney dysfunction worsens the prognosis considerably because the kidney plays a key role in compensating for massive pH and electrolyte abnormalities. Symptomatic cerebral edema occurs primarily in the pediatric population. Risk factors for its development include severe baseline acidosis, rapid correction of hyperglycemia, and excess volume administration in the first 4 hours. Onset of headache or deterioration in mental status during treatment should lead to consideration of this complication. Intravenous mannitol at a dosage of 1–2 g/kg given over 15 minutes is the mainstay of treatment. Excess crystalloid infusion can precipitate pulmonary edema. Acute respiratory distress syndrome is a rare complication of treatment of DKA.

After recovery and stabilization, patients should be instructed on how to recognize the early symptoms and signs of ketoacidosis. Urine ketones or capillary blood beta-hydroxybutyrate should be measured in patients with signs of infection or in insulin pump-treated patients when capillary blood glucose remains unexpectedly and persistently high. When heavy ketonuria and glycosuria persist on several successive examinations, supplemental rapid acting insulin should be administered and liquid foods such as lightly salted tomato juice and broth should be ingested to replenish fluids and electrolytes. The patient should be instructed to contact the clinician if ketonuria persists, and especially if there is vomiting and inability to keep down fluids. Recurrent episodes of severe ketoacidosis often indicate poor compliance with the insulin regimen, and these patients will require intensive counseling.

Savage MW et al. Joint British Diabetes Societies guideline for the management of diabetic ketoacidosis. Diabet Med. 2011 May;28(5):508–15. [PMID: 21255074]

HYPERGLYCEMIC HYPEROSMOLAR STATE

ESSENTIALS OF DIAGNOSIS

- Hyperglycemia greater than 600 mg/dL (33.3 mmol/L).
- Serum osmolality greater than 310 mOsm/kg.
- No acidosis; blood pH > 7.3.
- Serum bicarbonate greater than 15 mEq/L.
- Normal anion gap (less than 14 mEq/L).

General Considerations

This second most common form of hyperglycemic coma is characterized by severe hyperglycemia in the absence of significant ketosis, with hyperosmolality and dehydration. It occurs in patients with mild or occult diabetes, and most patients are typically middle-aged to elderly. Accurate figures are not available as to its true incidence, but from data on hospital discharges it is rarer than DKA even in older age groups. Underlying chronic kidney disease or heart failure is common, and the presence of either worsens the prognosis. A precipitating event such as infection, myocardial infarction, stroke, or recent operation is often present. Certain medications such as phenytoin, diazoxide, corticosteroids, and diuretics have been implicated in its pathogenesis, as have procedures associated with glucose loading such as peritoneal dialysis.

Pathogenesis

A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization of muscle, fat, and liver while inducing hyperglucagonemia and increasing hepatic glucose output. With massive glycosuria, obligatory water loss ensues. If a patient is unable to maintain adequate fluid intake because of an associated acute or chronic illness or has suffered excessive fluid loss, marked dehydration results. As the plasma volume contracts, kidney function becomes impaired, limiting the urinary glucose losses and exacerbating the hyperglycemia. Severe hyperosmolality develops that causes mental confusion and finally coma. It is not clear why ketosis is virtually absent under these conditions of insulin insufficiency, although reduced levels of growth hormone may be a factor, along with portal vein insulin concentrations sufficient to restrain ketogenesis.

Clinical Findings

A. Symptoms and Signs

Onset may be insidious over a period of days or weeks, with weakness, polyuria, and polydipsia. The lack of features of ketoacidosis may retard recognition of the syndrome and delay therapy until dehydration becomes more profound than in ketoacidosis. Reduced intake of fluid is not an uncommon historical feature, due to either inappropriate lack of thirst, nausea, or inaccessibility of fluids to elderly, bedridden patients. A history of ingestion of large quantities of glucose-containing fluids, such as soft drinks or orange juice, can occasionally be obtained. Lethargy and confusion develop as serum osmolality exceeds 310 mOsm/kg, and convulsions and coma can occur if osmolality exceeds 320–330 mOsm/kg. Physical examination confirms the presence of profound dehydration in a lethargic or comatose patient without Kussmaul respirations.

B. Laboratory Findings

Severe hyperglycemia is present, with blood glucose values ranging from 800 mg/dL to 2400 mg/dL (44.4 mmol/L to 133.2 mmol/L) (Table 27–12). In mild cases, where dehydration is less severe, dilutional hyponatremia as well as urinary sodium losses may reduce serum sodium to 120–125 mEq/L, which protects to some extent against extreme hyperosmolality. However, as dehydration progresses, serum sodium can exceed 140 mEq/L, producing serum osmolality readings of 330–440 mOsm/kg. Ketosis and acidosis are usually absent or mild. Prerenal azotemia is the rule, with serum urea nitrogen elevations over 100 mg/dL (35.7 mmol/L) being typical.

Treatment

A. Fluid Replacement

Fluid replacement is of paramount importance in treating nonketotic hyperglycemic coma. The onset of hyperosmolarity is more insidious in elderly people without ketosis than in younger individuals with high serum ketone levels, which provide earlier indicators of severe illness (vomiting, rapid deep breathing, acetone odor, etc).

Consequently, diagnosis and treatment are often delayed until fluid deficit has reached levels of 6–10 L.

If hypovolemia is present as evidenced by hypotension and oliguria, fluid therapy should be initiated with 0.9% saline. In all other cases, 0.45% saline appears to be preferable as the initial replacement solution because the body fluids of these patients are markedly hyperosmolar. As much as 4–6 L of fluid may be required in the first 8–10 hours. Careful monitoring of the patient is required for proper sodium and water replacement. An important end point of fluid therapy is to restore urinary output to 50 mL/h or more. Once blood glucose reaches 250 mg/dL (13.9 mmol/L), fluid replacement should include 5% dextrose in either water, 0.45% saline solution, or 0.9% saline solution. The rate of dextrose infusion should be adjusted to maintain glycemic levels of 250–300 mg/dL (13.9–16.7 mmol/L) in order to reduce the risk of cerebral edema.

B. Insulin

Less insulin may be required to reduce the hyperglycemia in nonketotic patients as compared to those with diabetic ketoacidotic coma. In fact, fluid replacement alone can reduce hyperglycemia considerably by correcting the hypovolemia, which then increases both glomerular filtration and renal excretion of glucose. Insulin treatment should therefore be delayed unless the patient has significant ketonemia (beta-hydroxybutyrate more than 1 mmol/L). Start the insulin infusion rate at 0.05 unit/kg/h (bolus is not needed) and titrate to lower blood glucose levels by 50–70 mg/dL per hour (2.8–3.9 mmol/L/h). Once the patient has stabilized and the blood glucose falls to around 250 mg/dL (13.9 mmol/L), insulin can be given subcutaneously.

C. Potassium

With the absence of acidosis, there may be no initial hyperkalemia unless associated end-stage chronic kidney disease is present. This results in less severe total potassium depletion than in DKA, and less potassium replacement is therefore needed. However, because initial serum potassium is usually not elevated and because it declines rapidly as a result of insulin's effect on driving potassium intracellularly, it is recommended that potassium replacement be initiated earlier than in ketotic patients, assuming that no chronic kidney disease or oliguria is present. Potassium chloride (10 mEq/L) can be added to the initial bottle of fluids administered if the patient's serum potassium is not elevated.

D. Phosphate

If severe hypophosphatemia (serum phosphate less than 1 mg/dL [0.32 mmol/L]) develops during insulin therapy, phosphate replacement can be given as described for ketoacidotic patients (at 3 mmol/h).

Prognosis

The severe dehydration and low output state may predispose the patient to complications such as myocardial infarction, stroke, pulmonary embolism, mesenteric vein thrombosis, and disseminated intravascular coagulation. Fluid replacement remains the primary approach to the prevention of these complications. Low-dose heparin prophylaxis is reasonable but benefits of routine anticoagulation remain doubtful. Rhabdomyolysis is a recognized complication and should be looked for and treated.

The overall mortality rate of hyperglycemic hyperosmolar state coma is more than ten times that of DKA, chiefly because of its higher incidence in older patients, who may have compromised cardiovascular systems or associated major illnesses and whose dehydration is often excessive because of delays in recognition and treatment. (When patients are matched for age, the prognoses of these two hyperglycemic emergencies are reasonably comparable.) When prompt therapy is instituted, the mortality rate can be reduced from nearly 50% to that related to the severity of coexistent disorders.

After the patient is stabilized, the appropriate form of long-term management of the diabetes must be determined. Insulin treatment should be continued for a few weeks but patients usually recover sufficient endogenous insulin secretion to make a trial of diet or diet plus oral agents worthwhile. When the episode occurs in a patient who has known diabetes, then education of the patient and caregivers should be instituted. They should be taught how to recognize situations (nausea and vomiting, infection) that predispose to recurrence of the hyperglycemic, hyperosmolar state, as well as detailed information on how to prevent the escalating dehydration that culminates in hyperosmolar coma (small sips of sugar-free liquids, increase in usual hypoglycemic therapy, or early contact with the clinician).

LACTIC ACIDOSIS

ESSENTIALS OF DIAGNOSIS

- Severe metabolic acidosis with compensatory hyperventilation.
- Blood pH < 7.30.
- Serum bicarbonate less than 15 mEq/L.
- Anion gap greater than 15 mEq/L.
- Absent serum ketones.
- Serum lactate greater than 5 mmol/L.

General Considerations

Lactic acidosis is characterized by accumulation of excess lactic acid in the blood. Normally, the principal sources of this acid are the erythrocytes (which lack enzymes for aerobic oxidation), skeletal muscle, skin, and brain. Conversion of lactic acid to glucose and its oxidation principally by the liver but also by the kidneys represent the chief pathways for its removal. Hyperlactatemia and acidosis occur when lactate production exceeds lactate consumption. Causes include tissue hypoxia (global or local), disorders that increase epinephrine levels (severe asthma with excess beta-adrenergic agonist use, cardiogenic or hemorrhagic shock, pheochromocytoma), and drugs that impair oxidative phosphorylation (antiretroviral agents and propofol). Most cases of metformin-associated lactic acidosis occur in patients in whom there were contraindications to the use of metformin, in particular kidney failure. Metformin levels are usually greater than 5 mcg/L when metformin is implicated as the cause of lactic acidosis. Other causes of lactic acidosis include several inborn errors of metabolism and the MELAS syndrome (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes). D-lactic acidosis can occur in patients with short bowel syndrome when unabsorbed carbohydrates are presented as substrate for fermentation by colonic bacteria.

Clinical Findings

A. Symptoms and Signs

The main clinical feature of lactic acidosis is marked hyperventilation. When lactic acidosis is secondary to tissue hypoxia or vascular collapse, the clinical presentation is variable, being that of the prevailing catastrophic illness. However, in the idiopathic, or spontaneous, variety, the onset is rapid (usually over a few hours), blood pressure is normal, peripheral circulation is good, and there is no cyanosis.

B. Laboratory Findings

Plasma bicarbonate and blood pH are quite low, indicating the presence of severe metabolic acidosis. Ketones are usually absent from plasma and urine or at least not prominent. The first clue may be a high anion gap (serum sodium minus the sum of chloride and bicarbonate anions [in mEq/L] should be no greater than 15). A higher value indicates the existence of an abnormal compartment of anions. If this cannot be clinically explained by an excess of keto acids (diabetes), inorganic acids (uremia), or anions from medication overdosage (salicylates, methyl alcohol, ethylene glycol), then lactic acidosis is probably the correct diagnosis. (See also Chapter 21.) In the absence of azotemia, hyperphosphatemia may be a clue to the presence of lactic acidosis for reasons that are not clear. The diagnosis is confirmed by a plasma lactic acid concentration of 5 mmol/L or higher (values as high as 30 mmol/L have been reported). Normal plasma values average 1 mmol/L, with a normal lactate/pyruvate ratio of 10:1. This ratio is greatly exceeded in lactic acidosis.[1]

Treatment

Aggressive treatment of the precipitating cause of lactic acidosis is the main component of therapy, such as ensuring adequate oxygenation and vascular perfusion of tissues. Empiric antibiotic coverage for sepsis should be given after culture samples are obtained in any patient in whom the cause of the lactic acidosis is not apparent (Table 30–5).

Alkalinization with intravenous sodium bicarbonate to keep the pH above 7.2 has been recommended by some in the emergency treatment of lactic acidosis; as much as 2000 mEq in 24 hours has been used. However, there is no evidence that the mortality rate is favorably affected by administering bicarbonate, and its use remains controversial. Hemodialysis may be useful in cases where large sodium loads are poorly tolerated and in cases associated with metformin toxicity.

Prognosis

The mortality rate of spontaneous lactic acidosis is high. The prognosis in most cases is that of the primary disorder that produced the lactic acidosis.

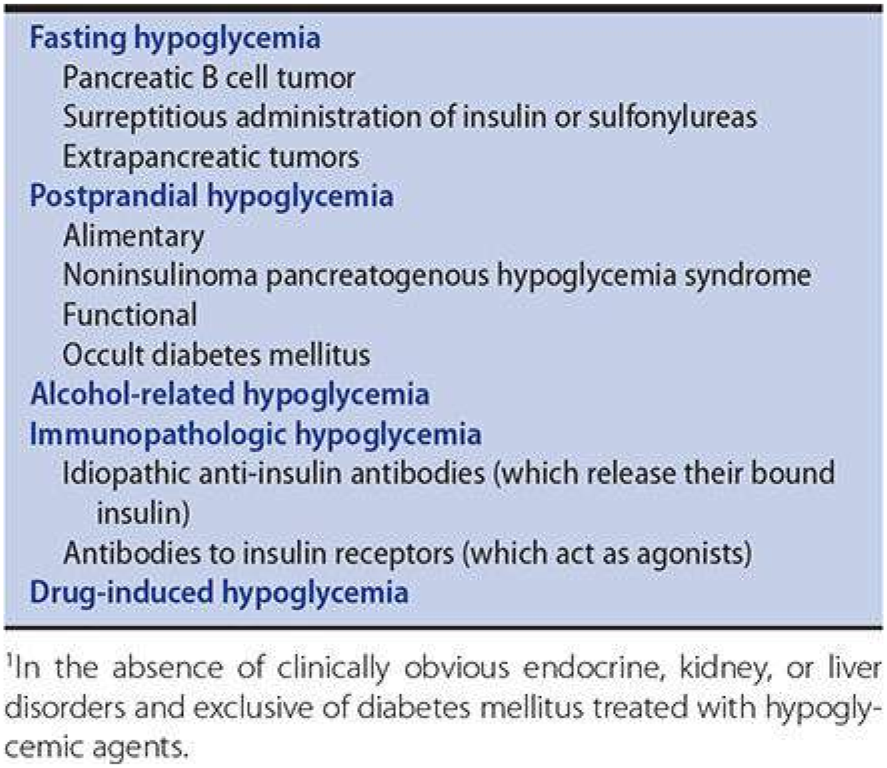
DeFronzo R et al. Metformin-associated lactic acidosis: current perspectives on causes and risk. Metabolism. 2016 Feb;65(2):20–9. [PMID: 26773926]

THE HYPOGLYCEMIC STATES

Spontaneous hypoglycemia in adults is of two principal types: fasting and postprandial. Symptoms begin at plasma glucose levels in the range of 60 mg/dL (3.3 mmol/L) and impairment of brain function at approximately 50 mg/dL (2.8 mmol/L). Fasting hypoglycemia is often subacute or chronic and usually presents with neuroglycopenia as its principal manifestation; postprandial hypoglycemia is relatively acute and is often heralded by symptoms of neurogenic autonomic discharge (sweating, palpitations, anxiety, tremulousness).

Differential Diagnosis (Table 27–13)

Table 27–13. Common causes of hypoglycemia in adults.[1]



- **Fasting hypoglycemia**
  - Pancreatic B cell tumor
  - Surreptitious administration of insulin or sulfonylureas
  - Extrapancreatic tumors
- **Postprandial hypoglycemia**
  - Alimentary
  - Noninsulinoma pancreatogenous hypoglycemia syndrome
  - Functional
  - Occult diabetes mellitus
- **Alcohol-related hypoglycemia**
- **Immunopathologic hypoglycemia**
  - Idiopathic anti-insulin antibodies (which release their bound insulin)
  - Antibodies to insulin receptors (which act as agonists)
- **Drug-induced hypoglycemia**

[1] In the absence of clinically obvious endocrine, kidney, or liver disorders and exclusive of diabetes mellitus treated with hypoglycemic agents.

Fasting hypoglycemia may occur in certain endocrine disorders, such as hypopituitarism, Addison disease, or myxedema; in disorders related to liver malfunction, such as acute alcoholism or liver failure; and in instances of end-stage chronic kidney disease, particularly in patients requiring dialysis. These conditions are usually obvious, with hypoglycemia being only a secondary feature. When fasting hypoglycemia is a primary manifestation developing in adults without apparent endocrine disorders or inborn metabolic diseases from childhood, the principal diagnostic possibilities include (1) hyperinsulinism, due to either pancreatic B cell tumors, iatrogenic or surreptitious administration of insulin or sulfonylurea; and (2) hypoglycemia due to extrapancreatic tumors.

Postprandial (reactive) hypoglycemia may be seen after gastrointestinal surgery and is particularly associated with the dumping syndrome after gastrectomy and Roux-en-Y gastric bypass surgery. Occult diabetes very occasionally presents with postprandial hypoglycemia. Rarely, it occurs with islet cell hyperplasia—the so-called noninsulinoma pancreatogenous hypoglycemia syndrome.

Alcohol-related hypoglycemia is due to hepatic glycogen depletion combined with alcohol-mediated inhibition of gluconeogenesis. It is most common in malnourished individuals with excessive alcohol intake but can occur in anyone who is unable to ingest food after an acute alcoholic episode followed by gastritis and vomiting.

Immunopathologic hypoglycemia is an extremely rare condition in which anti-insulin antibodies or antibodies to insulin receptors develop spontaneously.

HYPOGLYCEMIA DUE TO PANCREATIC B CELL TUMORS

ESSENTIALS OF DIAGNOSIS

- Hypoglycemic symptoms—often neuroglycopenic (confusion, blurred vision, anxiety, convulsions).
- Immediate recovery upon administration of glucose.
- Blood glucose less than 45 mg/dL (2.5 mmol/L) with a serum insulin level of 6 microunits/mL or more.

General Considerations

Fasting hypoglycemia in an otherwise healthy, well-nourished adult is rare and is most commonly due to an adenoma of the islets of Langerhans. Ninety percent of such tumors are single and benign, but multiple adenomas can occur as well as malignant tumors with functional metastases. Adenomas may be familial, and multiple adenomas have been found in conjunction with tumors of the parathyroids and pituitary (MEN type 1 [MEN 1]). It has been reported that about 30% of sporadic insulinoma tumors have a somatic mutation in the YY1 gene (T372R) that encodes the transcriptional repressor YY1. Over 99% of insulinomas are located within the pancreas and less than 1% in ectopic pancreatic tissue.

Clinical Findings

A. Symptoms and Signs

The most important prerequisite to diagnosing an insulinoma is simply to consider it, particularly in relatively healthy-appearing persons who have fasting hypoglycemia associated with some degree of central nervous system dysfunction such as confusion or abnormal behavior. A delay in diagnosis can result in unnecessary treatment for psychomotor epilepsy or psychiatric disorders and may cause irreversible brain damage. In long-standing cases, obesity can result as a consequence of overeating to relieve symptoms.

The so-called Whipple triad is characteristic of hypoglycemia regardless of the cause. It consists of (1) a history of hypoglycemic symptoms, (2) an associated low plasma glucose level (40–50 mg/dL), and (3) relief of symptoms upon ingesting fast-acting carbohydrates in approximately 15 minutes. The hypoglycemic symptoms in insulinoma often develop in the early morning or after missing a meal. Occasionally, they occur after exercise.

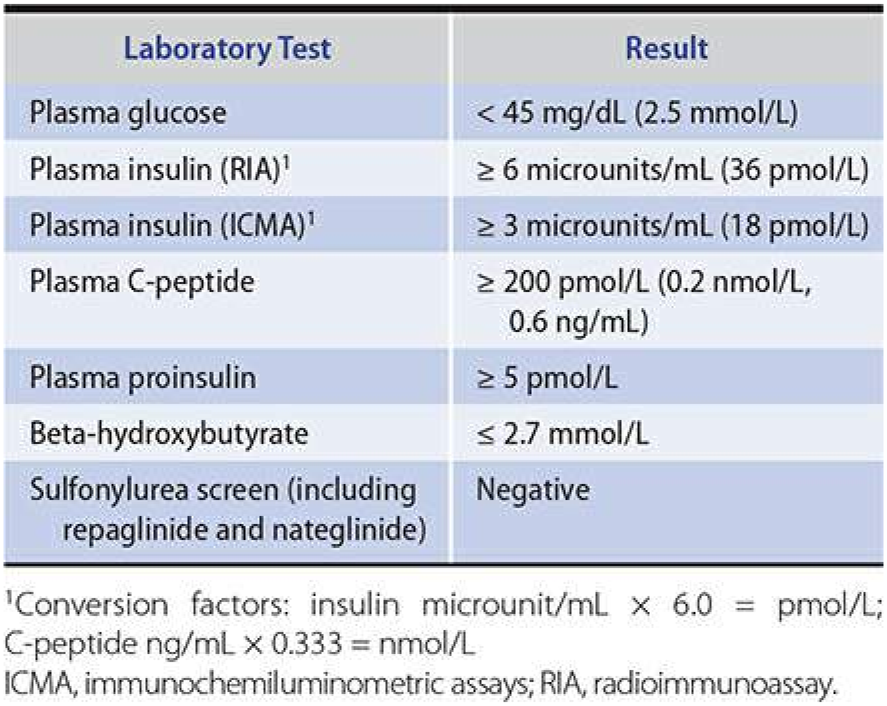
Patients typically complain of neuroglycopenic symptoms such as blurred vision or diplopia, headache, feelings of detachment, slurred speech, and weakness. Personality and mental changes vary from anxiety to psychotic behavior, and neurologic deterioration can result in convulsions or coma. Hypoglycemic unawareness is very common and adrenergic symptoms of palpitations and sweating may be blunted. With the ready availability of home blood glucose–monitoring systems, patients sometimes present with documented fingerstick blood glucose levels in 40s and 50s at time of symptoms. Access to diabetic medications (sulfonylureas or insulin) should be explored—does a family member have diabetes, or does the patient or family member work in the medical field? Medication-dispensing errors should be excluded—has the patient's prescription medication changed in shape or color? Patients with insulinoma or factitious hypoglycemia usually have a normal physical examination.

B. Laboratory Findings

B cell adenomas do not reduce secretion of insulin in the presence of hypoglycemia, and the critical diagnostic test is to demonstrate inappropriately elevated serum insulin, proinsulin, and C-peptide levels, at a time when plasma glucose level is below 45 mg/dL.

The diagnostic criteria for insulinoma after a 72-hour fast are listed in Table 27–14. Other causes of hyperinsulinemic hypoglycemia include factitious administration of insulin or sulfonylureas. Factitious use of insulin will result in suppression of endogenous insulin secretion and low C-peptide levels. In patients who have injected insulin, the insulin/C-peptide ratio (pmol/L) will be greater than 1. An elevated circulating proinsulin level in the presence of fasting hypoglycemia is characteristic of most B cell adenomas and does not occur in factitious hyperinsulinism. Thus, C-peptide levels (by immunochemiluminometric assays [ICMA]) of greater than 200 pmol/L and proinsulin levels (by radioimmunoassay [RIA]) of greater than 5 pmol/L are characteristic of insulinomas. In patients with insulinoma, plasma beta-hydroxybutyrate levels are suppressed to 2.7 mmol/L or less. No single hormone measurement (insulin, proinsulin, C-peptide) is 100% sensitive and specific for the diagnosis of insulinoma, and insulinoma cases have been reported with insulin levels below 3 microunits/mL (ICMA assay) or proinsulin level below 5 pmol/L. These hormonal assays are also not standardized between laboratories, and there can be significant variation in the results. Therefore, the diagnosis should be based on multiple biochemical parameters.

Table 27–14. Diagnostic criteria for insulinoma after a 72-hour fast.



Laboratory Test	Result
Plasma glucose	< 45 mg/dL (2.5 mmol/L)
Plasma insulin (RIA)[1]	≥ 6 microunits/mL (36 pmol/L)
Plasma insulin (ICMA)[1]	≥ 3 microunits/mL (18 pmol/L)
Plasma C-peptide	≥ 200 pmol/L (0.2 nmol/L, 0.6 ng/mL)
Plasma proinsulin	≥ 5 pmol/L
Beta-hydroxybutyrate	≤ 2.7 mmol/L
Sulfonylurea screen (including repaglinide and nateglinide)	Negative

[1] Conversion factors: insulin microunit/mL × 6.0 = pmol/L; C-peptide ng/mL × 0.333 = nmol/L

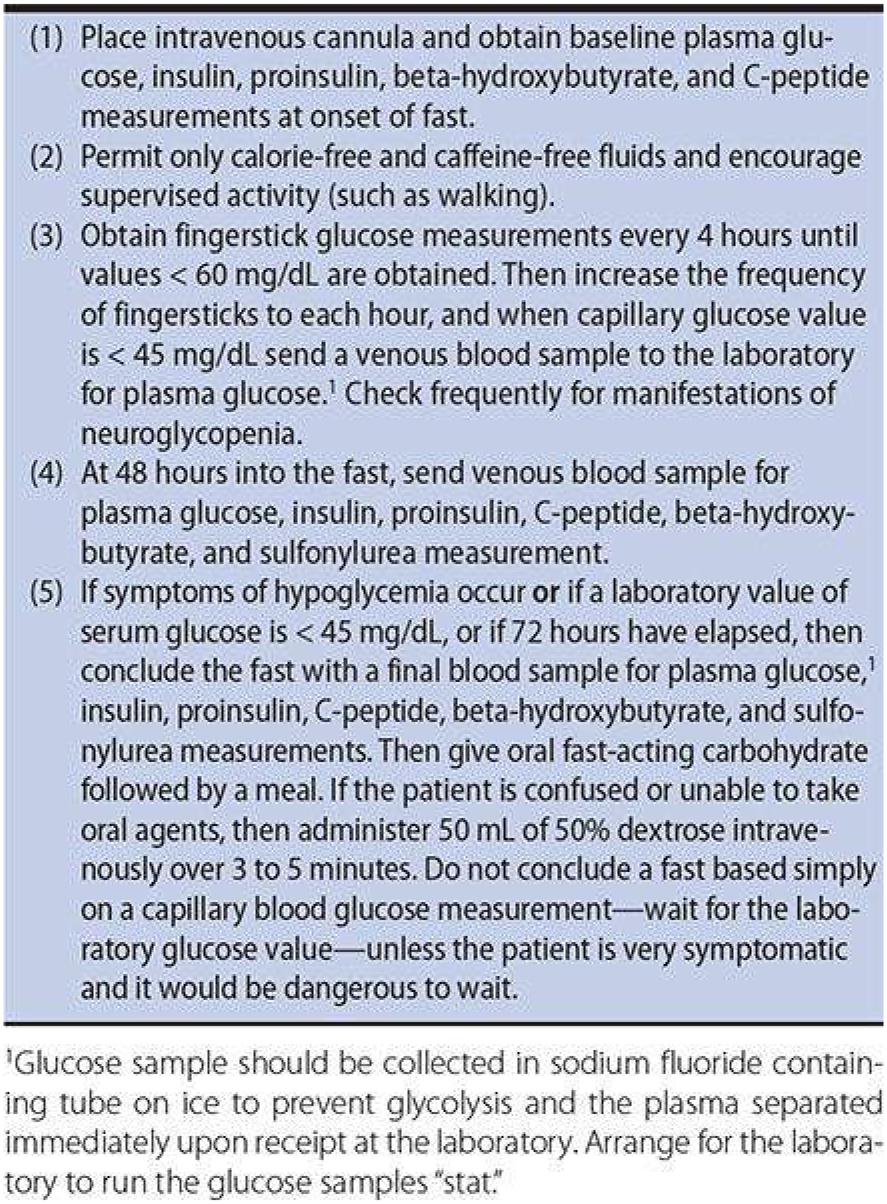
ICMA, immunochemiluminometric assays; RIA, radioimmunoassay.

In patients with epigastric distress, a history of renal calculi, or menstrual or erectile dysfunction, a serum calcium, gastrin, or prolactin level may be useful in screening for MEN 1 associated with insulinoma.

C. Diagnostic Tests

If the history is consistent with episodic spontaneous hypoglycemia, patients should be given a home blood glucose monitor and advised to monitor blood glucose levels at the time of symptoms and before consumption of carbohydrates, if this can be done safely. Patients with insulinomas frequently report fingerstick blood glucose levels between 40 mg/dL (2.2 mmol/L) and 50 mg/dL (2.8 mmol/L) at the time of symptoms. The diagnosis, however, cannot be made based on a fingerstick blood glucose. It is necessary to have a low laboratory glucose concomitantly with elevated plasma insulin, proinsulin, and C-peptide levels and a negative sulfonylurea screen. When patients give a history of symptoms after only a short period of food withdrawal or with exercise, then an outpatient assessment can be attempted. The patient should be brought by a family member to the office after an overnight fast and observed in the office. Activity such as walking should be encouraged and fingerstick blood glucose measured repeatedly during observation. If symptoms occur or fingerstick blood glucose is below 50 mg/dL (2.8 mmol/L) then samples for plasma glucose, insulin, C-peptide, proinsulin, sulfonylurea screen, serum ketones, and antibodies to insulin should be sent. If outpatient observation does not result in symptoms or hypoglycemia and if the clinical suspicion remains high, then the patient should undergo an inpatient supervised 72-hour fast. A suggested protocol for the supervised fast is shown in Table 27–15.

Table 27–15. Suggested hospital protocol for supervised fast in diagnosis of insulinoma.



(1) Place intravenous cannula and obtain baseline plasma glucose, insulin, proinsulin, beta-hydroxybutyrate, and C-peptide measurements at onset of fast.
(2) Permit only calorie-free and caffeine-free fluids and encourage supervised activity (such as walking).
(3) Obtain fingerstick glucose measurements every 4 hours until values < 60 mg/dL are obtained. Then increase the frequency of fingersticks to each hour, and when capillary glucose value is < 45 mg/dL send a venous blood sample to the laboratory for plasma glucose.[1] Check frequently for manifestations of neuroglycopenia.
(4) At 48 hours into the fast, send venous blood sample for plasma glucose, insulin, proinsulin, C-peptide, beta-hydroxybutyrate, and sulfonylurea measurement.
(5) If symptoms of hypoglycemia occur **or** if a laboratory value of serum glucose is < 45 mg/dL, or if 72 hours have elapsed, then conclude the fast with a final blood sample for plasma glucose,[1] insulin, proinsulin, C-peptide, beta-hydroxybutyrate, and sulfonylurea measurements. Then give oral fast-acting carbohydrate followed by a meal. If the patient is confused or unable to take oral agents, then administer 50 mL of 50% dextrose intravenously over 3 to 5 minutes. Do not conclude a fast based simply on a capillary blood glucose measurement—wait for the laboratory glucose value—unless the patient is very symptomatic and it would be dangerous to wait.

[1] Glucose sample should be collected in sodium fluoride containing tube on ice to prevent glycolysis and the plasma separated immediately upon receipt at the laboratory. Arrange for the laboratory to run the glucose samples "stat."

In 30% of patients with insulinoma, the blood glucose levels often drop below 45 mg/dL (2.5 mmol/L) after an overnight fast, but some patients require up to 72 hours to develop symptomatic hypoglycemia. However, the term "72-hour fast" is actually a misnomer in most cases since the fast should be immediately terminated as soon as symptoms appear and laboratory confirmation of hypoglycemia is available. In normal male subjects, the blood glucose does not fall below 55–60 mg/dL (3.1–3.3 mmol/L) during a 3-day fast. In contrast, in normal premenopausal women who have fasted for only 24 hours, the plasma glucose may fall normally to such an extent that it can reach values as low as 35 mg/dL (1.9 mmol/L). In these cases, however, the women are not symptomatic, presumably owing to the development of sufficient ketonemia to supply energy needs to the brain. Insulinoma patients, on the other hand, become symptomatic when plasma glucose drops to subnormal levels, since inappropriate insulin secretion restricts ketone formation. Moreover, the demonstration of a nonsuppressed insulin level of 3 microunits/mL or more using a ICMA assay (greater than 6 microunits/mL using an RIA assay) in the presence of hypoglycemia suggests the diagnosis of insulinoma. If hypoglycemia does not develop in a male patient after fasting for up to 72 hours—and particularly when this prolonged fast is terminated with a period of moderate exercise—insulinoma must be considered an unlikely diagnosis.

Stimulation with pancreatic B cell secretagogues such as tolbutamide, glucagon, or leucine has been devised to demonstrate exaggerated and prolonged insulin secretion in the presence of insulinomas. However, because insulin-secreting tumors have a wide range of granule content and degrees of differentiation, they are variably responsive to these secretagogues; and a negative response does not necessarily rule out an insulinoma. For these reasons, stimulation tests are not recommended in the diagnostic workup of insulinoma.

An oral glucose tolerance test is of no value in the diagnosis of insulin-secreting tumors. HbA_{1c} levels may be low but there is considerable overlap with normal patients and no particular value is diagnostic.

D. Preoperative Localization of B Cell Tumors

After the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings, studies to localize the tumor should be initiated. The focus of attention should be directed to the pancreas since that is where virtually all insulinomas originate. Ectopic cases are very rare.

Because of the small size of these tumors (averaging 1.5 cm in diameter in one large series), imaging studies do not necessarily identify all of them. A pancreatic dual phase helical CT scan with thin section can identify 82–94% of the lesions. MRI scans with gadolinium can be helpful in detecting a tumor in 85% of cases. One case report suggests that diffusion-weighted MRI can be useful for detecting and localizing small insulinomas, especially for those with no hypervascular pattern. ^{111}In-octreotide scans for insulinomas, which typically express somatostatin receptor type 3, are positive in only 50–70% of cases. Newer PET/CT scans, using gallium-labeled somatostatin analogs such as DOTA-1-NaI3-octreotide (DOTA-NOC), which have a higher affinity for somatostatin receptor subtypes 2, 3, and 5, have been reported to be useful in localizing the tumors. Insulinomas express GLP-1 receptors, and radiolabeled GLP-1 receptor agonists such as Lys(40)(Ahx-hydrazinonicotinamide [HYNIC]-[(99m)Tc)NH(2)]-exendin-4 for SPECT/CT have also been reported to visualize the tumors. The imaging study used will depend on local availability and local radiologic skill. If the imaging study is normal, then an endoscopic ultrasound should be performed. In experienced hands, about 80–90% of tumors can be detected with this procedure. Fine-needle aspiration of the identified lesion can be attempted to confirm the presence of a neuroendocrine tumor. If the tumor is not identified or the imaging result is equivocal, then the patient should undergo selective calcium-stimulated angiography, which has been reported to localize the tumor to a particular region of the pancreas approximately 90% of the time. In this test, angiography is combined with injections of calcium gluconate into the gastroduodenal, splenic, and superior mesenteric arteries, and insulin levels are measured in the hepatic vein effluent. The procedure is performed after an overnight fast. Calcium gluconate 10% solution diluted to a volume of 5 mL with 0.95% saline is bolused into the selected artery at a dose of 0.0125 mmol calcium/kg (0.005 mmol calcium/kg for obese patients). Small samples of blood (5 mL) are taken from the hepatic effluent at times 0, 30, 60, 90, 120, and 180 seconds after the calcium injection. Fingerstick blood glucose levels are measured at intervals and a dextrose infusion is maintained throughout the procedure to prevent hypoglycemia. Calcium stimulates insulin release from insulinomas but not normal islets, and so a step-up from baseline in insulin levels at 30 or 60 seconds (twofold or greater) regionalizes the source of the hyperinsulinism to the head of the pancreas for the gastroduodenal artery, the uncinate process for the superior mesenteric artery, and the body and tail of the pancreas for the splenic artery calcium infusions. A less than twofold elevation of insulin in the 120-second sample may represent effects of recirculating calcium and is not considered a positive localization. In a single insulinoma, the response is in one artery alone unless the tumor resides in an area fed by two arteries or if there are multiple insulinomas (eg, in MEN 1). Patients who have diffuse islet hyperplasia (the noninsulinoma pancreatogenous hypoglycemia syndrome) will have positive responses in multiple arteries. Because diazoxide may interfere with this test, it should be discontinued for at least 48–72 hours before sampling. Patients should be closely monitored during the procedure to avoid hypoglycemia (as well as hyperglycemia, which could affect insulin gradients). These studies combined with careful intraoperative ultrasonography and palpation by a surgeon experienced in insulinoma surgery identifies up to 98% of tumors.

Treatment

The treatment of choice for insulin-secreting tumors is surgical resection. While waiting for surgery, patients should be given oral diazoxide. Divided doses of 300–400 mg/day usually suffice, although an occasional patient may require up to 800 mg/day. Side effects include edema due to sodium retention, gastric irritation, and mild hirsutism. Hydrochlorothiazide, 25–50 mg daily, can be used to counteract the sodium retention and edema as well potentiate diazoxide’s hyperglycemic effect.

In patients with a single benign pancreatic B cell adenoma, 90–95% have a successful cure at the first surgical attempt when intraoperative ultrasound is used by a skilled surgeon. Diazoxide should be administered on the day of the surgery because it reduces the risk of hypoglycemia during surgery. Typically, it does not mask the glycemic rise indicative of surgical cure. Blood glucose should be monitored throughout surgery, and 5% or 10% dextrose infusion should be used to maintain euglycemia. In cases where the diagnosis has been established but no adenoma is located after careful palpation and use of intraoperative ultrasound, it is no longer advisable to blindly resect the body and tail of the pancreas, since a nonpalpable tumor missed by ultrasound is most likely embedded within the fleshy head of the pancreas that is left behind with subtotal resections. Most surgeons prefer to close the incision and schedule a selective arterial calcium stimulation with hepatic venous sampling to locate the tumor site prior to a repeat operation. Laparoscopy using ultrasound and enucleation has been successful with a single tumor of the body or tail of the pancreas, but open surgery remains necessary for tumors in the head of the pancreas.

In patients with inoperable functioning islet cell carcinoma with and without hepatic metastasis and in approximately 5–10% of MEN 1 cases when subtotal removal of the pancreas has failed to produce cure, the treatment approach is the same as for other types of pancreatic neuroendocrine tumors (pNETs). Diazoxide is the treatment of choice in preventing hypoglycemia. Frequent carbohydrate feedings (every 2–3 hours) can also be helpful, although weight gain can become a problem. Somatostatin analogs, octreotide or lanreotide, should be considered if diazoxide is ineffective or if there is tumor progression. Surgery or embolization (bland, chemo- and radio-) or thermal ablation (radiofrequency, microwave, and cryoablation) can be used to reduce tumor burden and also provide symptomatic relief. Chemotherapy regimens that can be considered include combination of streptozocin, 5–fluorouracil, and doxorubicin; capecitabine and oxaliplatin; and capecitabine and temozolomide. Targeted therapies against multiple steps in PI3K/AKT/mTor pathway have been shown to be helpful. Everolimus, an inhibitor of mTor, is approved for treatment of advanced pNETs. Sunitinib, a monoclonal antibody against VEGF receptors 2 and 3, PDGFR alpha and beta, and c-kit, has been shown to slow growth of pNETs. Treatment with radioisotopes (indium-111 or yttrium-90 or lutetium-177) linked to a somatostatin analog have been reported to show benefit in a proportion of patients.

Cryer PE et al. Evaluation and management of adult hypoglycemic disorders: an Endocrine Society Clinical Practice Guideline. J Clin Endocrinol Metab. 2009 Mar;94(3):709–28. [PMID: 19088155]

Mathur A et al. Insulinoma. Surg Clin North Am. 2009 Oct;89(5):1105–21. [PMID: 19836487]

NONISLET CELL TUMOR HYPOGLYCEMIA

These rare causes of hypoglycemia include mesenchymal tumors such as retroperitoneal sarcomas, hepatocellular carcinomas, adrenocortical carcinomas, and miscellaneous epithelial-type tumors. The tumors are frequently large and readily palpated or visualized on CT scans or MRI.

In many cases the hypoglycemia is due to the expression and release of an incompletely processed insulin-like growth factor 2 (IGF-2) by the tumor.

The diagnosis is supported by laboratory documentation of serum insulin levels below 5 microunit/mL with plasma glucose levels of 45 mg/dL (2.5 mmol/L) or lower. Values for growth hormone and IGF-1 are also decreased. Levels of IGF-2 may be increased but often are “normal” in quantity, despite the presence of the immature, higher-molecular-weight form of IGF-2, which can be detected only by special laboratory techniques.

Not all the patients with nonislet cell tumor hypoglycemia have elevated pro-IGF-2. Ectopic insulin production has been described in bronchial carcinoma, ovarian carcinoma, and small cell carcinoma of the cervix. Hypoglycemia due to IGF-1 released from a metastatic large cell carcinoma of the lung has also been reported. GLP-1–secreting tumors (ovarian and pNETs) can also cause hypoglycemia by stimulating insulin release from normal pancreatic islets.

The prognosis for these tumors is generally poor, and surgical removal should be attempted when feasible. Dietary management of the hypoglycemia is the mainstay of medical treatment, since diazoxide is usually ineffective.

Bodnar TW et al. Management of non-islet-cell tumor hypoglycemia: a clinical review. J Clin Endocrinol Metab. 2014 Mar;99(3):713–22. [PMID: 24423303]

POSTPRANDIAL HYPOGLYCEMIA

1. Hypoglycemia Following Gastric Surgery

Hypoglycemia sometimes develops in patients who have undergone gastric surgery (eg, gastrectomy, vagotomy, pyloroplasty, gastrojejunostomy, Nissan fundoplication, Billroth II procedure, and Roux-en-Y), especially when they consume foods containing high levels of readily absorbable carbohydrates. This late dumping syndrome occurs about 1–3 hours after a meal and is a result of rapid delivery of high concentration of carbohydrates in the proximal small bowel and rapid absorption of glucose. The hyperinsulinemic response to the high carbohydrate load causes hypoglycemia. Excessive release of gastrointestinal hormones such as GLP-1 likely play a role in the hyperinsulinemic response. The symptoms include lightheadedness, sweating, confusion and even loss of consciousness after eating a high carbohydrate meal. To document hypoglycemia, the patient should consume a meal that leads to symptoms during everyday life. An oral glucose tolerance test is not recommended because many normal persons have false-positive test results. There have been case reports of insulinoma and noninsulinoma pancreatogenous hypoglycemia syndrome in patients with hypoglycemia post Roux-en-Y surgery. It is unclear how often this occurs. A careful history may identify patients who have a history of hypoglycemia with exercise or missed meals, and these individuals may require a formal 72-hour fast to rule out an insulinoma.

Treatment for secondary dumping includes dietary modification, but this may be difficult to sustain. Patients can try more frequent meals with smaller portions of less rapidly digested carbohydrates. Alpha-glucosidase therapy may be a useful adjunct to a low carbohydrate diet. Octreotide 50 mcg administered subcutaneously two or three times a day 30 minutes prior to each meal has been reported to improve symptoms due to late dumping syndrome. Treatment with exendin 9-39, a GLP-1 receptor agonist, may prevent post gastric bypass hypoglycemia. Various surgical procedures to delay gastric emptying have been reported to improve symptoms but long-term efficacy studies are lacking.

2. Functional Alimentary Hypoglycemia

Patients have symptoms suggestive of increased sympathetic activity, including anxiety, weakness, tremor, sweating or palpitations after meals. Physical examination and laboratory tests are normal. It is not recommended that patients with symptoms suggestive of increased sympathetic activity undergo either a prolonged oral glucose tolerance test or a mixed meal test. Instead, the patients should be given home blood glucose monitors (with memories) and instructed to monitor fingerstick glucose levels at the time of symptoms. Only patients who have symptoms when their fingerstick blood glucose is low (less than 50 mg/dL) and who have resolution of symptoms when the glucose is raised by eating rapidly released carbohydrate need additional evaluation. Patients who do not have evidence for low glucose levels at time of symptoms are generally reassured by their findings. Counseling and support should be the mainstays in therapy, with dietary manipulation only an adjunct.

3. Occult Diabetes

This condition is characterized by a delay in early insulin release from pancreatic B cells, resulting in initial exaggeration of hyperglycemia during a glucose tolerance test. In response to this hyperglycemia, an exaggerated insulin release produces a late hypoglycemia 4–5 hours after ingestion of glucose. These patients are often obese and frequently have a family history of diabetes mellitus.

Patients with this type of postprandial hypoglycemia often respond to reduced intake of refined sugars with multiple, spaced, small feedings high in dietary fiber. In the obese, treatment is directed at weight reduction to achieve ideal weight. These patients should be considered to have prediabetes or early diabetes (type 1 or 2) and advised to have periodic medical evaluations.

4. Autoimmune Hypoglycemia

Patients with autoimmune hypoglycemia have early postprandial hyperglycemia followed by hypoglycemia 3–4 hours later. The hypoglycemia is attributed to a dissociation of insulin-antibody immune complexes, releasing free insulin.

The disorder is associated with methimazole treatment for Graves disease, although it can also occur in patients treated with various other sulfhydryl-containing medications (captopril, penicillamine) as well as other drugs such as hydralazine, isoniazid, and procainamide. In addition, it has been reported in patients with autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, and polymyositis as well as in plasma cell myeloma (formerly multiple myeloma) and other plasma cell dyscrasias where paraproteins or antibodies cross-react with insulin. There is also an association with the HLA class II alleles (DRB1*0406, DQA1*0301, and DQB1*0302). These alleles are 10 to 20 times more common in Japanese and Korean populations, which explains why the disorder has been reported mostly in Japanese patients.

High titers of insulin autoantibodies, usually IgG class, can be detected. Insulin, proinsulin, and C-peptide levels may be elevated, but the results may be erroneous because of the interference of the insulin antibodies with the immunoassays for these peptides.

In most cases, the hypoglycemia is transient and usually resolves spontaneously within 3–6 months of diagnosis, particularly when the offending medications are stopped. The most consistent therapeutic benefit in management of this syndrome has been achieved by dietary treatment with small, frequent low-carbohydrate meals. Prednisone (30–60 mg orally daily) has been used to lower the titer of insulin antibodies.

Lupsa BC et al. Autoimmune forms of hypoglycemia. Medicine (Baltimore). 2009 May;88(3):141–53. [PMID: 19440117]

FACTITIOUS HYPOGLYCEMIA

Factitious hypoglycemia may be difficult to document. A suspicion of self-induced hypoglycemia is supported when the patient is associated with the health professions or has access to insulin or sulfonylurea medications taken by a diabetic member of the family. The triad of hypoglycemia, high immunoreactive insulin, and suppressed plasma C-peptide immunoreactivity is pathognomonic of exogenous insulin administration.

Insulin and C-peptide are secreted in a 1:1 molar ratio. A large fraction of the endogenous insulin is cleared by the liver, whereas C-peptide, which is cleared by the kidney, has a lower metabolic clearance rate. For this reason, the molar ratio of insulin and C-peptide in a hypoglycemic patient should be less than 1.0 in cases of insulinoma and is greater than 1.0 in cases of exogenous insulin administration. When sulfonylureas, repaglinide, and nateglinide are suspected as a cause of factitious hypoglycemia, a plasma level of these medications to detect their presence may be required to distinguish laboratory findings from those of insulinoma.

HYPOGLYCEMIA DUE TO INSULIN RECEPTOR ANTIBODIES

Hypoglycemia due to insulin receptor autoantibodies is an extremely rare syndrome; most cases have occurred in women often with a history of autoimmune disease. Almost all of these patients have also had episodes of insulin-resistant diabetes and acanthosis nigricans. Their hypoglycemia may be either fasting or postprandial and is often severe and is attributed to an agonistic action of the antibody on the insulin receptor. Balance between the antagonistic and agonistic effects of the antibodies determines whether insulin-resistant diabetes or hypoglycemia occurs. Hypoglycemia was found to respond to corticosteroid therapy but not to plasmapheresis or immunosuppression.

Kim CH et al. Autoimmune hypoglycemia in a type 2 diabetic patient with anti-insulin and insulin receptor antibodies. Diabetes Care. 2004 Jan;27(1):288–9. [PMID: 14694017]

MEDICATION-INDUCED HYPOGLYCEMIA

A number of medications apart from the sulfonylureas can occasionally cause hypoglycemia. Common offenders include the fluoroquinolones such as gatifloxacin and levofloxacin, pentamidine, quinine, ACE inhibitors, salicylates and beta-adrenergic blocking agents. The fluoroquinolones, particularly gatifloxacin, have been associated with both hypoglycemia and hyperglycemia. It is thought that the drug acts on the ATP sensitive potassium channels in the beta cell. Hypoglycemia is an early event, and hyperglycemia occurs several days into therapy. Intravenous pentamidine is cytotoxic to beta cells and causes acute hyperinsulinemia and hypoglycemia followed by insulinopenia and hyperglycemia. Fasting patients taking noncardioselective beta-blockers can have an exaggerated hypoglycemic response to starvation. The beta-blockade inhibits fatty acids and gluconeogenesis substrate release and reduces plasma glucagon response. Therapy with ACE inhibitors increases the risk of hypoglycemia in patients who are taking insulin or sulfonylureas presumably because these drugs increase sensitivity to circulating insulin by increasing blood flow to the muscle. Some opioids cause hypoglycemia. Tramadol use has been associated with increased risk of hospitalization for hypoglycemia. Methadone overdose has also been reported to cause hypoglycemia and a rapid dose escalation of methadone in cancer patients can lower glucose levels.

Ethanol-associated hypoglycemia may be due to hepatic alcohol dehydrogenase activity depleting NAD. The resultant change in the redox state—increase in NADH to NAD^+ ratio—causes a partial block at several points in the gluconeogenic pathway. With prolonged starvation, glycogen reserves become depleted within 18–24 hours and hepatic glucose output becomes totally dependent on gluconeogenesis. Under these circumstances, a blood concentration of ethanol as low as 45 mg/dL (9.8 mmol/L) can induce profound hypoglycemia by blocking gluconeogenesis. Neuroglycopenia in a patient whose breath smells of alcohol may be mistaken for alcoholic stupor. Prevention consists of adequate food intake during ethanol ingestion. Therapy consists of glucose administration to replenish glycogen stores until gluconeogenesis resumes.

When sugar-containing soft drinks are used as mixers to dilute alcohol in beverages (gin and tonic, rum and cola), there seems to be a greater insulin release than when the soft drink alone is ingested and a tendency for more of a late hypoglycemic overswing to occur 3–4 hours later. Prevention would consist of avoiding sugar mixers while ingesting alcohol and ensuring supplementary food intake to provide sustained absorption.

Lipid Disorders

Michael J. Blaha, MD, MPH
Robert B. Baron, MD, MS

The “Lipid Hypothesis” of cardiovascular disease (CVD)—stating that cholesterol is causal in the development of atherosclerotic cardiovascular disease (ASCVD) and that lowering of cholesterol is associated with lower cardiovascular event rates—is generally accepted throughout the medical community. For patients with known CVD (secondary prevention), studies have shown that cholesterol lowering leads to a consistent reduction in total mortality and in recurrent cardiovascular events in men and women; other studies have documented lowered mortality and events in middle-aged and older patients. Among patients without CVD (primary prevention), the data are generally consistent, with rates of cardiovascular events, heart disease mortality, and all-cause mortality differing among studies. Treatment guidelines have been designed to assist clinicians in selecting patients for cholesterol-lowering therapy based on their overall risk of developing CVD.

There are several genetic disorders that provide insight into the pathogenesis of lipid-related diseases. **Familial hypercholesterolemia,** rare in the homozygous state (about one per million), causes markedly high low-density lipoprotein (LDL) levels and early CVD. The most common genetic defects involve absent or defective LDL receptors, resulting in unregulated LDL metabolism, genetic mutations of apolipoprotein B, or gain of function in proprotein convertase subtilisin/kexin type 9 (PCSK9), a protein that regulates breakdown of LDL receptors. Patients with two abnormal genes (homozygotes) have extremely high levels—up to eight times normal—and present with atherosclerotic disease in childhood. Homozygotes may require liver transplantation or plasmapheresis to correct their severe lipid abnormalities. Those with one defective gene (heterozygotes) have LDL concentrations twice normal; persons with this condition may develop CVD in their 30s or 40s.

Another rare condition is caused by an abnormality of lipoprotein lipase, the enzyme that enables peripheral tissues to take up triglyceride from chylomicrons and very-low-density lipoprotein (VLDL) particles. Patients with this condition, one cause of **familial chylomicronemia syndrome,** have marked hypertriglyceridemia with recurrent pancreatitis and hepatosplenomegaly in childhood.

Numerous other genetic abnormalities of lipid metabolism are named for the abnormality noted when serum is electrophoresed (eg, dysbetalipoproteinemia) or from combinations of lipid abnormalities in families (eg, familial combined hyperlipidemia).

When to Refer

- Known genetic lipid disorders.
- Striking family history of hyperlipidemia or premature atherosclerosis.
- Extremely high serum LDL cholesterol or triglycerides, or extremely low serum high-density lipoprotein (HDL) cholesterol.

Khera AV et al. Diagnostic yield and clinical utility of sequencing familial hypercholesterolemia genes in patients with severe hypercholesterolemia. J Am Coll Cardiol. 2016 Jun 7;67(22):2578–89. [PMID: 27050191]

LIPID FRACTIONS & THE RISK OF CORONARY HEART DISEASE

In serum, cholesterol is carried primarily on three different lipoproteins—the VLDL, LDL, and HDL molecules. Total cholesterol equals the sum of these three components:

$$\text{Total cholesterol} = \text{HDL cholesterol} + \text{VLDL cholesterol} + \text{LDL cholesterol}$$

Using these assumptions, the Friedewald equation states that LDL cholesterol can be estimated as:

$$\begin{matrix}\text{LDL}\\ \text{cholesterol}\end{matrix} = \begin{matrix}\text{Total}\\ \text{cholesterol}\\ \text{(mg/dL)}\end{matrix} - \begin{matrix}\text{HDL}\\ \text{cholesterol}\\ \text{(mg/dL)}\end{matrix} - \frac{\begin{matrix}\text{Triglycerides}\\ \text{(mg/dL)}\end{matrix}}{5}$$

When using SI units, the formula becomes

$$\begin{matrix}\text{LDL}\\ \text{cholesterol}\end{matrix} = \begin{matrix}\text{Total}\\ \text{cholesterol}\\ \text{(mmol/L)}\end{matrix} - \begin{matrix}\text{HDL}\\ \text{cholesterol}\\ \text{(mmol/L)}\end{matrix} - \frac{\begin{matrix}\text{Triglycerides}\\ \text{(mmol/L)}\end{matrix}}{2.2}$$

Modern research has questioned several of the assumptions underlying the Friedewald equation, particularly the assumption that VLDL is always best estimated as triglycerides/5, which is inaccurate when triglycerides are above 150 mg/dL and when

LDL cholesterol is less than 70 mg/dL. Therefore, many commercial laboratories have switched to the Martin/Hopkins equation, which uses a flexible factor for deriving VLDL from triglycerides (as opposed to always using 5). The Martin/Hopkins equation reduces the systematic underestimation of LDL cholesterol when triglycerides are greater than 150 mg/dL and LDL is less than 70 mg/dL, and is more accurate in estimating LDL from nonfasting blood specimens.

Non-HDL cholesterol is increasingly recognized as an important measure of the total quantity of apolipoprotein B–containing atherogenic lipid particles. Non-HDL cholesterol is calculated as: total cholesterol – HDL cholesterol. Advantages of non-HDL cholesterol are that it is less sensitive to fasting status and it is a better predictor of cardiovascular risk compared to LDL cholesterol.

Lipoprotein(a), a subfraction of LDL that is largely genetically determined, has also been recognized as a casual factor in atherosclerosis. Lipoprotein(a) may be useful to measure in patients with a strong family history or with early signs of early ASCVD.

It is difficult to assign a “normal” range for serum lipids. This is because our cholesterol values are vastly higher than our evolutionary ancestors and because mean values vary across the world. In Western populations, cholesterol values are about 20% higher than in Asian populations and exceed 300 mg/dL (7.76 mmol/L) in nearly 5% of adults. About 10% of adults have LDL cholesterol levels above 200 mg/dL (5.17 mmol/L).

THERAPEUTIC EFFECTS OF LOWERING CHOLESTEROL

Reducing cholesterol levels in healthy middle-aged men without coronary heart disease (CHD) (in **primary prevention studies**) reduces their risk in direct proportion to the reduction in LDL cholesterol. Treated adults have statistically significant and clinically important reductions in the rates of myocardial infarctions, strokes, new cases of angina, and need for coronary artery bypass procedures. The West of Scotland Study showed a 31% decrease in myocardial infarctions in middle-aged men treated with pravastatin compared with placebo. The Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS) study showed similar results with lovastatin. As with any primary prevention interventions, large numbers of healthy patients need to be treated to prevent a single event. The numbers of patients needed to treat (NNT) to prevent one nonfatal myocardial infarction or one coronary artery disease death in these two studies were 46 and 50, respectively. The Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) study of atorvastatin in persons with hypertension and other risk factors but without CHD demonstrated a 36% reduction in CHD events. The Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) study showed a 44% reduction in a combined end point of myocardial infarction, stroke, revascularization, hospitalization for unstable angina, or death from cardiovascular causes in both men and women. The NNT for 1 year to prevent one event was 169. The Heart Outcomes Prevention Evaluation (HOPE-3) trial of rosuvastatin showed a 24% reduction in cardiovascular events. The NNT over 5.6 years was 91.

Primary prevention studies have found a less consistent effect on total mortality. The West of Scotland study found a 20% decrease in total mortality, tending toward statistical significance. The AFCAPS/TexCAPS study with lovastatin showed no difference in total mortality. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) also showed no reduction either in all-cause mortality or in CHD events when pravastatin was compared with usual care. Subjects treated with atorvastatin in the ASCOT study had a 13% reduction in mortality, but the result was not statistically significant. This study, however, was stopped early due to the marked reduction in CHD events. The JUPITER trial demonstrated a statistically significant 20% reduction in death from any cause. The NNT for 1 year was 400. The HOPE-3 trial showed a 7% reduction in all-cause mortality, but the result was not statistically significant.

In **secondary prevention studies** among patients with established CVD, the benefits of cholesterol lowering are clearer. Major studies with statins have shown significant reductions in cardiovascular events, cardiovascular deaths, and all-cause mortality in men and women with coronary artery disease. The NNT to prevent a non-fatal myocardial infarction or a coronary artery disease death in these studies was between 12 and 34. Aggressive cholesterol lowering with these agents causes regression of atherosclerotic plaques in some patients, reduces the progression of atherosclerosis in saphenous vein grafts, and can slow or reverse carotid artery atherosclerosis. Results with other classes of medications, particularly those with little effect on LDL or the LDL receptor, have been less consistent. For example, patients treated with gemfibrozil had fewer cardiovascular events, but there was no benefit in all-cause mortality when compared with placebo. The benefits and adverse effects of cholesterol lowering may be specific to each type of drug; the clinician cannot assume that the effects of new drugs with novel mechanisms of action will generalize to other classes of medication.

The disparities in results between primary and secondary prevention studies highlight a critical aspect of clinical cholesterol lowering. The net benefits from cholesterol lowering depend on the underlying risk of ASCVD as well as the competing risks of other diseases. In middle-aged patients with atherosclerosis and high cholesterol, morbidity and mortality rates are high, and measures that reduce cholesterol-related risk are more likely to provide a robust net benefit to the patient. In older patients with little atherosclerosis and lower cholesterol levels, there may be no meaningful net benefit to cholesterol lowering.

SECONDARY CONDITIONS THAT AFFECT LIPID METABOLISM

Several factors, including drugs, can influence serum lipids. These are important for two reasons: abnormal lipid levels (or changes in lipid levels) may be the presenting sign of some of these conditions, and correction of the underlying condition may obviate the need to treat an apparent lipid disorder. Thyroid disease, particularly hypothyroidism, is associated with a high LDL. Poorly controlled diabetes mellitus and alcohol use, in particular, are commonly associated with high triglyceride levels that decline with improvements in glycemic control or reduction in alcohol use, respectively. Thus, secondary causes of high blood lipids should be considered in each patient with a lipid disorder before lipid-lowering therapy is started. In most instances, special testing is not needed: a history and physical examination are sufficient.

CLINICAL PRESENTATIONS

Most patients with high cholesterol levels have no specific symptoms or signs. The vast majority of patients with lipid abnormalities are detected by the laboratory, either as part of the workup of a patient with CVD or as part of a preventive screening strategy. Extremely high levels of chylomicrons or VLDL particles (triglyceride level above 1000 mg/dL or 10 mmol/L) result in the formation of **eruptive xanthomas** (Figure 28–1) (red-yellow papules, especially on the buttocks). High LDL concentrations result in **tendinous xanthomas** on certain tendons (Achilles, patella, back of the hand). Such xanthomas usually indicate one of the underlying genetic hyperlipidemias. **Lipemia retinalis** (cream-colored blood vessels in the fundus) is seen with extremely high triglyceride levels (above 2000 mg/dL or 20 mmol/L).

hyperlipidemia and diabetes mellitus. (Used, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. The Color Atlas of Family Medicine, 2nd ed. McGraw-Hill, 2013.)

SCREENING & TREATMENT OF HIGH BLOOD CHOLESTEROL

While screening of all children for cholesterol disorders remains controversial, all adults should have their lipids checked before middle age. Patients with CVD and diabetes deserve the most scrutiny of their lipids since these patients are at the highest risk for suffering additional manifestations in the near term and thus have the most to gain from lipid lowering. In such patients, a complete lipid profile (serum total cholesterol, HDL cholesterol, and triglyceride levels) should be obtained. Additional risk reduction measures for atherosclerosis are discussed in Chapter 10; lipid lowering should be just one aspect of a program to reduce the progression and effects of atherosclerosis.

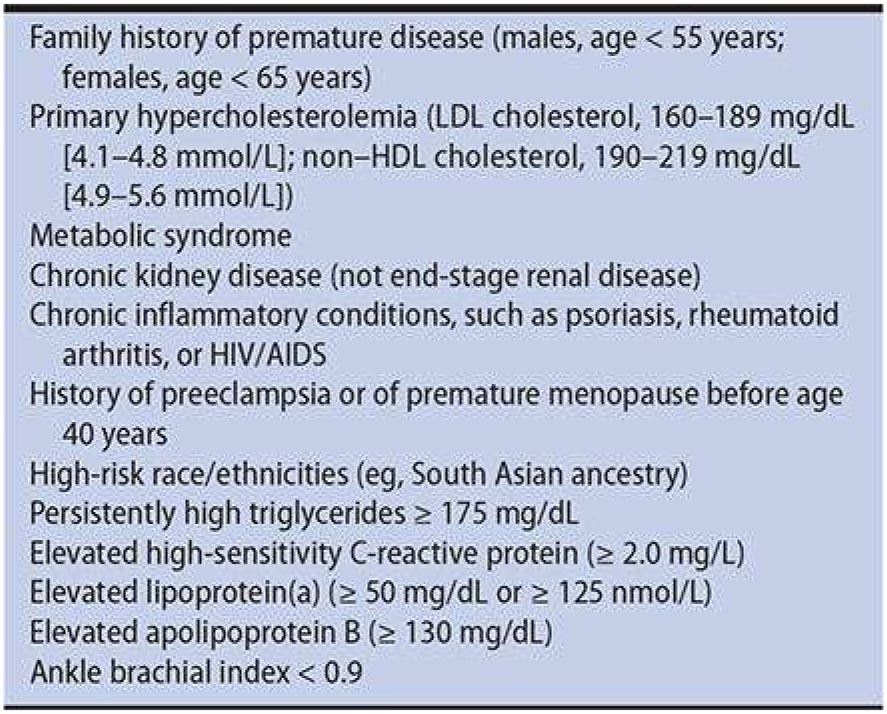
The best screening and treatment strategy for adults who do not have ASCVD is less clear. Several algorithms have been developed to guide the clinician in treatment decisions, but management decisions must always be individualized based on the patient's risk to maximize net benefit.

The 2018 American Heart Association/American College of Cardiology (AHA/ACC)/Multi-specialty guidelines recommend screening of all adults aged 20 years or older for high blood cholesterol. The 2016 United States Preventive Services Task Force (USPSTF) guidelines recommend beginning at age 20 years only if there are other cardiovascular risk factors such as tobacco use, diabetes, hypertension, obesity, or a family history of premature CVD. For men without other risk factors, screening is recommended beginning at age 35 years. For women and for men aged 20 to 35 without increased risk, the USPSTF makes no recommendation for or against routine screening for lipid disorders. Although there is no established interval for screening, screening can be repeated every 5 years for those with average or low risk and more often for those whose levels are close to therapeutic thresholds.

Individuals without CVD should have their 10-year risk of CVD calculated. Although those with LDL cholesterol greater than 190 mg/dL (4.91 mmol/L) are recommended for treatment independent of their 10-year risk of CVD, all other patients are recommended for treatment based on their overall cardiovascular risk. While other calculators (such as SCORE or QRISK) may be more appropriate for other parts of the world, the best method for estimating 10-year risk in the United States is the Pooled Cohort Equations. First introduced in the 2013 ACC/AHA guidelines, the Pooled Cohort Equations include separate equations for white and black patients and estimate the 10-year risk of heart attack, stroke, and cardiovascular death. This represents an improvement over older Framingham 10-year calculator, which includes CHD but not stroke risk. The ACC/AHA risk estimator can be found at http://www.cvriskcalculator.com/, and mobile apps are available for download. While it has been shown to overestimate risk in some modern populations, including those with at least moderate socioeconomic status, the ACC/AHA risk estimator remains an excellent starting point for a risk discussion. Recalibrated versions of the calculator are available for countries across the world.

The 2018 AHA/ACC/Multi-specialty guidelines identify a set of **"risk-enhancing factors"** that might influence a clinician and patient to favor cholesterol-lowering treatment. Table 28–1 lists these risk-enhancing factors that may be considered, particularly for patients at borderline to intermediate risk (5–20% 10-year cardiovascular risk).

Table 28–1. Risk-enhancing factors that help identify patients who may benefit most from lipid-lowering therapy: 2018 AHA/ACC/Multi-specialty guidelines.



Family history of premature disease (males, age < 55 years; females, age < 65 years)
Primary hypercholesterolemia (LDL cholesterol, 160–189 mg/dL [4.1–4.8 mmol/L]; non–HDL cholesterol, 190–219 mg/dL [4.9–5.6 mmol/L])
Metabolic syndrome
Chronic kidney disease (not end-stage renal disease)
Chronic inflammatory conditions, such as psoriasis, rheumatoid arthritis, or HIV/AIDS
History of preeclampsia or of premature menopause before age 40 years
High-risk race/ethnicities (eg, South Asian ancestry)
Persistently high triglycerides ≥ 175 mg/dL
Elevated high-sensitivity C-reactive protein (≥ 2.0 mg/L)
Elevated lipoprotein(a) (≥ 50 mg/dL or ≥ 125 nmol/L)
Elevated apolipoprotein B (≥ 130 mg/dL)
Ankle brachial index < 0.9

Importantly, the 2018 AHA/ACC/Multi-specialty guidelines also identify the **coronary artery calcium score** as the single best test for risk stratification. The coronary calcium score is a simple noncontrast cardiac-gated CT scan that takes about 10–15 minutes to do, is associated with approximately 1 mSv of radiation, and costs between $75 and $300. As opposed to the risk-enhancing factors, which may incline a clinician and patient toward treatment, the coronary artery calcium score may also help identify patients who are unlikely to benefit from cholesterol-lowering therapy. For example, when the coronary artery calcium score is zero in the absence of smoking or diabetes, the patient is low risk and less likely to receive net benefit from therapy; instead, the calcium artery calcium score can be repeated in 5 years. The USPSTF does not endorse calcium scoring as a screening test; rather the test should be reserved for situations in which additional data will inform shared decision making and potentially change a therapeutic decision.

Statins are nearly always the first-line therapy. Treatment decisions are based on the presence of clinical CVD or diabetes, LDL cholesterol greater than 190 mg/dL (4.91 mmol/L), patient age, and the estimated 10-year risk of developing CVD. The 2018 AHA/ACC/Multi-specialty guidelines define four groups of patients who benefit from statin medications: (1) individuals with clinical ASCVD; (2) individuals with primary elevation of LDL cholesterol greater than 190 mg/dL (4.91 mmol/L); (3) individuals aged 40–75 with diabetes and LDL greater than or equal to 70 mg/dL (1.81 mmol/L); and (4) individuals aged 40–75 without clinical ASCVD or diabetes, with LDL 70–189 mg/dL (1.81–4.91 mmol/L), and estimated 10-year CVD risk of 7.5% or higher.

Ezetimibe and PCSK9 inhibitors have the strongest recommendations as second-line therapy for patients with (1) CVD whose LDL on statin therapy remains above the 70 mg/dL treatment threshold or (2) possible familial hypercholesterolemia with baseline LDL greater than 190 mg/dL (4.91 mmol/L) whose LDL remains above the 100 mg/dL treatment threshold. In high-risk patients, ezetimibe therapy is favored, while in very high-risk patients, PCSK9 inhibitor therapy should be considered.

Screening & Treatment in Women

The foregoing screening and treatment guidelines are designed for both men and women. Meta-analysis of studies including women with known heart disease has found that statins prevent recurrent myocardial infarctions in women. Although most experts recommend application of the same primary prevention guidelines for women as for men, clinicians should be aware of the uncertainty in this area. Estimating the 10-year cardiovascular risk is particularly important in women since a larger percentage of women than men will have estimated 10-year cardiovascular risks below 7.5% per year and thus be advised not to take statins unless their LDL is very high (greater than 190 mg/dL [4.91 mmol/L]).

Screening & Treatment in Older Patients

Meta-analysis of evidence relating cholesterol to CVD in older adults suggests that cholesterol is a weak risk factor for CVD for persons over age 75 years. Clinical trials have rarely included such individuals. One exception is the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER). In this study, elderly patients with CVD (secondary prevention) benefited from statin therapy, whereas those without CVD (primary prevention) did not. The 2018 AHA/ACC/Multi-specialty guidelines suggest continuing statin treatment in patients over age 75 who have CVD. The guidelines, however, suggest selectively treating patients over the age of 75 who do not have evidence of CVD. Individual patient decisions to discontinue statin therapy should be based on overall functional status and life expectancy, comorbidities, and patient preference and should be made in context with overall therapeutic goals and end-of-life decisions.

TREATMENT OF HIGH LDL CHOLESTEROL

Reduction of LDL cholesterol with statins is just one part of a program to reduce the risk of CVD. Other measures—including diet, exercise, smoking cessation, hypertension control, diabetes control, and antithrombotic therapy—are also of central importance. For example, exercise (and weight loss) may reduce the LDL cholesterol and increase the HDL.

The use of medications to raise the HDL cholesterol has not been demonstrated to provide additional benefit. For example, cholesteryl ester transfer protein inhibitors are a class of medicines being investigated to raise HDL levels; however, agents in this class have not been shown to be effective in so doing. The addition of niacin to statins has also been carefully studied in the AIM-HIGH study and the HPS2-THRIVE study in patients at high risk for CVD and shown not to produce any further benefit (ie, to decrease parameters of cardiovascular risk).

Diet Therapy

Studies of nonhospitalized adults have reported only modest cholesterol-lowering benefits of dietary therapy, typically in the range of a 5–10% decrease in LDL cholesterol, and even less over the long term. The effect of diet therapy, however, varies considerably among individuals; some patients will have striking reductions in LDL cholesterol—up to a 25–30% decrease—whereas others will have clinically important increases. Thus, the results of diet therapy should be assessed about 4 weeks after initiation.

Several nutritional approaches to diet therapy are available. Most Americans currently eat over 35% of calories as fat, of which 15% is saturated fat. A traditional cholesterol-lowering diet recommends reducing total fat to 25–30% and saturated fat to less than 7% of calories, with complete elimination of trans fats. These diets replace fat, particularly saturated fat, with carbohydrate. Other diet plans, including the Dean Ornish Diet, the Pritikin Diet, and most vegetarian diets, restrict fat even further. Low-fat, high-carbohydrate diets may, however, result in insulin resistance and reductions in HDL cholesterol.

An alternative strategy is the Mediterranean diet, which maintains total fat at approximately 35–40% of total calories but replaces saturated fat with monounsaturated fat such as that found in canola oil and in olives, peanuts, avocados, and their oils. This diet is equally effective at lowering LDL cholesterol, and is less likely to lead to reductions in HDL cholesterol. Several studies have suggested that this diet may also be associated with reductions in endothelial dysfunction, insulin resistance, and markers of vascular inflammation and may result in better resolution of the metabolic syndrome than traditional cholesterol-lowering diets. A clinical trial demonstrated reduced cardiovascular events in persons on a Mediterranean diet supplemented with additional nuts or extra-virgin olive oil compared to persons on a less intensive standard Mediterranean diet.

Other dietary changes may also result in beneficial changes in blood lipids. Soluble fiber, such as that found in oat bran or psyllium, may reduce LDL cholesterol by 5–10%. Plant stanols and sterols can reduce LDL cholesterol by 10%. Intake of garlic, soy protein, vitamin C, and pecans may also yield modest reductions of LDL cholesterol. Because oxidation of LDL cholesterol is a potential initiating event in atherogenesis, diets rich in antioxidants, found primarily in fruits and vegetables, may be helpful (see Chapter 29). Studies have suggested that when all of these elements are combined into a single dietary prescription, the impact of diet on LDL cholesterol may approach that of statin medications, lowering LDL cholesterol by close to 30%.

Pharmacologic Therapy

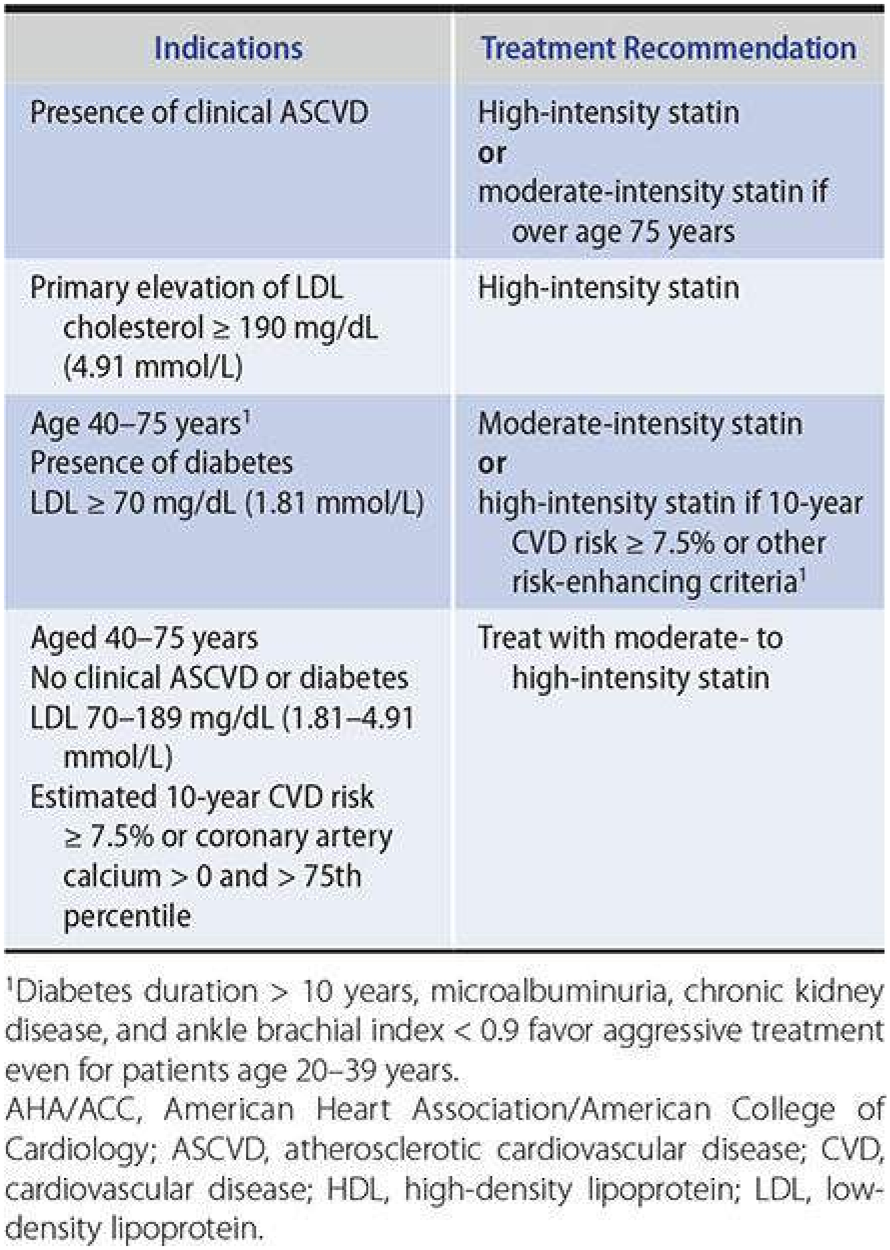
There are seven types of medications to consider in patients who require drug treatment of an elevated cholesterol. As discussed above, statins are the cornerstone of nearly all medical regimens, and current guidelines define four groups of patients who benefit from statin medications. The evidence is then strongest for ezetimibe and PCSK9 inhibitors, with less evidence for cholesterol absorption inhibitors, fibrates, and niacin, with strong emerging randomized controlled trial evidence for select omega-3 fatty acid preparations.

A. Statins (Hydroxymethylglutaryl-Coenzyme A [HMG-CoA] Reductase Inhibitors)

The statins (HMG-CoA reductase inhibitors) work by inhibiting the rate-limiting enzyme in the formation of cholesterol. Cholesterol synthesis in the liver is reduced, with a compensatory increase in hepatic LDL receptors (presumably so that the liver can take more of the cholesterol that it needs from the blood) and a reduction in the circulating LDL cholesterol level by 50% or more at the highest doses. There are also modest increases in HDL levels, substantial decreases in triglyceride levels, and marked reductions in high-sensitivity C-reactive protein levels.

The 2018 AHA/ACC/Multi-specialty guidelines divide statins into two categories: “high-intensity” and “moderate-intensity” statins (Table 28–2). High-intensity statins lower LDL cholesterol by approximately 50%. Examples include high-dose atorvastatin 40–80 mg/day and rosuvastatin 20–40 mg/day (Table 28–3). Moderate-intensity statins lower LDL cholesterol by approximately 30–50%. Examples include simvastatin 20–40 mg/day, pravastatin 40–80 mg/day, and lovastatin 40 mg/day, as well as low-dose atorvastatin 10–20 mg/day and rosuvastatin 5–10 mg/day. All statins are given once daily in the morning or evening.

Table 28–2. Indications for high-intensity and moderate-intensity statins: recommendations of the 2018 AHA/ACC/Multi-specialty guidelines.



Indications	Treatment Recommendation
Presence of clinical ASCVD	High-intensity statin **or** moderate-intensity statin if over age 75 years
Primary elevation of LDL cholesterol ≥ 190 mg/dL (4.91 mmol/L)	High-intensity statin
Age 40–75 years[1] Presence of diabetes LDL ≥ 70 mg/dL (1.81 mmol/L)	Moderate-intensity statin **or** high-intensity statin if 10-year CVD risk ≥ 7.5% or other risk-enhancing criteria[1]
Aged 40–75 years No clinical ASCVD or diabetes LDL 70–189 mg/dL (1.81–4.91 mmol/L) Estimated 10-year CVD risk ≥ 7.5% or coronary artery calcium > 0 and > 75th percentile	Treat with moderate- to high-intensity statin

[1] Diabetes duration > 10 years, microalbuminuria, chronic kidney disease, and ankle brachial index < 0.9 favor aggressive treatment even for patients age 20–39 years.

AHA/ACC, American Heart Association/American College of Cardiology; ASCVD, atherosclerotic cardiovascular disease; CVD, cardiovascular disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Table 28–3. Effects of selected lipid-modifying drugs (listed alphabetically).

Drug	Lipid-Modifying Effects		Triglyceride	Initial Daily Dose	Maximum Daily Dose	Cost for 30 Days of Treatment With Dose Listed[1]
	LDL	HDL				
Alirocumab (Praluent)	–45 to –60%	±	±	75 mg once every 2 weeks	150 mg once every 2 weeks	$1344.00 (75 mg every 2 weeks)
Atorvastatin (Lipitor)	–25 to –40%	+5 to 10%	↓↓	10 mg once	80 mg once	$15.75 (20 mg once)
Cholestyramine (Questran, others)	–15 to –25%	+5%	±	4 g twice a day	24 g divided	$21.00 (8 g divided)
Colesevelam (WelChol)	–10 to –20%	+10%	±	625 mg, 6–7 tablets once	625 mg, 6–7 tablets once	$749.52 (6 tablets once)
Colestipol (Colestid)	–15 to –60%	+5%	±	5 g twice a day	30 g divided	$235.82 (10 g divided)
Evolocumab (Repatha)	–50 to –60%	±	±	140 mg once every 2 weeks	420 mg once monthly	$1340.59 (140 mg every 2 weeks)
Ezetimibe (Zetia)	–20%	+5%	±	10 mg once	10 mg once	$308.43 (10 mg once)
Fenofibrate (Tricor, others)	–10 to –15%	+15 to 25%	↓↓	48 mg once	145 mg once	$37.20 (145 mg once)
Fenofibric acid (Trilipix)	–10 to –15%	+15 to 25%	↓↓	45 mg once	135 mg once	$160.20 (135 mg once)
Fluvastatin (Lescol)	–20 to –30%	+5 to 10%	↓	20 mg once	40 mg once	$113.40 (20 mg once)
Gemfibrozil (Lopid, others)	–10 to –15%	+15 to 20%	↓↓	600 mg once	1200 mg divided	$71.40 (600 mg twice a day)
Lomitapide (Juxtapid)[2,3]	–40 to –50%[4]	–7%[4]	↓↓	5 mg once	60 mg once	$44,390.40 (any dose)
Lovastatin (Mevacor, others)	–25 to –40%	+5 to 10%	↓	10 mg once	80 mg divided	$63.00 (20 mg once)
Mipomersen (Kynamro)[2,3]	–20 to –25%[5]	+11%[5]	↓	200 mg subcutaneously once weekly	200 mg subcutaneously once weekly	$36,532.96 (200 mg weekly)
Niacin (OTC, Niaspan)	–15 to –25%	+25 to 35%	↓↓	100 mg once	3–4.5 g divided	$9.00 (1.5 g twice a day, OTC) $449.40 (2 g Niaspan)
Omega-3 fatty acid ethyl esters (Lovaza)			↓↓	4 g once	4 g once	$348.76 (4 g daily)
Omega-3 fatty acid icosapent ethyl (Vascepa)			↓↓	2 g twice	2 g twice	$334.30 (2 g twice day)
Pitavastatin (Livalo, Zypitamag)	–30 to 40%	+10 to 25%	↓↓	2 mg once	4 mg once	$331.50 (2 mg once)
Pravastatin (Pravachol)	–25 to –40%	+5 to 10%	↓	20 mg once	80 mg once	$75.00 (20 mg once)
Rosuvastatin (Crestor)	–40 to –50%	+10 to 15%	↓↓	10 mg once	40 mg once	$43.20 (20 mg once)
Simvastatin (Zocor, others)	–25 to –40%	+5 to 10%	↓↓	5 mg once	80 mg once	$6.00 (10 mg once)

[5] No plasma lipoprotein apheresis allowed in clinical trial.

HDL, high-density lipoprotein; LDL, low-density lipoprotein; ± variable, if any; others, indicates availability of less expensive generic preparations; OTC, over the counter.

Statin-associated muscle aches, with normal serum creatine kinase levels, occur in up to 10% of patients, and often such patients can tolerate the statin upon rechallenge. More serious, but very uncommon, muscle disease includes myositis and rhabdomyolysis, with moderate and marked elevations of serum creatine kinase levels, respectively. Such muscle disease occurs more often when the statin is taken with niacin or a fibrate, as well as with erythromycin, antifungal medications, nefazodone, or cyclosporine. Simvastatin at the highest approved dose (80 mg) is associated with an elevated risk of muscle injury or myopathy; this dose should be used only in patients who have been taking simvastatin at a lower dose for longer than 1 year without muscle toxicity. Liver disease, with elevations of serum transaminases, is another side effect of statin therapy and is again more common in patients who are also taking fibrates or niacin. Manufacturers of statins recommend monitoring liver enzymes before initiating therapy and as clinically indicated thereafter. Liver failure can occur but is extremely uncommon. Finally, statin therapy is associated with mild gastrointestinal symptoms and a 10% increase in risk of developing diabetes mellitus.

B. Ezetimibe

Ezetimibe inhibits the intestinal absorption of dietary and biliary cholesterol across the intestinal wall by inhibiting a cholesterol transporter. The dose of ezetimibe is 10 mg/day orally. Ezetimibe reduces LDL cholesterol between 15% and 20% when used as monotherapy, reduces high-sensitivity C-reactive protein, and can further reduce LDL in patients taking statins in whom the therapeutic goal has not been reached. While beneficial effects of ezetimibe monotherapy on cardiovascular outcomes are available from only a large open-label trial, the double-blind IMPROVE-IT trial showed that adding ezetimibe to a statin resulted in a small incremental 5–10% relative risk reduction in cardiovascular outcomes. At the end of 7 years of study, patients taking ezetimibe-simvastatin had a 2% absolute reduction in cardiovascular events compared to patients taking simvastatin alone. Current guidelines recommend adding ezetimibe therapy to maximally tolerated statin therapy in patients at high risk for CVD whose LDL cholesterol remains above the treatment threshold of 70 mg/dL.

C. Proprotein Convertase Subtilisin/Kexin Type 9 (PCSK9) Inhibitors

PCSK9 inhibitors are fully human monoclonal antibodies that inhibit PCSK9-mediated LDL-receptor degradation and lower LDL cholesterol levels by 50–60% and lipoprotein(a) by up to 20–30%. Two agents, alirocumab and evolocumab, are approved for use in the United States for patients with familial hypercholesterolemia or CVD who require additional lowering of LDL cholesterol. The medications are injected subcutaneously every 2–4 weeks. No significant increase in adverse events has been observed compared to placebo. The FOURIER (Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk) trial compared evolocumab with placebo in 27,564 patients with established atherosclerotic disease already taking statin therapy; participants were monitored for a median of 2.2 years. LDL cholesterol was reduced by 59%. Patients receiving the evolocumab plus statin had a 15% reduction in the primary composite endpoint of cardiovascular death, myocardial infarction, stroke, hospital admission for unstable angina, or coronary revascularization and a 20% reduction in the secondary outcome of cardiovascular death, myocardial infarction, or stroke. The ODYSSEY-OUTCOMES study randomized 18,924 patients with recent acute coronary syndrome to alirocumab or placebo, demonstrating a 15% reduction in the primary composite cardiovascular endpoint and a 15% reduction in all-cause mortality in secondary statistical testing after median 2.8-year follow-up.

However, despite encouraging results from multiple clinical trials, initial cost-effectiveness models suggested that PCSK9 inhibitors were not cost-effective. After marked price reductions in 2018 and 2019, PCSK9 inhibitors are closer to being cost-effective; however, guidelines suggest that their relatively high cost must still remain part of the consideration regarding their use. Current guidelines recommend addition of PCSK9 inhibitors to statins at maximally tolerated doses in patients at very high risk for CVD when on-treatment LDL cholesterol remains above 70 mg/dL (or above 100 mg/dL in patients with familial hypercholesterolemia). Patients considered to be at very high-risk for CVD include those with recent acute coronary syndrome within 12 months; multiple prior myocardial infarctions or strokes; significant unrevascularized coronary artery disease; and polyvascular disease (coronary plus cerebrovascular or peripheral vascular disease).

D. Bile Acid–Binding Resins

The bile acid–binding resins include cholestyramine, colesevelam, and colestipol. In the pre-statin era, treatment with these agents reduced the incidence of coronary events in middle-aged men by about 20%, with no significant effect on total mortality. The resins work by binding bile acids in the intestine. The resultant reduction in the enterohepatic circulation causes the liver to increase its production of bile acids, using hepatic cholesterol to do so. Thus, hepatic LDL receptor activity increases, with a decline in plasma LDL levels. The triglyceride level tends to increase slightly in some patients treated with bile acid–binding resins; these resins should be used with caution in patients with elevated triglycerides and probably not at all in patients who have triglyceride levels above 500 mg/dL. The clinician can anticipate a reduction of 15–25% in the LDL cholesterol level, with insignificant effects on the HDL level.

These agents often cause gastrointestinal symptoms, such as constipation and gas.

They may interfere with the absorption of fat-soluble vitamins (thereby complicating the management of patients receiving warfarin) and may bind other drugs in the intestine. Concurrent use of psyllium may ameliorate the gastrointestinal side effects.

E. Omega-3 Fatty Acid Preparations

Omega-3 fatty acids are essential fatty acids that must be consumed in the diet and are a prominent feature of Mediterranean-style diets. In pharmacologic doses, omega-3 fatty acid preparations can lower triglycerides by up to 30%, with modest reductions in apolipoprotein-B–containing lipoproteins and high-sensitivity C-reactive protein. Pharmacologic therapy should be differentiated from dietary omega-3 fatty acid supplements. The former is an FDA-approved product usually given at a much higher dose; dietary supplements are variable and not currently regulated.

There is weak evidence that omega-3 fatty acids reduce myocardial infarctions, though with no reduction in total or cardiovascular mortality. Omega-3 ethyl esters have not been associated with cardiovascular event reduction when added to statin therapy. In contrast, icosapent ethyl, which is a highly purified eicosapentaenoic acid (EPA) only preparation, was shown to reduce cardiovascular deaths, nonfatal myocardial infarctions, nonfatal strokes, coronary revascularizations, and unstable angina by 25% in statin-treated patients with triglycerides greater than 135 mg/dL in the 8179 person REDUCE-IT randomized clinical trial. The mechanism of icosapent ethyl is not yet clear but likely involves multiple mechanisms beyond lipid lowering, including antiplatelet activity, anti-inflammatory activity, and arrhythmia prevention.

F. Fibric Acid Derivatives

The fibrates are peroxisome proliferative-activated receptor-alpha (PPAR-alpha) agonists that result in significant reductions of plasma triglycerides and increases in HDL cholesterol. They reduce LDL levels by about 10–15% (although the result is quite variable) and triglyceride levels by about 40% and raise HDL levels by about 15–20%. The fibric acid derivatives or fibrates approved for use in the United States are gemfibrozil and fenofibrate. Ciprofibrate and bezafibrate are also available for use internationally.

Gemfibrozil monotherapy reduced CHD rates in hypercholesterolemic middle-aged men free of coronary disease in the Helsinki Heart Study. The effect was observed only among those who also had lower HDL cholesterol levels and high triglyceride levels. In a Veteran Affairs study, gemfibrozil monotherapy was also shown to reduce cardiovascular events in men with existing CHD whose primary lipid abnormality was a low HDL cholesterol. There was no effect on all-cause mortality.

However, fibrates have not been shown to reduce cardiovascular events in all statin-treated patients with CVD or diabetes. For example, in the ACCORD study, addition of fenofibrate to statin in patients with diabetes and mild triglyceride elevations resulted in no benefit.

The usual dose of gemfibrozil is 600 mg once or twice a day. Side effects include cholelithiasis, hepatitis, and myositis. The incidence of the latter two conditions may be higher among patients also taking other lipid-lowering agents. Fenofibrate, 48–145 mg daily, can be used and has slightly fewer side effects than gemfibrozil. Resins are the only lipid-modifying medication considered safe in pregnancy.

G. Niacin (Nicotinic Acid)

Niacin was the first lipid-lowering agent that was associated with a reduction in total mortality. Long-term follow-up of a secondary prevention trial in middle-aged men with previous myocardial infarction disclosed that about half of those who had been previously treated with niacin had died, compared with nearly 60% of the placebo group. This favorable effect on mortality was not seen during the trial itself, though there was a reduction in the incidence of recurrent coronary events. A meta-analysis of 10 randomized trials using niacin in the pre-statin era showed a 27% reduction in cardiovascular events.

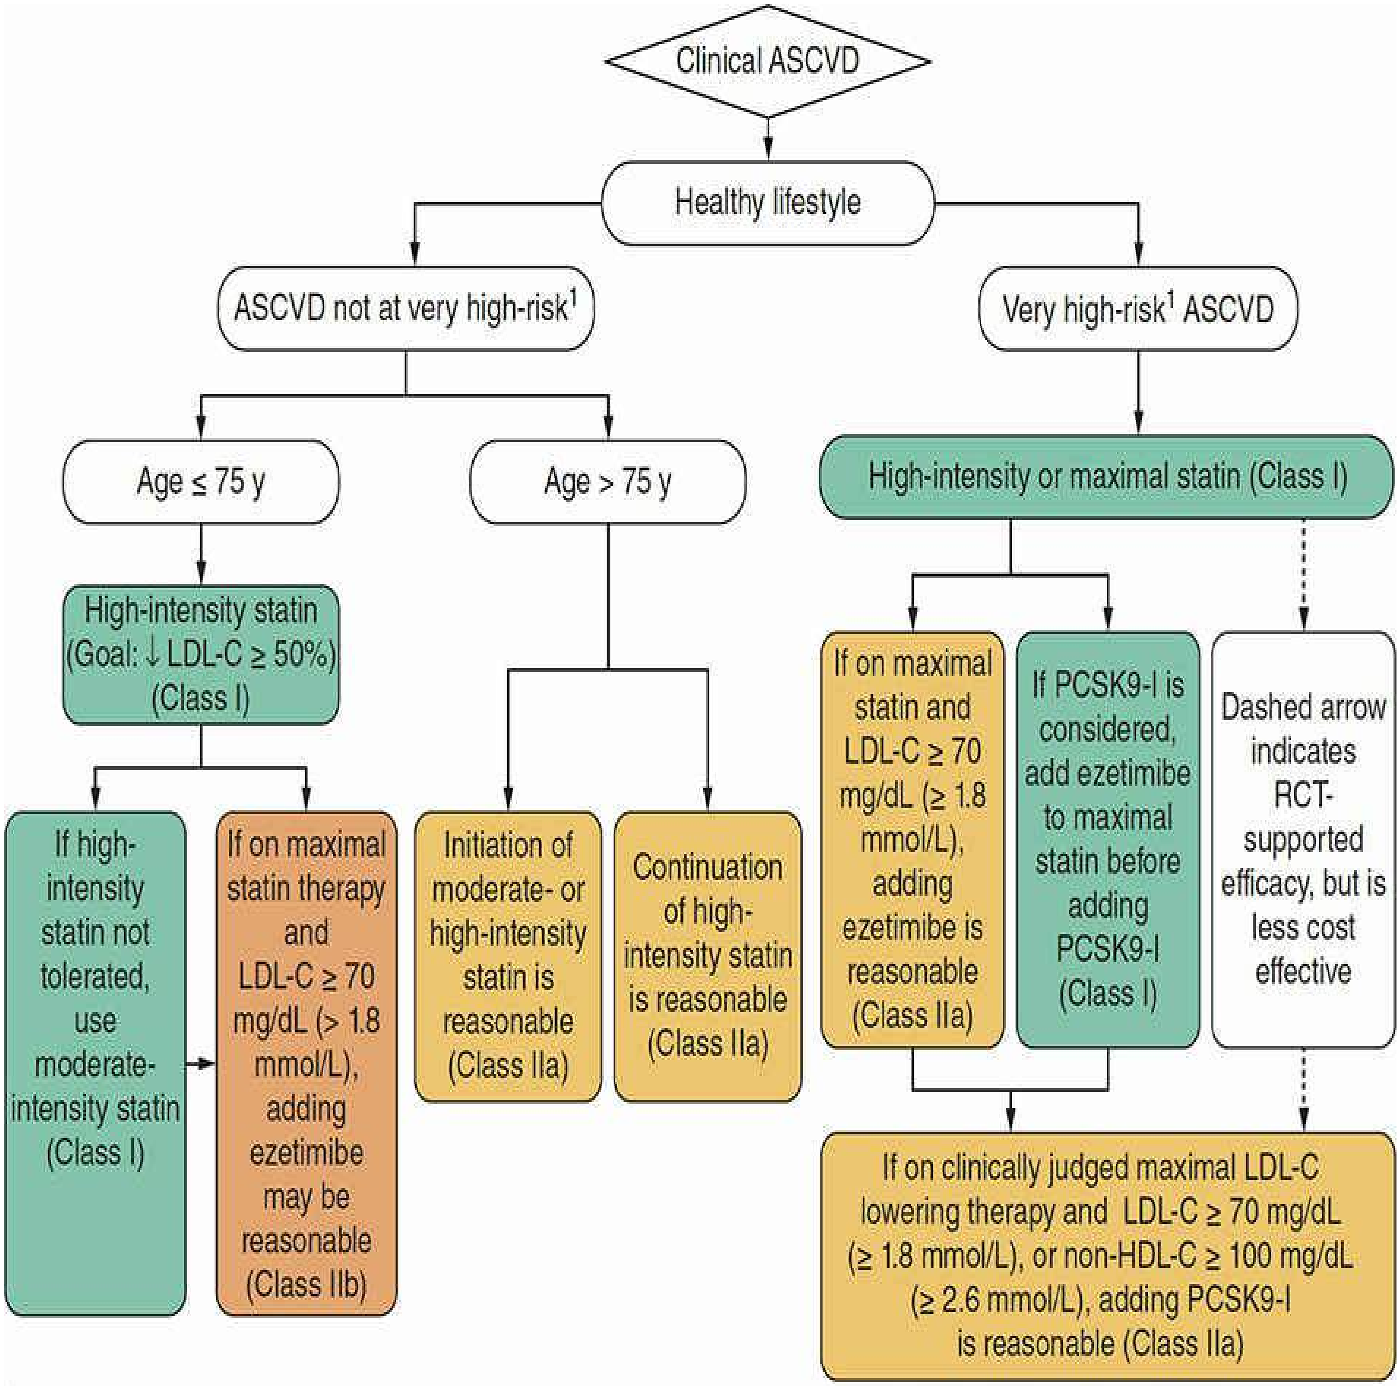
Niacin reduces the production of VLDL particles, with secondary reduction in LDL and increases in HDL cholesterol levels. The average effect of full-dose niacin therapy is a 15–25% reduction in LDL cholesterol and a 25–35% increase in HDL cholesterol. Full doses are required to obtain the LDL effect, but the HDL effect is observed at lower doses, eg, 1 g/day. Niacin also reduces triglycerides and can lower lipoprotein(a) (Lp[a]) levels. Intolerance to niacin is common; only 50–60% of patients can take full doses. Niacin causes a prostaglandin-mediated flushing that patients may describe as “hot flashes” or pruritus. It can be decreased with aspirin (81–325 mg/day) or other nonsteroidal anti-inflammatory agents taken an hour before niacin dosing. Extended-release niacin is better tolerated by most patients. Niacin can also exacerbate gout and peptic ulcer disease. Although niacin may increase blood sugar in some patients, clinical trials have shown that it can be safely used in diabetic patients.

In two large clinical trials, AIM-HIGH and HPS2-THRIVE, extended-release niacin did not reduce cardiovascular events when added to statin therapy in high-risk patients.

Treatment Algorithms

For patients who require a lipid-modifying medication, an HMG-CoA reductase inhibitor (statin) is recommended. In patients with CVD, this should generally be at its maximally tolerated dose.

Combination therapy is indicated for (1) patients with familial hypercholesterolemia with on-treatment LDL cholesterol that is above 100 mg/dL and (2) patients with existing CVD with on-treatment LDL cholesterol that remains above 70 mg/dL. Patients with homozygous familial hypercholesterolemia may need plasmapheresis and/or special lipid-lowering therapies uniquely approved for this population (Table 28–3). Patients with heterozygous familial hypercholesterolemia may need two or more medications to get below the treatment threshold, while those with CVD less commonly need multiple medications. The 2018 AHA/ACC/Multi-specialty guidelines recommend addition of ezetimibe in high-risk patients, while reserving PCSK9 inhibitor therapy for very high-risk patients or those taking maximally tolerated statins and ezetimibe with LDL cholesterol still not below 70 mg/dL (Figure 28–2).



Clinical ASCVD
Healthy lifestyle
ASCVD not at very high-risk¹
Very high-risk¹ ASCVD
Age ≤ 75 y
Age > 75 y
High-intensity or maximal statin (Class I)
High-intensity statin (Goal: ↓ LDL-C ≥ 50%) (Class I)
If high-intensity statin not tolerated, use moderate-intensity statin (Class I)
If on maximal statin therapy and LDL-C ≥ 70 mg/dL (> 1.8 mmol/L), adding ezetimibe may be reasonable (Class IIb)
Initiation of moderate- or high-intensity statin is reasonable (Class IIa)
Continuation of high-intensity statin is reasonable (Class IIa)
If on maximal statin and LDL-C ≥ 70 mg/dL (≥ 1.8 mmol/L), adding ezetimibe is reasonable (Class IIa)
If PCSK9-I is considered, add ezetimibe to maximal statin before adding PCSK9-I (Class I)
Dashed arrow indicates RCT-supported efficacy, but is less cost effective
If on clinically judged maximal LDL-C lowering therapy and LDL-C ≥ 70 mg/dL (≥ 1.8 mmol/L), or non-HDL-C ≥ 100 mg/dL (≥ 2.6 mmol/L), adding PCSK9-I is reasonable (Class IIa)

[1] Very high-risk groups include patients with recent acute coronary syndrome within 12 months; multiple prior myocardial infarctions or strokes; significant unrevascularized coronary artery disease; and polyvascular disease (coronary + cerebrovascular or peripheral vascular)

(Class I = Strong recommendation [benefit >>> risk]; Class IIa = Moderately strong recommendation [benefit >> risk]; Class IIb = Weak recommendation [benefit > risk])

HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; PCSK9-I, proprotein convertase subtilisin/kexin type 9 inhibitor; RCT, randomized controlled trial.

HIGH BLOOD TRIGLYCERIDES

Patients with very high levels of serum triglycerides (greater than 1000 mg/dL) are at risk for pancreatitis. The pathophysiology is not certain, since pancreatitis never develops in some patients with very high triglyceride levels. Most patients with congenital abnormalities in triglyceride metabolism present in childhood; hypertriglyceridemia-induced pancreatitis first presenting in adults is more commonly due to an acquired problem in lipid metabolism.

Although there are no clear triglyceride levels that predict pancreatitis, most clinicians treat fasting levels above 500 mg/dL (5 mmol/L). The risk of pancreatitis may be more related to the triglyceride level following consumption of a fatty meal. Because postprandial increases in triglyceride are inevitable if fat-containing foods are eaten, fasting triglyceride levels in persons prone to pancreatitis should be kept well below that level.

The primary therapy for high triglyceride levels is dietary, avoiding alcohol, simple sugars, refined starches, and saturated and trans fatty acids, and restricting total calories. Control of secondary causes of high triglyceride levels may also be helpful. In patients with fasting triglycerides greater than or equal to 500 mg/dL (5 mmol/L) despite adequate dietary compliance—and certainly in those with a previous episode of pancreatitis—therapy with a triglyceride-lowering drug (eg, statins, fibric acid derivative, omega-3-acid ethyl esters, or niacin) is indicated. Combinations of these medications may also be used.

Currently, drug treatment for patients with triglycerides greater than 150 mg/dL (1.5 mmol/L) is reserved for those with established CVD with well-controlled LDL cholesterol on maximally tolerated therapy with statins or other agents. Currently, data are strongest for icosapent ethyl.

Nutritional Disorders

Katherine H. Saunders, MD
Leon I. Igel, MD, FACP, FTOS
Robert B. Baron, MD, MS

NUTRITIONAL DISORDERS

PROTEIN–ENERGY MALNUTRITION

ESSENTIALS OF DIAGNOSIS

- Decreased intake of energy or protein, increased nutrient losses, or increased nutrient requirements.
- **Kwashiorkor:** caused by protein deficiency.
- **Marasmus:** caused by combined protein and energy deficiency.
- Protein loss correlates with weight loss: 35–40% total body weight loss is usually fatal.

General Considerations

Protein–energy malnutrition occurs as a result of a relative or absolute deficiency of energy and protein. It may be primary, due to inadequate food intake, or secondary, as a result of other illness. For most developing nations, primary protein–energy malnutrition remains among the most significant health problems. It occurs in two distinct syndromes. **Kwashiorkor,** caused by a deficiency of protein in the presence of adequate energy, is typically seen in weaning infants at the birth of a sibling in areas where foods containing protein are insufficient. **Marasmus,** caused by combined protein and energy deficiency, is seen where adequate quantities of food are simply not available.

In industrialized societies, protein–energy malnutrition is most often secondary to other diseases. **Kwashiorkor-like secondary protein–energy malnutrition** occurs primarily in association with hypermetabolic acute illnesses such as trauma, burns, and sepsis. **Marasmus-like secondary protein–energy malnutrition** typically results from chronic diseases such as chronic obstructive pulmonary disease (COPD), heart failure, cancer, or AIDS. These two syndromes are estimated to be present in at least 20% of hospitalized patients. A substantially greater number of patients have risk factors that could result in them. In both syndromes, protein–energy malnutrition is caused either by decreased intake of energy and protein or by increased nutrient losses related to the underlying illness. For example, diminished energy intake may result from poor dentition or various gastrointestinal disorders. Increased nutrient losses result from malabsorption, diarrhea, and glycosuria. Increased nutrient requirements occur with fever, surgery, neoplasia, and burns.

Clinical Findings

Clinical manifestations of protein–energy malnutrition range from mild growth retardation and weight loss to a number of distinct clinical syndromes. In the developing world, children manifest marasmus and kwashiorkor. In industrialized nations, clinical manifestations of secondary protein–energy malnutrition are affected by the patient's nutritional status prior to illness, illness resulting in the protein and energy deficiency, and degree of the deficiency.

Progressive wasting that begins with weight loss and proceeds to more severe cachexia typically develops in most patients with marasmus-like secondary protein–energy malnutrition. In the most severe form of this disorder, most body fat stores disappear and muscle mass decreases, most noticeably in the temporalis and interosseous muscles. Laboratory studies may be unremarkable—serum albumin, for example, may be normal or slightly decreased, rarely decreasing to less than 2.8 g/dL (28 g/L). In contrast, owing to its rapidity of onset, kwashiorkor-like secondary protein–energy malnutrition may develop in patients with normal subcutaneous fat and muscle mass or, if the patient has obesity, even in patients with excess fat and muscle. The serum protein level, however, typically declines and the serum albumin is often less than 2.8 g/dL (28 g/L). Dependent edema, ascites, or anasarca may develop. As with primary protein–energy malnutrition, combinations of the marasmus-like and kwashiorkor-like syndromes can occur simultaneously, typically in patients with progressive chronic disease in whom a superimposed acute illness develops.

Treatment

The treatment of severe protein–energy malnutrition is a slow process requiring great care. Initial efforts should be directed at correcting fluid and electrolyte abnormalities and infections. Of particular concern are depletion of potassium, magnesium, and calcium and acid–base abnormalities. The second phase of treatment is directed at repletion of protein, energy, and micronutrients. Treatment is started with modest quantities of protein and calories calculated based on the patient's actual body weight. Adult patients are given 1 g/kg of protein and 30 kcal/kg of calories. Concomitant administration of vitamins and minerals is obligatory. Either the enteral or parenteral route can be used, although the former is preferable. Enteral fat and lactose are withheld initially. Patients with less severe protein–calorie undernutrition can be given calories and protein simultaneously with the correction of fluid and electrolyte abnormalities. Similar quantities of protein and calories are recommended for initial treatment.

Patients treated for protein–energy malnutrition require close follow-up. In adults, both calories and protein are advanced as tolerated, adults to 1.5 g/kg/day of protein and 40 kcal/kg/day of calories.

Patients who are refed too rapidly may develop a number of untoward clinical sequelae. During refeeding, circulating potassium, magnesium, phosphorus, and glucose move intracellularly and can result in low serum levels of each. The administration of water and sodium with carbohydrate refeeding can result in heart failure in persons with depressed cardiac function. Enteral refeeding can lead to malabsorption and diarrhea due to abnormalities in the gastrointestinal tract.

Refeeding edema is a benign condition to be differentiated from heart failure. Changes in renal sodium reabsorption and poor skin and blood vessel integrity result in the development of dependent edema without other signs of heart disease. Treatment includes reassurance, elevation of the dependent area, and modest sodium restriction. Diuretics are usually ineffective, may aggravate electrolyte deficiencies, and should not be used.

The prevention and early detection of protein–energy malnutrition in hospitalized patients require awareness of its risk factors and early symptoms and signs. Patients at risk require formal assessment of nutritional status and close observation of dietary intake, body weight, and nutritional requirements during the hospital stay.

OBESITY

ESSENTIALS OF DIAGNOSIS

- Excess adipose tissue; body mass index (BMI) greater than 30.
- Upper body obesity (abdomen and flank) of greater health consequence than lower body obesity (buttocks and thighs).
- Many associated comorbid conditions, including diabetes mellitus, hypertension, hyperlipidemia, heart disease, stroke, and sleep apnea.

Definition & Measurement

Obesity is a multifactorial, chronic disease characterized by an accumulation of visceral and subcutaneous fat. Obesity predisposes to a wide variety of comorbid conditions. The **BMI** correlates with excess adipose tissue. It is calculated by dividing body weight in kilograms by height in meters squared. The National Institutes of Health (NIH) defines a normal BMI as 18.5–24.9. Overweight is defined as BMI 25–29.9. Class I obesity is 30–34.9, class II obesity is 35–39.9, and class III obesity is BMI greater than or equal to 40. Upper body obesity (excess fat around the waist and flank) is a greater health hazard than lower body obesity (fat in the thighs and buttocks). Patients with obesity and increased abdominal circumference (greater than 102 cm or 40 inches in men and 88 cm or 35 inches in women) or high waist–hip ratios (greater than 1.0 in men and 0.85 in women) have a greater risk of weight-related comorbid conditions and early death than patients with the same BMI and lower ratios. Furthermore, visceral fat within the abdominal cavity is more hazardous to health than subcutaneous fat around the abdomen. US survey data demonstrate that almost 40% of Americans have obesity.

Etiology

Both genetic and environmental factors contribute to the development of obesity. Twin studies have demonstrated that genetics account for 50–90% of the variation in BMI. Only a small percentage of human obesity is thought to be due to single gene mutations. Most human obesity develops from the interactions of multiple genes, environmental factors, and behavior. The rapid increase in obesity in the last several decades points to major roles for environmental and behavioral factors in its development.

Medical Evaluation of the Patient with Obesity

Historical information should be obtained about age at onset, recent weight changes, family history of obesity, occupational history, eating and exercise behavior, cigarette and alcohol use, previous weight loss experience, and psychosocial factors including assessment for depression and eating disorders.

Physical examination should assess the BMI, degree and distribution of body fat, overall nutritional status, and signs of secondary causes of obesity. Less than 1% of patients with obesity have an identifiable secondary cause of obesity. Hypothyroidism and Cushing syndrome are important examples that can be diagnosed by physical examination, laboratory testing, and imaging studies in patients with unexplained recent weight gain. Such patients require endocrinologic evaluation (see Chapter 26). All patients with obesity should be assessed for weight-related comorbid conditions. Blood pressure, waist circumference, fasting glucose, comprehensive metabolic profile, lipid panel, and hemoglobin A_{1c} should be measured as well as other laboratory tests as clinically indicated.

Treatment

Weight loss of 5–10% body weight is sufficient for clinically relevant improvements in many risk factors among patients with obesity and risk reduction appears to be dose-related. Magnitude of weight loss at 1 year is strongly associated with improvements in many parameters including blood sugar, blood pressure, triglycerides, and high-density lipoprotein (HDL) cholesterol. Successful treatment of obesity requires a multidisciplinary approach to counteract the body’s resistance to weight loss. Diet, physical activity, and behavioral modifications are the cornerstones of weight management. Many **dietary strategies** can be effective for weight loss. Recommendations should be tailored to a patient’s preferences as dietary adherence is associated with greater weight loss and greater reductions in cardiac risk factors. Dietary instructions should emphasize intake of a variety of predominantly “unprocessed” foods, with special attention to limiting foods that provide large amounts of calories without other nutrients, ie, sugary drinks, fast food, junk food and sweets. A

Mediterranean diet can be a good option for patients at high cardiovascular risk, since it has been shown to reduce the incidence of major cardiovascular events. A low-glycemic-index diet can curb hunger and decrease cravings by reducing blood sugar fluctuations. Meal replacement diets can also be used effectively to achieve weight loss. Registered dietitians can provide dietary education and customize diet plans.

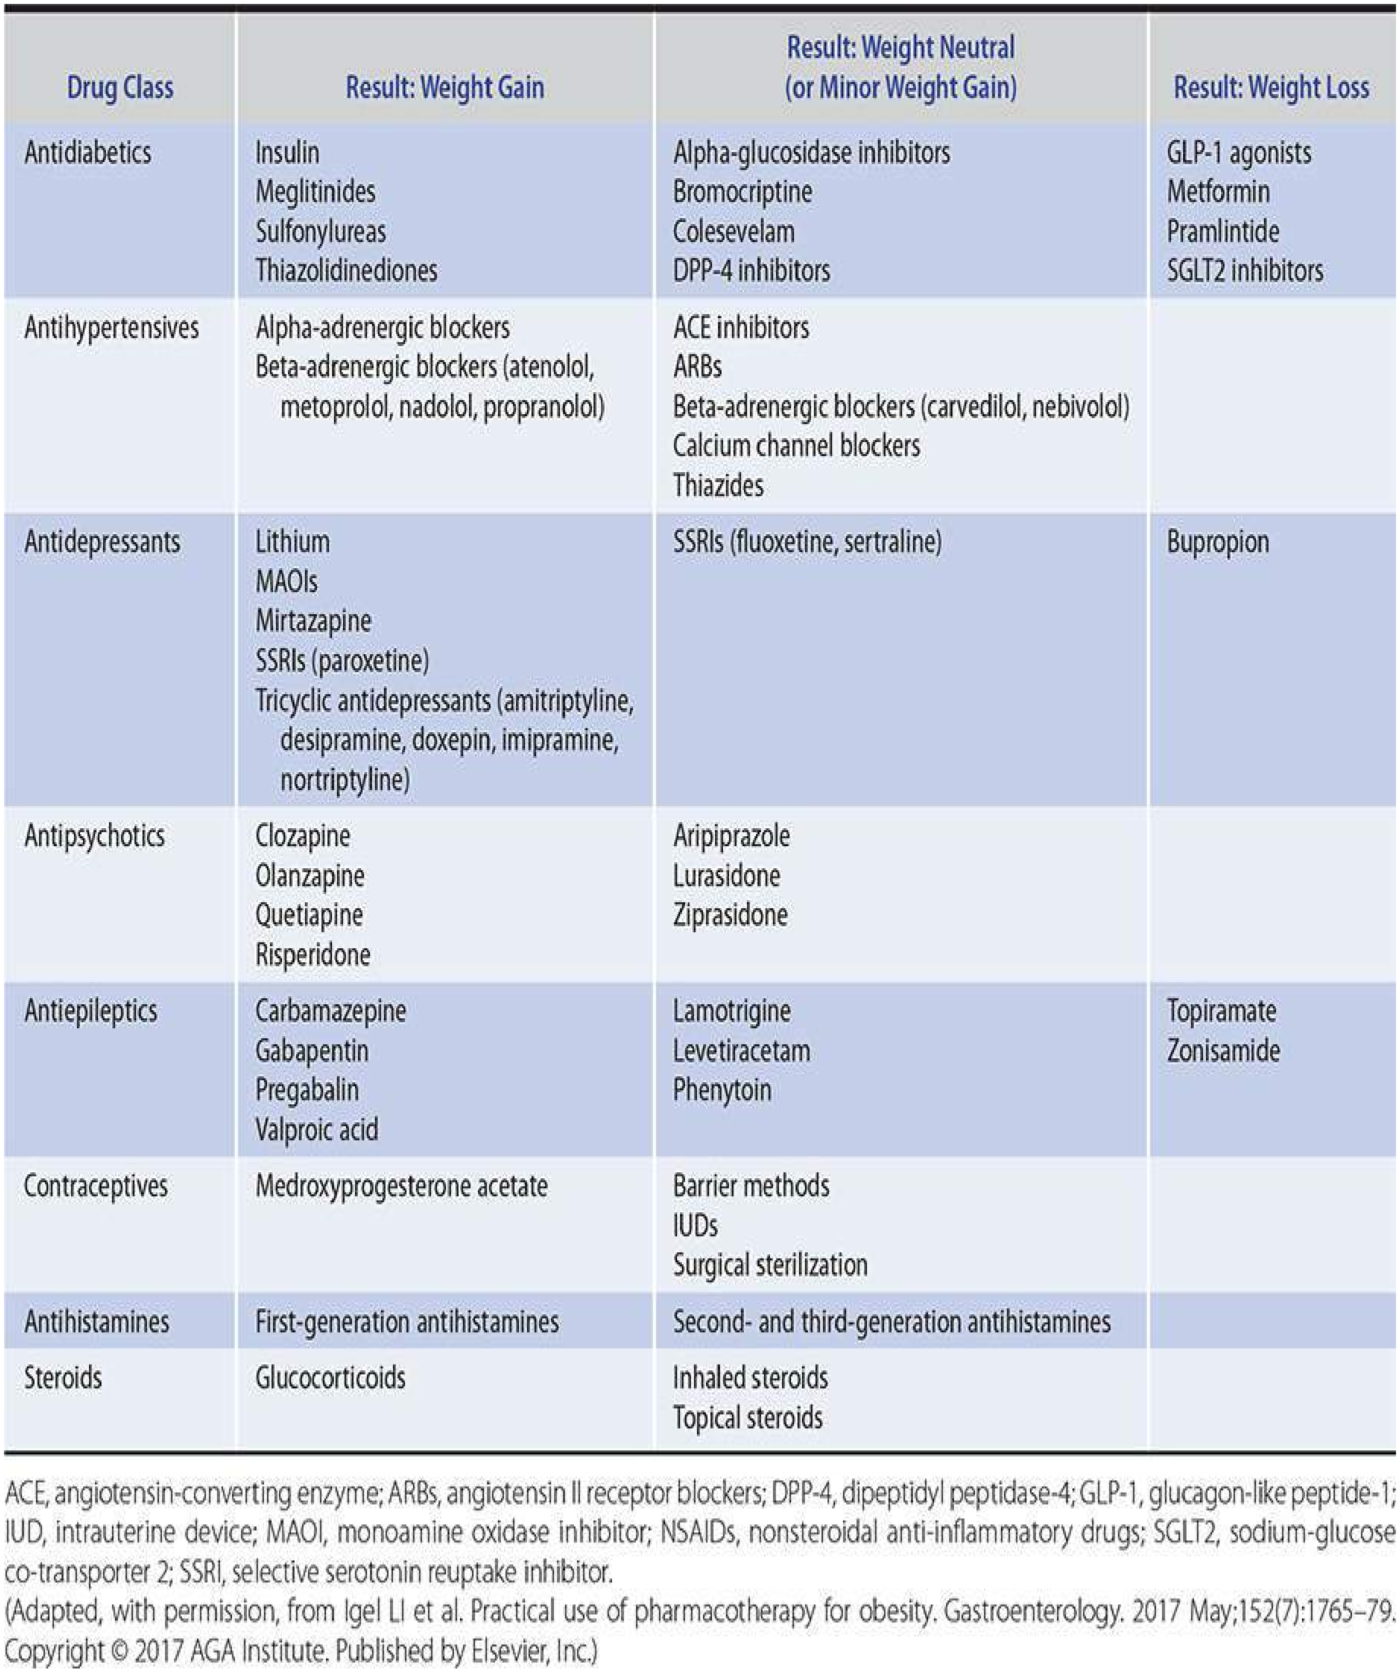
Long-term changes in eating behavior are required to maintain weight loss and formal **behavior modification** programs are available. It is important to emphasize planning and self-monitoring, including weighing at regular intervals and keeping a food log to track caloric intake. Self-monitoring not only aids in behavioral change but also provides the practitioner with additional data from which to tailor recommendations. Patients can learn to recognize "eating cues" (emotional, situational, etc) and how to avoid or control them. As weight maintenance can be more challenging than initial weight loss, it is important that patients continue self-monitoring and regular follow up to ensure long-term adherence to their treatment plan.

Exercise offers several advantages for patients trying to lose weight and maintain weight loss. Aerobic exercise directly increases daily energy expenditure and is particularly useful for long-term weight maintenance. Exercise also preserves lean body mass and partially prevents the decrease in basal energy expenditure (BEE) resulting from weight loss. Compared to no treatment, exercise alone results in small amounts of weight loss. Exercise plus diet results in slightly greater weight loss than diet alone. A greater intensity of exercise is associated with a greater amount of weight loss. Up to 1 hour of moderate exercise per day is associated with long-term weight maintenance in individuals who have successfully lost weight.

The American College of Sports Medicine recommends 150 minutes of moderate-intensity aerobic physical activity (such as tennis or brisk walking) per week, 75 minutes of vigorous-intensity aerobic exercise (such as jogging or swimming laps) per week, or an equivalent combination of moderate- and vigorous-intensity aerobic activity. Episodes should last at least 10 minutes and, if possible, be spread out throughout the week. Weight resistance is also recommended at least twice per week. Exercise physiologists, physical therapists, and trainers can provide additional support for patients.

Medications can have unpredictable and variable effects on patients' weight, so it is important to review patients' medication regimens and balance the benefits of treatment against the probability of weight gain. Multiple medications are associated with weight gain, including corticosteroids, contraceptives and other hormonal agents as well as certain antidiabetic, antihypertensive, antidepressant, antipsychotic, antiepileptic, and antihistamine agents. Table 29–1 provides an overview of weight-gaining medications as well as potential alternatives. When possible, clinicians should prescribe weight-neutral or weight loss–promoting medications. If there are no alternatives, weight gain can be prevented or lessened by selecting the lowest dose needed to produce clinical efficacy for the shortest duration necessary.

Table 29–1. Medications and their effects on weight.



Drug Class	Result: Weight Gain	Result: Weight Neutral (or Minor Weight Gain)	Result: Weight Loss
Antidiabetics	Insulin Meglitinides Sulfonylureas Thiazolidinediones	Alpha-glucosidase inhibitors Bromocriptine Colesevelam DPP-4 inhibitors	GLP-1 agonists Metformin Pramlintide SGLT2 inhibitors
Antihypertensives	Alpha-adrenergic blockers Beta-adrenergic blockers (atenolol, metoprolol, nadolol, propranolol)	ACE inhibitors ARBs Beta-adrenergic blockers (carvedilol, nebivolol) Calcium channel blockers Thiazides	
Antidepressants	Lithium MAOIs Mirtazapine SSRIs (paroxetine) Tricyclic antidepressants (amitriptyline, desipramine, doxepin, imipramine, nortriptyline)	SSRIs (fluoxetine, sertraline)	Bupropion
Antipsychotics	Clozapine Olanzapine Quetiapine Risperidone	Aripiprazole Lurasidone Ziprasidone	
Antiepileptics	Carbamazepine Gabapentin Pregabalin Valproic acid	Lamotrigine Levetiracetam Phenytoin	Topiramate Zonisamide
Contraceptives	Medroxyprogesterone acetate	Barrier methods IUDs Surgical sterilization	
Antihistamines	First-generation antihistamines	Second- and third-generation antihistamines	
Steroids	Glucocorticoids	Inhaled steroids Topical steroids	

ACE, angiotensin-converting enzyme; ARBs, angiotensin II receptor blockers; DPP-4, dipeptidyl peptidase-4; GLP-1, glucagon-like peptide-1; IUD, intrauterine device; MAOI, monoamine oxidase inhibitor; NSAIDs, nonsteroidal anti-inflammatory drugs; SGLT2, sodium-glucose co-transporter 2; SSRI, selective serotonin reuptake inhibitor.

Weight loss achieved by lifestyle modifications alone is often limited and difficult to maintain. As a result, patients may require antiobesity medications, bariatric surgery, devices, or endoscopic bariatric therapies to achieve and maintain clinically significant weight loss.

Antiobesity medications (Table 29–2) can be considered in patients with a BMI 30 or higher or a BMI 27 or higher with weight-related comorbidities. Since obesity is a chronic disease, most medications for weight loss are approved for long-term treatment. Medications approved for weight management should be viewed as additions to diet and exercise for patients who have been unsuccessful with lifestyle changes alone. The six most widely prescribed antiobesity medications approved by the FDA are phentermine, orlistat, phentermine/topiramate extended release (ER), lorcaserin, naltrexone sustained-release (SR)/bupropion SR, and liraglutide 3.0 mg. Table 29–2 provides an overview of these medications.

Table 29–2. Medications tested in clinical trials for treatment of obesity.

Medication	Mechanism, Dosage, and Available Formulations	Trial and Duration	Trial Arms	Weight Loss (%)	Most Common Adverse Events	Good Candidates	Poor Candidates
Phentermine (Adipex,[1] Ionamin,[2] Lomaira[3]) Schedule IV controlled substance NOTE: approved for short-term use (up to 3 months)	Adrenergic agonist 8–37.5 mg daily (8 mg dose can be prescribed up to three times daily) Capsule, tablet	Aronne LJ et al.[4] 28 weeks	15 mg daily	6.06*	Dry mouth, insomnia, dizziness, irritability	Younger patients who need assistance with appetite suppression	Patients with uncontrolled hypertension, active or unstable coronary disease, hyperthyroidism, glaucoma, anxiety, insomnia, or general sensitivity to stimulants Patients with a history of drug abuse or recent MAOI use Patients who are pregnant
			7.5 mg daily	5.45*			
			Placebo (topiramate ER and phentermine/topiramate ER arms excluded)	1.71			
Orlistat (Alli,[5] Xenical[6])	Lipase inhibitor 60–120 mg three times daily with meals Capsule	XENDOS[7] 208 weeks	120 mg three times daily	9.6 (week 52)* 5.25 (week 208)*	Fecal urgency, oily stool, flatus with discharge, fecal incontinence	Patients with hypercholesterolemia and/or constipation who can limit their intake of dietary fat	Patients with malabsorption syndromes or other GI conditions that predispose to GI upset/diarrhea Patients who cannot modify the fat content of their diets Patients who are pregnant
			Placebo	5.61 (week 52) 2.71 (week 208)			
Phentermine/Topiramate Extended Release (Qsymia)[8] Schedule IV controlled substance	Adrenergic agonist/neurostabilizer 3.75/23–15/92 mg daily (dose titration) Capsule	EQUIP[9] 56 weeks	15/92 mg daily	10.9*	Paresthesias, dizziness, dysgeusia, insomnia, constipation, dry mouth	Younger patients who need assistance with appetite suppression	Patients with uncontrolled hypertension, active or unstable coronary disease, hyperthyroidism, glaucoma, anxiety, insomnia, or general sensitivity to stimulants Patients with a history of drug abuse or recent MAOI use Patients with a history of nephrolithiasis Patients who are pregnant or trying to conceive
			3.75/23 mg daily	5.1*			
			Placebo	1.6			
		CONQUER[10] 56 weeks	15/92 mg daily	9.8*			
			7.5/46 mg daily	7.8*			
			Placebo	1.2 (weeks 0–56)			
		SEQUEL[11] 108 weeks (52-week extension of CONQUER trial)	15/92 mg daily	10.5*			
			7.5/46 mg daily	9.3*			
			Placebo	1.8 (weeks 0-108)			

Lorcaserin (Belviq, Belviq XR)[12] Schedule IV controlled substance	Serotonin $(5\text{-HT})_{2C}$ receptor agonist 10 mg twice daily or 20 mg extended release daily Tablet	BLOOM[13] 52 weeks	10 mg twice daily	5.8^{*}	Headache, dizziness, fatigue, nausea, dry mouth, constipation	Patients who would benefit from appetite suppression	Patients on other serotonin-modulating medications, and patients with known cardiac valvular disease Patients who are pregnant
			Placebo	2.2			
		BLOSSOM[14] 52 weeks	10 mg twice daily	5.8^{*}			
			10 mg daily	4.7^{*}			
			Placebo	2.8			
		BLOOM-DM[15] 52 weeks	10 mg twice daily	4.5^{*}			
			10 mg daily	5.0^{*}			
			Placebo	1.5			
Naltrexone/Bupropion Sustained-Release (Contrave)[16]	Opioid receptor antagonist/dopamine and norepinephrine reuptake inhibitor 8/90 mg daily to 16/180 mg twice daily Tablet	COR-I[17] 56 weeks	16/180 mg twice daily	6.1^{*}	Nausea, vomiting, constipation, headache, dizziness, insomnia, dry mouth	Patients who describe cravings for food and/or addictive behaviors related to food; patients who are trying to quit smoking, reduce alcohol intake, and/or who have concomitant depression	Patients with uncontrolled hypertension, uncontrolled pain, recent MAOI use, history of seizures, or any condition that predisposes to seizure, such as anorexia/bulimia nervosa, abrupt discontinuation of alcohol, benzodiazepines, barbiturates, or antiepileptic drugs Patients who are pregnant
			8/180 mg twice daily	5.0^{*}			
			Placebo	1.3			
		COR-II[18] 56 weeks	16/180 mg twice daily	6.4^{*}			
			Placebo	1.2			
		COR-BMOD[19] 56 weeks	16/180 mg twice daily	9.3^{*}			
			Placebo	5.1			
		COR-DIABETES[20] 56 weeks	16/180 mg twice daily	5.0^{*}			
			Placebo	1.8			
Liraglutide 3.0 mg (Saxenda)[21]	GLP-1 receptor agonist 0.6 to 3.0 mg daily Prefilled pen for subcutaneous injection	SCALE Obesity and Prediabetes[22] 56 weeks	3.0 mg daily	8.0^{*}	Nausea, vomiting, diarrhea, constipation, dyspepsia, abdominal pain	Patients who report inadequate meal satiety, and/or have type 2 diabetes, prediabetes, or impaired glucose tolerance Patients requiring use of concomitant psychiatric medications	Patients with a history of pancreatitis, personal/family history of MTC or MEN2 Patients with an aversion to needles Patients who are pregnant
			Placebo	2.6			
		SCALE Diabetes[23] 56 weeks	3.0 mg daily	6^{*}			
			1.8 mg daily	4.7^{*}			
			Placebo	2.0			
		SCALE Maintenance[24] 56 weeks (after initial ≥ 5% weight loss with low-calorie diet)	3.0 mg daily	6.2^{*}			
			Placebo	0.2

Phentermine is the most commonly prescribed adrenergic agonist and antiobesity medication in the United States; other adrenergic agonists include diethylpropion, benzphetamine, and phendimetrazine. In a 28-week randomized controlled trial, participants taking phentermine 15 mg daily lost an average of 6.0 kg compared with 1.5 kg among those assigned to placebo. The recommended dosage of phentermine is up to 37.5 mg daily, but the dosage should be individualized to achieve response with the lowest effective dose.

Orlistat works in the gastrointestinal tract to inhibit intestinal lipase, thus reducing dietary fat absorption. Not unexpectedly, it may cause diarrhea, gas, and cramping and perhaps reduced absorption of fat-soluble vitamins. Orlistat is associated with a 5.8 kg weight loss after 4 years compared to 3.0 kg with placebo. The recommended dose is 120 mg (Xenical, prescription-strength) or 60 mg (Alli, over-the-counter) three times a day with each main meal containing fat.

Lorcaserin, a selective serotonin 2C receptor agonist available at a dose of 10 mg orally twice daily or 20 mg ER once daily, is associated with 5.8% weight loss compared to 2.2% with placebo at 52 weeks. In the CAMELLIA-TIMI 61 trial, which enrolled a high-risk population of persons with obesity and overweight, lorcaserin facilitated sustained weight loss without a higher rate of major cardiovascular events compared to placebo.

The combination of **phentermine** and **topiramate ER** (3.75 mg/23 mg orally daily for 14 days, then 7.5 mg/46 mg orally daily, to a maximum dosage of 15 mg/92 mg orally daily) targets two different weight-regulation mechanisms simultaneously. In a 56-week clinical trial, participants taking 15/92 mg lost significantly more weight (9.8 kg) than those assigned to 7.5/46 mg (7.8 kg) or placebo (1.2 kg). The FDA requires a Risk Evaluation and Mitigation Strategy to inform women of reproductive potential and prescribers about a potential increased risk of orofacial clefts in infants exposed to the medication during the first trimester of pregnancy.

The combination of **naltrexone SR** and **bupropion SR** (8 mg/90 mg, increasing from 1 tablet orally daily by 1 additional daily tablet each week to a maximum of 2 tablets twice daily) reduces both appetite and food cravings by targeting two areas of the brain: the arcuate nucleus of the hypothalamus and the mesolimbic dopamine reward circuit. Naltrexone 32 mg/bupropion 360 mg is associated with a 6.1% reduction in body weight compared to 1.3% with placebo after 56 weeks. As with all antidepressants, bupropion carries a black box warning related to a potential increase in suicidality among younger patients during the early phase of treatment. Two cardiovascular outcome trials were terminated early.

Liraglutide, an injectable glucagon-like peptide-1 receptor agonist, is approved at a dose of 0.6 mg subcutaneously daily, increasing by 0.6 mg daily each week to a maximum of 3 mg subcutaneously daily. Liraglutide was initially FDA approved in 2010 for the treatment of type 2 diabetes at doses up to 1.8 mg subcutaneously daily. Liraglutide 3.0 mg subcutaneously daily is associated with 6.0% weight loss compared to 2.0% with placebo after 56 weeks. Thyroid C-cell tumors were found in rodents given supratherapeutic doses of liraglutide, but there is no evidence of liraglutide causing C-cell tumors in humans. Liraglutide 1.8 mg subcutaneously daily has been approved for cardiovascular risk reduction in patients with type 2 diabetes at elevated cardiovascular risk and a cardiovascular outcomes trial of liraglutide 3.0 mg is being conducted in patients with obesity.

Bariatric surgery is the most effective treatment for obesity. The three most common bariatric procedures in the United States are the sleeve gastrectomy, the Roux-en-Y gastric bypass, and the laparoscopic adjustable gastric band. Bariatric surgery can be considered in patients with a BMI 40 or higher or with a BMI 35 or higher plus one or more obesity-related complications who are motivated to lose weight but have not achieved sufficient weight loss to address health goals following lifestyle modification, with or without pharmacotherapy. Long-term medical follow up, lifestyle changes, and adherence to a vitamin regimen are crucial to the success of bariatric surgery; however, some patients have difficulty maintaining weight loss and regain some portion of the lost weight.

Sleeve gastrectomy involves removing approximately 70% of the stomach along the greater curvature. The pyloric valve and the small intestine remain intact. The fundus of the stomach, which secretes ghrelin, a hormone that stimulates appetite, is removed. Sleeve gastrectomy is associated with approximately 25% total body weight loss after 1 year. Because this procedure is mainly restrictive, there is a lower risk of nutritional deficiencies. In general, sleeve gastrectomy is associated with fewer complications than both the Roux-en-Y gastric bypass and laparoscopic adjustable gastric band. Early adverse events include bleeding, leakage along the staple line, stenosis, and vomiting. Late complications include gastroesophageal reflux, nutritional deficiencies, and stomach expansion, leading to decreased restriction. Unlike the other two procedures, sleeve gastrectomy is not reversible.

The **Roux-en-Y gastric bypass** attaches a small pouch created from the proximal stomach to the jejunum, thus bypassing the remainder of the stomach, duodenum, and most of the jejunum. Roux-en-Y gastric bypass is associated with approximately 30–35% total body weight loss at 2 years and greater improvements in comorbid disease markers compared to the two other procedures. Roux-en-Y gastric bypass is associated with a lower rate of gastroesophageal reflux than sleeve gastrectomy and can even alleviate gastroesophageal reflux in patients who have it. Roux-en-Y gastric bypass is often recommended over sleeve gastrectomy for patients with mild or moderate type 2 diabetes because it leads to greater long-term remission; however, both procedures have low efficacy for type 2 diabetes remission among patients with limited pancreatic beta cell reserve. Early adverse events associated with Roux-en-Y gastric bypass include obstruction, stricture, leak, and failure of the staple partition of the upper stomach. Late adverse events include nutritional deficiencies and anastomosis ulceration. Dumping syndrome can develop at any time. Roux-en-Y gastric bypass is technically a reversible procedure; however, it is generally only reversed in extreme circumstances.

The **laparoscopic adjustable gastric band** is an inflatable device that is placed around the fundus of the stomach to create a small pouch. This procedure is associated with 15% total body weight loss at 2 years. Laparoscopic adjustable gastric band is reversible and less invasive than the other two procedures, but it is associated with more complications than sleeve gastrectomy and Roux-en-Y gastric bypass. The most common adverse events include nausea, vomiting, obstruction, band erosion or migration, and esophageal dysmotility leading to acid reflux.

When to Refer

- Patients with a BMI greater than or equal to 30 or a BMI greater than or equal to 27 with weight-related comorbidities may be referred to an obesity medicine specialist.
- Patients with a BMI greater than or equal to 40 (or greater than or equal to 35 with obesity-related morbidities) who have not achieved sufficient weight loss to address health goals following behavioral treatment, with or without pharmacotherapy, may be referred to a bariatric surgeon.

EATING DISORDERS

ANOREXIA NERVOSA

ESSENTIALS OF DIAGNOSIS

- Disturbance of body image and intense fear of becoming fat.
- Weight loss leading to body weight 15% below expected.
- In females, absence of three consecutive menstrual cycles.

General Considerations

Anorexia nervosa typically begins in the years between adolescence and young adulthood. Ninety percent of patients are female, most of middle and upper socioeconomic status.

The prevalence of anorexia nervosa is greater than previously suggested. Many adolescent girls have features of the disorder without the severe weight loss.

The cause of anorexia nervosa is not known. Although multiple endocrinologic abnormalities exist in these patients, most authorities believe they are secondary to malnutrition and not primary disorders. Most experts favor a primary psychiatric origin, but no hypothesis explains all cases. The patient characteristically comes from a family whose members are highly goal-oriented. The parents may be directive and concerned with slimness and physical fitness, and family conversation often centers around dietary matters. One theory holds that the patient’s refusal to eat is an attempt to regain control of one’s body in defiance of parental control. The patient’s unwillingness to inhabit an “adult body” may also represent a rejection of adult responsibilities and the implications of adult interpersonal relationships. Patients are often perfectionistic in behavior and exhibit obsessional personality characteristics.

Clinical Findings

A. Symptoms and Signs

Patients with anorexia nervosa may exhibit severe emaciation and may complain of cold intolerance or constipation. Amenorrhea is almost always present. Bradycardia, hypotension, and hypothermia may be present in severe cases. Examination demonstrates loss of body fat, dry and scaly skin, and increased lanugo body hair.

Parotid enlargement and edema may also occur.

B. Laboratory Findings

Laboratory findings are variable but may include anemia, leukopenia, electrolyte abnormalities, and elevations of blood urea nitrogen (BUN) and serum creatinine. Serum cholesterol levels are often increased. Endocrine abnormalities include depressed levels of luteinizing and follicle-stimulating hormones and impaired response of luteinizing hormone to luteinizing hormone-releasing hormone.

Diagnosis & Differential Diagnosis

The diagnosis is based on weight loss to a body weight 15% below expected, distorted body image, fear of weight gain or of loss of control over food intake and, in females, absence of at least three consecutive menstrual cycles. Other medical or psychiatric illnesses that can account for anorexia and weight loss must be excluded.

Behavioral features required for the diagnosis include intense fear of developing obesity, disturbance of body image, and refusal to exceed a minimal normal weight.

The differential diagnosis includes endocrine and metabolic disorders (eg, panhypopituitarism, Addison disease, hyperthyroidism, and diabetes mellitus); gastrointestinal disorders (eg, Crohn disease and gluten enteropathy); chronic infections (eg, tuberculosis); cancers (eg, lymphoma); and rare central nervous system disorders (eg, hypothalamic tumor).

Treatment

The goal of treatment is restoration of normal body weight and improvement in psychological difficulties. Hospitalization may be necessary. Treatment programs conducted by experienced teams are successful in about two-thirds of cases, restoring normal weight and menstruation. The remainder continue to experience difficulties with eating behaviors and psychiatric problems. About 2% to 6% of patients die of the complications of the disorder or commit suicide.

Various treatment methods have been used without clear evidence of superiority of one over another. Supportive care by clinicians and family is probably the most important feature of therapy. Cognitive-behavioral therapy, intensive psychotherapy, and family therapy may be tried. A variety of medications including tricyclic antidepressants, selected serotonin reuptake inhibitors (SSRIs), and lithium carbonate are effective in some cases; however, clinical trial results have been disappointing. Patients with severe malnutrition must be hemodynamically stabilized and may require enteral or parenteral feeding. Forced feedings should be reserved for life-threatening situations, since the goal of treatment is to reestablish normal eating behavior.

When to Refer

- Adolescents and young adults with otherwise unexplained profound weight loss should be evaluated by a psychiatrist.
- All patients with diagnosed anorexia nervosa should be co-managed with a psychiatrist.

When to Admit

- Signs of hypovolemia, major electrolyte disorders, and severe protein–energy malnutrition.
- Failure to improve with outpatient management.

Westmoreland P et al. Medical complications of anorexia nervosa and bulimia. Am J Med. 2016 Jan;129(1):30–7. [PMID: 26169883]

BULIMIA NERVOSA

ESSENTIALS OF DIAGNOSIS

- Uncontrolled episodes of binge eating at least twice weekly for 3 months.
- Recurrent inappropriate compensation to prevent weight gain such as self-induced vomiting, laxatives, diuretics, fasting, or excessive exercise.
- Overconcern with weight and body shape.

General Considerations

Bulimia nervosa is the episodic uncontrolled ingestion of large quantities of food followed by recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting, diuretic or cathartic use, strict dieting, or vigorous exercise.

Like anorexia nervosa, bulimia nervosa is predominantly a disorder of young, white, middle- and upper-class women. It is more difficult to detect than anorexia, and some studies have estimated that the prevalence may be as high as 19% in college-aged women.

Clinical Findings

Patients with bulimia nervosa typically consume large quantities of easily ingested high-calorie foods, usually in secrecy. Some patients may have several such episodes a day over multiple days; others report regular and persistent patterns of binge eating. Binging is usually followed by vomiting, cathartics, or diuretics and accompanied by feelings of guilt or depression. Periods of binging may be followed by intervals of self-imposed starvation. Body weight may fluctuate but generally is within 20% of desirable weight.

Some patients with bulimia nervosa also have a cryptic form of anorexia nervosa with significant weight loss and amenorrhea. Family and psychological issues are generally similar to those of patients with anorexia nervosa. Bulimic patients, however, have a higher incidence of premorbid obesity, greater use of cathartics and diuretics, and more impulsive or antisocial behavior. Menstruation is usually preserved.

Medical complications are numerous. Gastric dilatation and pancreatitis have been reported after binges. Vomiting can result in poor dentition, pharyngitis, esophagitis, aspiration, and electrolyte abnormalities. Cathartic and diuretic abuse can also cause electrolyte abnormalities or dehydration. Constipation is common.

Treatment

Treatment of bulimia nervosa requires supportive care and psychotherapy. Individual, group, family, and behavioral therapy have all been utilized. Antidepressant medications may be helpful. The best results have been with fluoxetine and other SSRIs. Although death from bulimia is rare, the long-term psychiatric prognosis in severe bulimia is worse than that in anorexia nervosa.

When to Refer

All patients with diagnosed bulimia should be co-managed with a psychiatrist.

Linardon J et al. Psychotherapy for bulimia nervosa on symptoms of depression: a meta-analysis of randomized controlled trials. Int J Eat Disord. 2017 Oct;50(10):1124–36. [PMID: 28804915]

DISORDERS OF VITAMIN METABOLISM

THIAMINE (B_1) DEFICIENCY

ESSENTIALS OF DIAGNOSIS

- Most common in patients with chronic alcoholism.
- Early symptoms of anorexia, muscle cramps, paresthesias, irritability.
- Advanced syndromes of high-output heart failure (“wet beriberi”), peripheral nerve disorders, and Wernicke-Korsakoff syndrome (“dry beriberi”).

General Considerations

Most thiamine deficiency in the United States is due to chronic alcoholism, with poor dietary intake of thiamine and impaired thiamine absorption, metabolism, and storage.

Thiamine deficiency is also associated with malabsorption, dialysis, and other causes of chronic protein–calorie undernutrition. Thiamine deficiency can be precipitated in patients with marginal thiamine status given intravenous dextrose solutions.

Clinical Findings

Early manifestations of thiamine deficiency include anorexia, muscle cramps, paresthesias, and irritability. Advanced deficiency primarily affects the cardiovascular system ("wet beriberi") or the nervous system ("dry beriberi"). Wet beriberi occurs in thiamine deficiency accompanied by severe physical exertion and high carbohydrate intake. Dry beriberi occurs in thiamine deficiency accompanied by inactivity and low-calorie intake.

Wet beriberi is characterized by marked peripheral vasodilation resulting in high-output heart failure with dyspnea, tachycardia, cardiomegaly, pulmonary edema, and peripheral edema with warm extremities mimicking cellulitis.

Dry beriberi involves both the peripheral and the central nervous systems. Peripheral nerve involvement is typically a symmetric motor and sensory neuropathy with pain, paresthesias, and loss of reflexes. The legs are affected more than the arms. Central nervous system involvement results in Wernicke-Korsakoff syndrome. Wernicke encephalopathy consists of nystagmus progressing to ophthalmoplegia, truncal ataxia, and confusion. Korsakoff syndrome includes amnesia, confabulation, and impaired learning.

Diagnosis

In most instances, the clinical response to empiric thiamine therapy is used to support a diagnosis of thiamine deficiency. The most commonly used biochemical tests measure thiamine concentration directly, while other assays measure erythrocyte transketolase activity and urinary thiamine excretion. Normal thiamine values typically range from 70 nmol/L to 180 nmol/L.

Treatment

Thiamine deficiency is treated with large parenteral doses of thiamine. Fifty to 100 mg/day is administered intravenously for the first few days, followed by daily oral doses of 5–10 mg/day. All patients should simultaneously receive therapeutic doses of other water-soluble vitamins. Although treatment results in complete resolution in half of patients (one-fourth immediately and another one-fourth over days), the other half obtain only partial resolution or no benefit.

When to Refer

Patients with signs of dry beriberi or Wernicke-Korsakoff syndrome should be referred to a neurologist. Patients with signs of wet beriberi should be referred to a cardiologist.

THIAMINE TOXICITY

There is no known toxicity of thiamine.

Scalzo SJ et al. Wernicke-Korsakoff syndrome not related to alcohol use: a systematic review. J Neurol Neurosurg Psychiatry. 2015 Dec;86(12):1362–8. [PMID: 25589780]

RIBOFLAVIN (B_2) DEFICIENCY

Clinical Findings

Riboflavin deficiency almost always occurs in combination with deficiencies of other vitamins. Dietary inadequacy, interactions with a variety of medications, alcoholism, and other causes of protein–calorie undernutrition are the most common causes of riboflavin deficiency.

Manifestations of riboflavin deficiency include cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, weakness, corneal vascularization, and anemia.

Diagnosis

Riboflavin deficiency can be confirmed by measuring the riboflavin-dependent enzyme erythrocyte glutathione reductase. Activity coefficients greater than 1.2–1.4 are suggestive of riboflavin deficiency. Urinary riboflavin excretion and serum levels of plasma and red cell flavins can also be measured.

Treatment

Riboflavin deficiency is usually treated empirically when the diagnosis is suspected. It is easily treated with foods such as meat, fish, and dairy products or with oral preparations of the vitamin. Administration of 5–15 mg/day until clinical findings are resolved is usually adequate. Riboflavin can also be given parenterally, but it is poorly soluble in aqueous solutions.

RIBOFLAVIN TOXICITY

There is no known toxicity of riboflavin.

Saedisomeolia A et al. Riboflavin in human health: a review of current evidences. Adv Food Nutr Res. 2018;83:57–81. [PMID: 29477226]

NIACIN DEFICIENCY

General Considerations

“Niacin” is a generic term for nicotinic acid and other derivatives with similar nutritional activity. Unlike most other vitamins, niacin can be synthesized from the amino acid tryptophan. Niacin is an essential component of the co-enzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are involved in many oxidation-reduction reactions. The major food sources of niacin are proteins containing tryptophan and numerous cereals, vegetables, and dairy products.

Historically, niacin deficiency occurred when corn, which is relatively deficient in both tryptophan and niacin, was the major source of calories. Currently, niacin deficiency is more commonly due to alcoholism and nutrient–drug interactions. Niacin deficiency can also occur in inborn errors of metabolism. Niacin in the form of nicotinic acid is used therapeutically for the treatment of hypercholesterolemia and hypertriglyceridemia. Niacinamide (the form of niacin usually used to treat niacin deficiency) does not exhibit the lipid-lowering effects of nicotinic acid.

Clinical Findings

As with other B vitamins, early manifestations of niacin deficiency are nonspecific—anorexia, weakness, irritability, mouth soreness, glossitis, stomatitis, and weight loss. More advanced deficiency results in the classic triad of pellagra: dermatitis, diarrhea, and dementia. The dermatitis is symmetric, involving sun-exposed areas. Skin lesions are dark, dry, and scaling. The dementia begins with insomnia, irritability, and apathy and progresses to confusion, memory loss, hallucinations, and psychosis. The diarrhea can be severe and may result in malabsorption due to atrophy of the intestinal villi. Advanced pellagra can result in death.

Diagnosis

In early deficiency, diagnosis requires a high index of suspicion and attempts at confirmation of niacin deficiency. Niacin metabolites, particularly N-methylnicotinamide, can be measured in the urine. Low levels suggest niacin deficiency but may also be found in patients with generalized under-nutrition. Serum and red cell levels of NAD and NADP are also low but are similarly nonspecific. In advanced cases, the diagnosis of pellagra can be made on clinical grounds.

Treatment

Niacin deficiency can be effectively treated with oral niacin, usually given as nicotinamide (10–150 mg/day).

NIACIN TOXICITY

At the high doses of niacin used to treat hyperlipidemia, side effects are common. These include cutaneous flushing (partially prevented by pretreatment with aspirin, 81–325 mg/day, and use of extended-release preparations) and gastric irritation. Elevation of liver enzymes, hyperglycemia, and gout are less common untoward effects.

VITAMIN B_6 DEFICIENCY

Vitamin B_6 deficiency most commonly occurs as a result of alcoholism or interactions with medications, especially isoniazid, cycloserine, penicillamine, and oral contraceptives. A number of inborn errors of metabolism and other pyridoxine-responsive syndromes, particularly pyridoxine-responsive anemia, are not clearly due to vitamin deficiency but commonly respond to high doses of the vitamin. Patients with common variable immunodeficiency may have concomitant vitamin B_6 deficiency.

Clinical Findings

Vitamin B_6 deficiency results in clinical symptoms similar to those of other B vitamin deficiencies, including mouth soreness, glossitis, cheilosis, weakness, and irritability. Severe deficiency can result in peripheral neuropathy, anemia, and seizures.

Diagnosis

The diagnosis of vitamin B_6 deficiency can be confirmed by measurement of pyridoxal phosphate in blood. Normal levels vary per laboratory but are typically greater than 5.0 ng/mL.

Treatment

Vitamin B_6 deficiency can be effectively treated with vitamin B_6 supplements (10–20 mg/day orally). Some patients taking medications that interfere with pyridoxine metabolism (such as isoniazid) may need doses as high as 50–100 mg/day orally to prevent vitamin B_6 deficiency. This is particularly true for patients who are more likely to have diets marginally adequate in vitamin B_6, such as older patients, patients with alcoholism, or patients with lower socioeconomic status. Inborn errors of metabolism and pyridoxine-responsive syndromes often require doses up to 600 mg/day orally.

VITAMIN B_6 TOXICITY

A sensory neuropathy, at times irreversible, occurs in patients receiving large doses of vitamin B_6 (200–2000 mg/day).

Van Arsdale S et al. Pyridoxine deficiency after solid organ transplant. Prog Transplant. 2017 Sep;27(3):251–6. [PMID: 29187089]

VITAMIN B_{12} & FOLATE

Vitamin B_{12} (cobalamin) and folate are discussed in Chapter 13.

VITAMIN C (Ascorbic Acid) DEFICIENCY

Most cases of vitamin C deficiency seen in the United States are due to dietary inadequacy in patients with lower socioeconomic status, older patients, and patients with chronic alcoholism. Patients with chronic illnesses such as cancer and chronic kidney disease and individuals who smoke cigarettes are also at risk.

Clinical Findings

Early manifestations of vitamin C deficiency are nonspecific and include malaise and weakness. In more advanced stages, the typical features of scurvy develop. Manifestations include perifollicular hemorrhages, perifollicular hyperkeratotic papules, petechiae and purpura, splinter hemorrhages, bleeding gums, hemarthroses, and subperiosteal hemorrhages. Anemia is common, and wound healing is impaired. The late stages of scurvy are characterized by edema, oliguria, neuropathy, intracerebral hemorrhage, and death.

Diagnosis

The diagnosis of advanced scurvy can be made clinically on the basis of the skin lesions in the proper clinical situation. Atraumatic hemarthrosis is also highly suggestive. The diagnosis can be confirmed with decreased plasma ascorbic acid levels, typically below 0.2 mg/dL.

Treatment

Adult scurvy can be treated with ascorbic acid 300–1000 mg/day orally. Improvement typically occurs within days.

VITAMIN C TOXICITY

Very large doses of vitamin C can cause gastric irritation, flatulence, or diarrhea. Oxalate kidney stones are of theoretical concern because ascorbic acid is metabolized to oxalate, but stone formation has not been frequently reported. Vitamin C can also confound common diagnostic tests by causing false-negative results for some fecal occult blood tests and both false-negative and false-positive results for urine glucose.

VITAMIN A DEFICIENCY

Clinical Findings

Vitamin A deficiency is one of the most common vitamin deficiency syndromes, particularly in developing countries. In many such regions, it is the most common cause of blindness. In the United States, vitamin A deficiency is usually due to fat malabsorption syndromes or mineral oil laxative abuse and occurs most commonly in older adults and individuals of lower socioeconomic status.

Night blindness is the earliest symptom. Dryness of the conjunctiva (xerosis) and the development of small white patches on the conjunctiva (Bitot spots) are early signs. Ulceration and necrosis of the cornea (keratomalacia), perforation, endophthalmitis, and blindness are late manifestations. Xerosis and hyperkeratinization of the skin and loss of taste may also occur.

Diagnosis

Abnormalities of dark adaptation are strongly suggestive of vitamin A deficiency. Serum levels below the normal range of 30–65 mg/dL are commonly seen in advanced deficiency.

Treatment

Night blindness, poor wound healing, and other signs of early deficiency can be effectively treated with vitamin A 30,000 international units orally daily for 1 week. Advanced deficiency with corneal damage calls for administration of 20,000 international units/kg orally for at least 5 days. The potential antioxidant effects of beta-carotene can be achieved with supplements of 25,000–50,000 international units of beta-carotene.

VITAMIN A TOXICITY

Excess intake of beta-carotene (hypercarotenosis) results in staining of the skin a yellow-orange color but is otherwise benign. Skin changes are most marked on the palms and soles, while the scleras remain white, clearly distinguishing hypercarotenosis from jaundice.

Excessive vitamin A (hypervitaminosis A), on the other hand, can be quite toxic. Chronic toxicity usually occurs after ingestion of daily doses of over 50,000 international units/day for more than 3 months. Early manifestations include dry, scaly skin, hair loss, mouth sores, painful hyperostoses, anorexia, and vomiting. More serious findings include hypercalcemia; increased intracranial pressure with papilledema, headaches, and decreased cognition; and hepatomegaly, occasionally progressing to cirrhosis. Excessive vitamin A is also related to increased risk of hip fracture. Acute toxicity can result from ingestion of massive doses of vitamin A, such as in drug overdoses or consumption of polar bear liver. Manifestations include nausea, vomiting, abdominal pain, headache, papilledema, and lethargy.

The diagnosis can be confirmed by elevations of serum vitamin A levels. The only treatment is withdrawal of vitamin A from the diet. Most symptoms and signs improve rapidly.

Lu Z et al. Rapid diagnostic testing platform for iron and vitamin A deficiency. Proc Natl Acad Sci U S A. 2017 Dec 19; 114(51):13513–8. [PMID: 29203653]

VITAMIN D

Vitamin D is discussed in Chapter 26.

VITAMIN E DEFICIENCY

Clinical Findings

Clinical deficiency of vitamin E is most commonly due to severe malabsorption or abetalipoproteinemia in adults and chronic cholestatic liver disease, biliary atresia, or cystic fibrosis in children. Manifestations of deficiency include areflexia, disturbances of gait, decreased vibration and proprioception, and ophthalmoplegia.

Diagnosis

Plasma vitamin E levels can be measured; normal levels are 0.5–0.7 mg/dL or higher. Since vitamin E is normally transported in lipoproteins, the serum level should be interpreted in relation to circulating lipid levels.

Treatment

The optimum therapeutic dose of vitamin E has not been clearly defined. Large doses, often administered parenterally, can be used to improve the neurologic complications seen in abetalipoproteinemia and cholestatic liver disease. Several trials of supplemental vitamin E have shown slower cognitive decline in patients with Alzheimer disease. Vitamin E supplementation may also provide benefit in patients with nonalcoholic fatty liver disease.

VITAMIN E TOXICITY

Clinical trials have suggested an increase in all-cause mortality with high dose (400 international units/day or more) vitamin E supplements. Large doses of vitamin E can also increase the vitamin K requirement and can result in bleeding in patients taking oral anticoagulants.

Okebukola PO et al. Vitamin E supplementation in people with cystic fibrosis. Cochrane Database Syst Rev. 2017 Mar 6;3:CD009422. [PMID: 28262916]

VITAMIN K

Vitamin K is discussed in Chapter 14.

DIET THERAPY

In consultation with a registered dietician, specific therapeutic diets can be designed to facilitate the medical management of most common illnesses. Diet therapy is a difficult process, though, and not all patients are able to adhere to dietary recommendations. Requesting the patient to record dietary intake for 3–5 days may provide useful insight into the patient's motivation as well as providing nutrient information about the current diet.

Therapeutic diets can be divided into three groups: (1) diets that alter the consistency of food, (2) diets that restrict or otherwise modify dietary components, and (3) diets that supplement dietary components.

DIETS THAT ALTER CONSISTENCY

Clear Liquid Diet

This diet provides adequate water, 500–1000 kcal as simple sugar, and some electrolytes. It is fiber free and requires minimal digestion or intestinal motility.

A clear liquid diet is useful for patients with resolving postoperative ileus, acute gastroenteritis, partial intestinal obstruction, and as preparation for diagnostic gastrointestinal procedures. It is commonly used as the first diet for patients who have been taking nothing by mouth for long periods. Because of the low calorie and minimal protein content of the clear liquid diet, it is used only for short periods.

Full Liquid Diet

The full liquid diet provides adequate water and can be designed to provide adequate calories and protein. Vitamins and minerals—especially folic acid, iron, and vitamin B_6 —may be inadequate and should be provided in the form of supplements. Dairy products and soups are used to supplement clear liquids. Commercial oral supplements can also be incorporated into the diet or used alone.

This diet is low in residue and can be used in many instances instead of the clear liquid diet described above—especially in patients with difficulty chewing or swallowing, with partial obstructions, or in preparation for some diagnostic procedures. Full liquid diets are commonly used following clear liquid diets to advance diets in patients who have been taking nothing by mouth for long periods.

Soft Diets

Soft diets are designed for patients unable to chew or swallow hard or coarse food. Tender foods are used, and most raw fruits and vegetables as well as coarse breads and cereals are eliminated. Soft diets are commonly used to assist in progression from full liquid diets to regular diets in postoperative patients, in patients who are too weak or those whose dentition is too poor to handle a regular diet, in head and neck surgical patients, in patients with esophageal strictures, and in other patients who have difficulty with chewing or swallowing.

The soft diet can be designed to meet all nutritional requirements.

DIETS THAT RESTRICT NUTRIENTS

Diets can be designed to restrict (or eliminate) virtually any nutrient or food component. The most commonly used restricted diets are those that limit sodium, fat, carbohydrate, and protein. Other restrictive diets include gluten restriction in gluten enteropathy, potassium and phosphate reduction in chronic kidney disease, and various elimination diets for food allergies.

Sodium-Restricted Diets

Low-sodium diets are useful in the management of hypertension and in conditions in which sodium retention and edema are prominent features, particularly heart failure, chronic liver disease, and chronic kidney disease. Sodium restriction may be beneficial with or without diuretic therapy. When used in conjunction with diuretics, sodium restriction allows lower dosage of the diuretic medication and may prevent side effects. Potassium excretion, in particular, is directly related to distal renal tubule sodium delivery, and sodium restriction will decrease diuretic-related potassium losses.

Typical American diets contain 4–6 g (175–260 mEq) of sodium per day. A no-added-salt diet contains approximately 3 g (132 mEq) of sodium per day. Further restriction can be achieved with diets of 2 or 1 g of sodium per day. Diets with more severe restriction are poorly accepted by patients and are rarely used. Current Institute of Medicine guidelines recommend 2.3 g of sodium per day, which is approximately 1 teaspoon of salt.

Dietary sodium includes sodium naturally occurring in foods, sodium added during food processing, and sodium added by the consumer during cooking and at the table. About 80% of the current US dietary intake is from processed and pre-prepared foods. Diets designed for 2.3 g of sodium per day require elimination of most processed foods, added salt, and foods with particularly high sodium content. Many patients with mild hypertension will achieve significant reductions in blood pressure (approximately 5 mm Hg diastolic) with this degree of sodium restriction.

Diets allowing 1 g of sodium require further restriction of commonly eaten foods.

Special “low-sodium” products are available to facilitate such diets. These diets are difficult for most people to follow and are generally reserved for hospitalized patients, most commonly those with severe liver disease and ascites.

Fat-Restricted Diets & Low-Saturated-Fat Diets

Traditional fat-restricted diets are useful in the treatment of fat malabsorption syndromes. Such diets will improve the symptoms of diarrhea with steatorrhea independently of the primary physiologic abnormality by limiting the quantity of fatty acids that reach the colon. The degree of fat restriction necessary to control symptoms must be individualized. Patients with severe malabsorption can be limited to 40–60 g of fat per day. Diets containing 60–80 g of fat per day can be designed for patients with less severe abnormalities.

Fat-restricted diets that specifically restrict saturated fats are the mainstay of dietary treatment of hyperlipidemia with elevated low-density lipoprotein cholesterol (see Chapter 28). Similar diets are often recommended for the prevention of coronary artery disease (see Chapter 10). The large Women’s Health Initiative Dietary Modification Trial, however, did not show any significant benefit of a low-fat diet on weight control or prevention of cardiovascular disease or cancer. In contrast, a study of Mediterranean diets, supplemented by nuts or extra-virgin olive oil, did demonstrate a reduction in cardiovascular events.

The aim of low-fat diets is to restrict total fat to less than 30% of calories and to achieve a normal body weight by caloric restriction and increased physical activity. Saturated fat is restricted to 7% of calories. Saturated fat and total fat can be restricted further, but studies suggest that more extreme restriction offers little further advantage in overall modification of serum lipids. Low-fat diets can be augmented with the addition of plant stanols and sterols and with soluble dietary fiber to further reduce serum lipids.

Carbohydrate-Restricted Diets

Low carbohydrate diets restrict carbohydrate intake to at most 50–100 g/day (sometimes even lower). The consumption of foods that contain higher protein and fat with a lower carbohydrate content has been shown to promote satiety. Carbohydrate-restricted diets, including low glycemic index diets (see Chapter 27), can be particularly helpful for patients with type 2 diabetes and other forms of insulin resistance to reduce both blood sugar and weight. There have been several studies investigating the efficacy of low-fat versus low-carbohydrate diets for weight loss with no clear benefit of one versus the other.

Protein-Restricted Diets

Protein-restricted diets are most commonly used in patients with hepatic encephalopathy due to chronic liver disease and in patients with advanced chronic kidney disease to slow the progression of early disease and to decrease symptoms of uremia in more severe disease. Patients with selected inborn errors of amino acid metabolism and other abnormalities resulting in hyperammonemia also require restriction of protein or of specific amino acids.

Protein restriction is intended to limit the production of nitrogenous waste products. Energy intake must be adequate to facilitate the efficient use of dietary protein. Proteins must be of high biologic value and be provided in sufficient quantity to meet minimal requirements. For most patients, the diet should contain at least 0.6 g/kg/day of protein. Patients with encephalopathy who do not respond to this degree of restriction are unlikely to respond to more severe restriction.

DIETS THAT SUPPLEMENT NUTRIENTS

High-Fiber Diet

Dietary fiber is a diverse group of plant constituents that is resistant to digestion by the human digestive tract. Guidelines suggest that men should eat 30–38 g/day and women 21–25 g/day. Typical US diets, however, contain about half of that amount. Epidemiologic evidence has suggested that populations consuming greater quantities of fiber have a lower incidence of certain gastrointestinal disorders, including diverticulitis and, in some studies, colon cancer and a lower risk of cardiovascular disease. A meta-analysis of 22 studies suggested that each 7 g of dietary fiber was associated with a 9% decrease in first cardiovascular event.

Diets high in dietary fiber (21–38 g/day) are also commonly used in the management of a variety of gastrointestinal disorders, particularly irritable bowel syndrome and recurrent diverticulitis. Diets high in fiber, particularly soluble fiber, may also be useful to reduce blood sugar in patients with diabetes and to reduce cholesterol levels in patients with hypercholesterolemia. Good sources of soluble fiber are oats, nuts, seeds, legumes, and most fruits. Foods with insoluble fiber include whole wheat, brown rice, other whole grains, and most vegetables. For some patients, the addition of psyllium seed (2 tsp per day) or natural bran (one-half cup per day) may be a useful adjunct to increase dietary fiber.

High-Potassium Diets

Potassium-supplemented diets are used most commonly to compensate for potassium losses caused by diuretics. Although potassium losses can be partially prevented by using lower doses of diuretics, concurrent sodium restriction, and potassium-sparing diuretics, some patients require additional potassium to prevent hypokalemia. High-potassium diets may also have a direct antihypertensive effect. Typical American diets contain about 3 g (80 mEq) of potassium per day. High-potassium diets commonly contain 4.5–7 g (120–180 mEq) of potassium per day.

Most fruits, vegetables, and their juices contain high concentrations of potassium. Supplemental potassium can also be provided with potassium-containing salt substitutes (up to 20 mEq in one-quarter tsp) or as potassium chloride in solution or capsules, but this is rarely necessary if the above measures are followed to prevent potassium losses and to supplement dietary potassium.

High-Calcium Diets

Additional intake of dietary calcium has been recommended for the prevention of postmenopausal osteoporosis, the prevention and treatment of hypertension, and the prevention of colon cancer. The Women's Health Initiative, however, suggested that calcium and vitamin D supplementation did not prevent fractures or colon cancer. Observational studies have also suggested that calcium supplements, especially when taken without vitamin D, may be associated with an increased risk of coronary heart disease. The recommended dietary allowance for the total calcium intake (from food and supplements) in adults ranges from 1000 mg/day to 1200 mg/day. Average American daily intakes are approximately 700 mg/day.

Dairy products are the primary dietary sources of calcium in the United States. An 8-ounce glass of milk, for example, contains approximately 300 mg of calcium. Patients with lactose intolerance who cannot tolerate liquid dairy products may be able to use lactose-free milk, take supplemental lactase enzyme supplements, or tolerate nonliquid products such as yogurt and aged cheeses. Leafy green vegetables and canned fish with bones also contain high concentrations of calcium, although the latter is also high in sodium.

NUTRITIONAL SUPPORT

Nutritional support is the provision of nutrients to patients who cannot meet their nutritional requirements by eating standard diets. Nutrients may be delivered enterally, using oral nutritional supplements, nasogastric and nasoduodenal feeding tubes, and tube enterostomies, or parenterally, using lines or catheters placed in peripheral or central veins, respectively. Current nutritional support techniques permit adequate nutrient delivery to most patients. Nutrition support should be utilized, however, only if it is likely to improve the patient's clinical outcome. The financial costs and risks of side effects must be balanced against the potential advantages of improved nutritional status in each clinical situation.

INDICATIONS FOR NUTRITIONAL SUPPORT

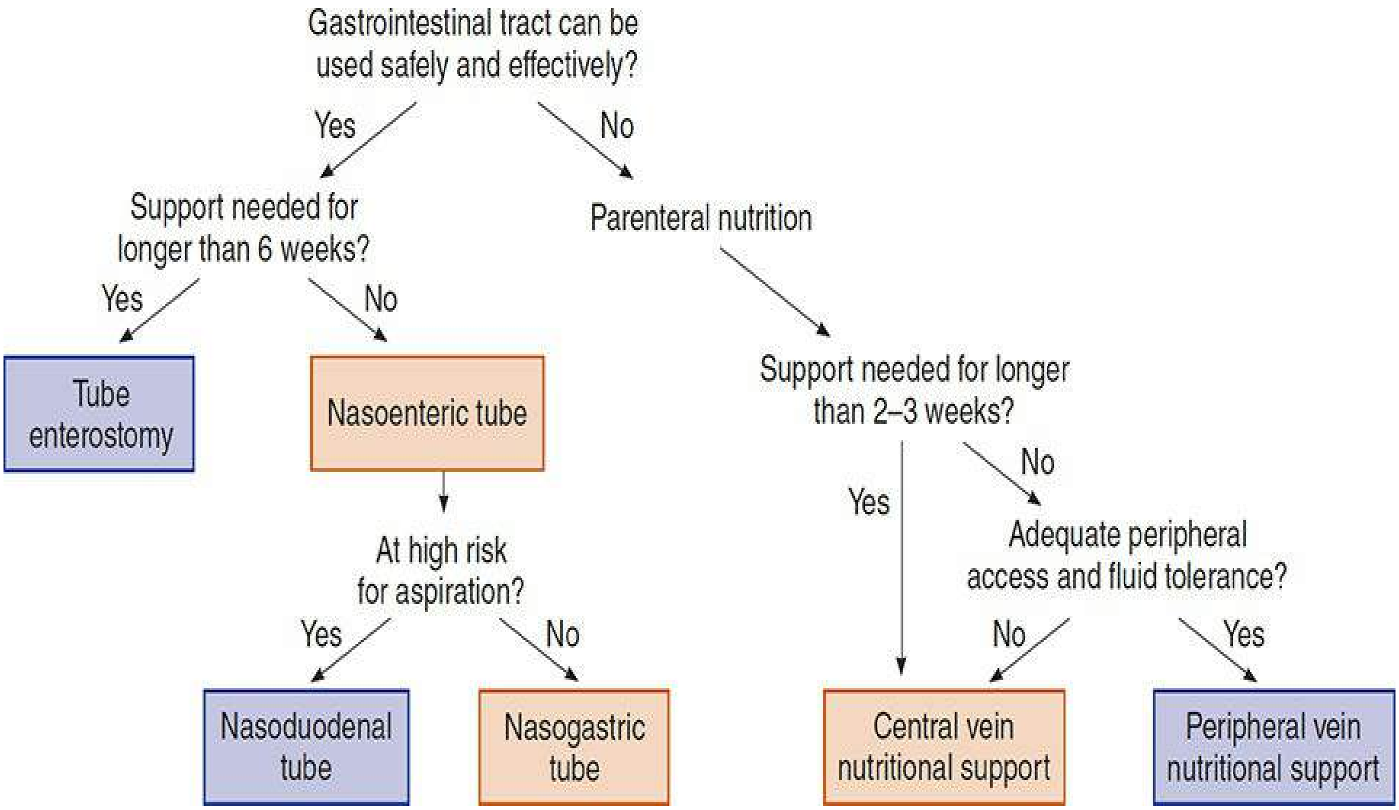
The precise indications for nutritional support remain controversial. Most authorities agree that nutritional support is indicated for at least four groups of adult patients: (1) those with inadequate bowel syndromes, (2) those with severe prolonged hypercatabolic states (eg, due to extensive burns, multiple trauma, mechanical ventilation), (3) those requiring prolonged therapeutic bowel rest, and (4) those with severe protein–calorie undernutrition with a treatable disease who have sustained a loss of over 25% of body weight.

It has been difficult to prove the efficacy of nutritional support in the treatment of most other conditions. In most cases it has not been possible to show a clear advantage of treatment by means of nutritional support over treatment without such support.

The American Society for Parenteral and Enteral Nutrition (ASPEN) has published recommendations for the rational use of nutritional support. The recommendations emphasize the need to individualize the decision to begin nutritional support, weighing the risks and costs against the benefits to each patient. They also reinforce the need to identify high-risk malnourished patients by nutritional assessment.

Nutritional Support Methods

Selection of the most appropriate nutritional support method involves consideration of gastrointestinal function, the anticipated duration of nutritional support, and the ability of each method to meet the patient's nutritional requirements. The method chosen should meet the patient's nutritional needs with the lowest risk and lowest cost possible. For most patients, enteral feeding is safer and cheaper and offers significant physiologic advantages. An algorithm for selection of the most appropriate nutritional support method is presented in Figure 29–1.



Gastrointestinal tract can be used safely and effectively?
Yes
No
Support needed for longer than 6 weeks?
Parenteral nutrition
Yes
No
Tube enterostomy
Nasoenteric tube
Support needed for longer than 2–3 weeks?
Yes
No
At high risk for aspiration?
Adequate peripheral access and fluid tolerance?
Yes
No
No
Yes
Nasoduodenal tube
Nasogastric tube
Central vein nutritional support
Peripheral vein nutritional support

▲ Figure 29–1. **Nutritional support method decision tree.**

Prior to initiating specialized enteral nutritional support, efforts should be made to supplement food intake. Attention to patient food preferences, timing of meals in relation to diagnostic procedures and required medications, and the use of foods brought to the hospital by family and friends can often increase oral intake. Patients unable to eat enough at regular mealtimes to meet nutritional requirements can be given **oral supplements** as snacks or to replace low-calorie beverages. Oral supplements of differing nutritional composition are available for the purpose of individualizing the diet in accordance with specific clinical requirements. Fiber and lactose content, caloric density, protein level, amino acid profiles, vitamin K, and calcium can all be modified as necessary.

Patients unable to take adequate oral nutrients who have functioning gastrointestinal tracts and who meet the criteria for nutritional support are candidates for **liquid artificial nutrition ("tube feedings")**. Small-bore feeding tubes are placed via the nose into the stomach or duodenum. Patients able to sit up in bed who can protect their airways can be fed into the stomach. Because of the increased risk of aspiration, patients who cannot adequately protect their airways should be fed nasoduodenally (though, as noted below, this may not prevent all aspirations, particularly if the pylorus is patulous). Feeding tubes can usually be passed into the duodenum by leaving an extra length of tubing in the stomach and placing the patient in the right decubitus position. Metoclopramide, 10 mg intravenously, can be given 20 minutes prior to insertion and continued every 6 hours thereafter to facilitate passage through the pylorus. Occasionally, patients will require fluoroscopic or endoscopic guidance to insert the tube distal to the pylorus. Placement of nasogastric and, particularly, nasoduodenal tubes should be confirmed radiographically before delivery of feeding solutions.

Liquid artificial nutrition can also be accomplished by placing tubes directly into the gastrointestinal tract using **tube enterostomies**. Most tube enterostomies are placed in patients who require long-term enteral nutritional support. Gastrostomies have the advantage of allowing bolus feedings, while jejunostomies require continuous infusions. Gastrostomies—like nasogastric feeding—should be used only in patients at low risk for aspiration. Gastrostomies can also be placed percutaneously with the aid of endoscopy. These tubes can then be advanced into the jejunum. Tube enterostomies can also be placed surgically.

Patients who require nutritional support but whose gastrointestinal tracts are nonfunctional should receive **parenteral nutritional support**. Most patients receive parenteral feedings via a central vein—most commonly the subclavian vein. Peripheral veins can be used in some patients, but this is rarely tolerated for more than a few weeks because of the high osmolality of parenteral solutions.

Peripheral vein nutritional support is most commonly used in patients with nonfunctioning gastrointestinal tracts who require immediate support but whose clinical status is expected to improve within 1–2 weeks, allowing enteral feeding. Peripheral vein nutritional support is administered via standard intravenous lines. Solutions should always include lipid and dextrose in combination with amino acids to provide adequate nonprotein calories. Serious side effects are infrequent, but there is a high incidence of phlebitis and infiltration of intravenous lines.

Central vein nutritional support is delivered via intravenous catheters placed percutaneously using aseptic technique. Proper placement in the superior vena cava is documented radiographically before the solution is infused. Catheters must be carefully maintained by experienced nursing personnel and used solely for nutritional support to prevent infection and other catheter-related complications.

NUTRITIONAL REQUIREMENTS

Each patient's nutritional requirements should be determined independently of the method of nutritional support. In most situations, solutions of equal nutrient value can be designed for delivery via enteral and parenteral routes, but differences in absorption must be considered. A complete nutritional support solution must contain water, energy, amino acids, electrolytes, vitamins, minerals, and essential fatty acids.

Water

For most patients, water requirements can be calculated by allowing 1500 mL for the first 20 kg of body weight plus 20 mL for every kilogram over 20. Additional losses should be replaced as they occur. For average-sized adult patients, fluid needs are about 30–35 mL/kg, or approximately 1 mL/kcal of energy required.

Energy

Energy requirements can be estimated by one of three methods: (1) by using standard equations to calculate BEE plus additional calories for activity and illness, (2) by applying a simple calculation based on calories per kilogram of body weight, or (3) by measuring energy expenditure with indirect calorimetry.

BEE can be estimated by the **Harris–Benedict equation**: for men, BEE = 666 + (13.7 × weight in kg) + (5 × height in cm) – (6.8 × age in years). For women, BEE = 655 + (9.5 × weight in kg) + (1.8 × height in cm) – (4.7 × age in years). For undernourished patients, actual body weight should be used; for patients with obesity, ideal body weight should be used. For most patients, an additional 20–50% of BEE is administered as nonprotein calories to accommodate energy expenditures during activity or relating to the illness. Occasional patients are noted to have energy expenditures greater than 150% of BEE.

Energy requirements can be estimated also by multiplying actual body weight in kilograms (for patients with obesity, ideal body weight) by 30–35 kcal.

Both of these methods provide imprecise estimates of actual energy expenditures, especially for the markedly underweight, overweight, and critically ill patient. Studies using indirect calorimetry have demonstrated that as many as 30–40% of patients will have measured expenditures 10% above or below estimated values. For a more accurate determination of energy expenditure, indirect calorimetry can be used.

Protein

Protein and energy requirements are closely related. If adequate calories are provided, most patients can be given 0.8–1.2 g of protein per kilogram per day. Patients undergoing moderate to severe stress should receive up to 1.5 g/kg/day. As in the case of energy requirements, actual weights should be used for normal and underweight patients and ideal weights for patients with significant obesity.

Patients who are receiving protein without adequate calories will catabolize protein for energy rather than utilizing it for protein synthesis. Thus, when energy intake is low, excess protein is needed for nitrogen balance. If both energy and protein intakes are low, extra energy will have a more significant positive effect on nitrogen balance than extra protein.

Electrolytes & Minerals

Requirements for sodium, potassium, and chloride vary widely. Most patients require 45–145 mEq/day of each. The actual requirement in individual patients will depend on the patient's cardiovascular, renal, endocrine, and gastrointestinal status as well as measurements of serum concentration.

Patients receiving enteral nutritional support should receive adequate vitamins and minerals according to the recommended daily allowances. Most premixed enteral solutions provide adequate vitamins and minerals as long as adequate calories are administered.

Patients receiving parenteral nutritional support require smaller amounts of minerals: calcium, 10–15 mEq/day; phosphorus, 15–20 mEq per 1000 nonprotein calories; and magnesium, 16–24 mEq/day. Most patients receiving nutritional support do not require supplemental iron because body stores are adequate. Iron nutrition should be monitored closely by following the hemoglobin concentration, mean corpuscular volume, and iron studies. Parenteral administration of iron is associated with a number of adverse effects and should be reserved for iron-deficient patients unable to take oral iron.

Patients receiving parenteral nutritional support should be given the trace elements zinc (about 5 mg/day) and copper (about 2 mg/day). Patients with diarrhea will require additional zinc to replace fecal losses. Additional trace elements—especially chromium, manganese, and selenium—are provided to patients receiving long-term parenteral nutrition.

Parenteral vitamins are provided daily. Standardized multivitamin solutions are currently available to provide adequate quantities of vitamins A, B_{12}, C, D, E, thiamine, riboflavin, niacin, pantothenic acid, pyridoxine, folic acid, and biotin. Vitamin K is not given routinely but administered when the prothrombin time becomes abnormal.

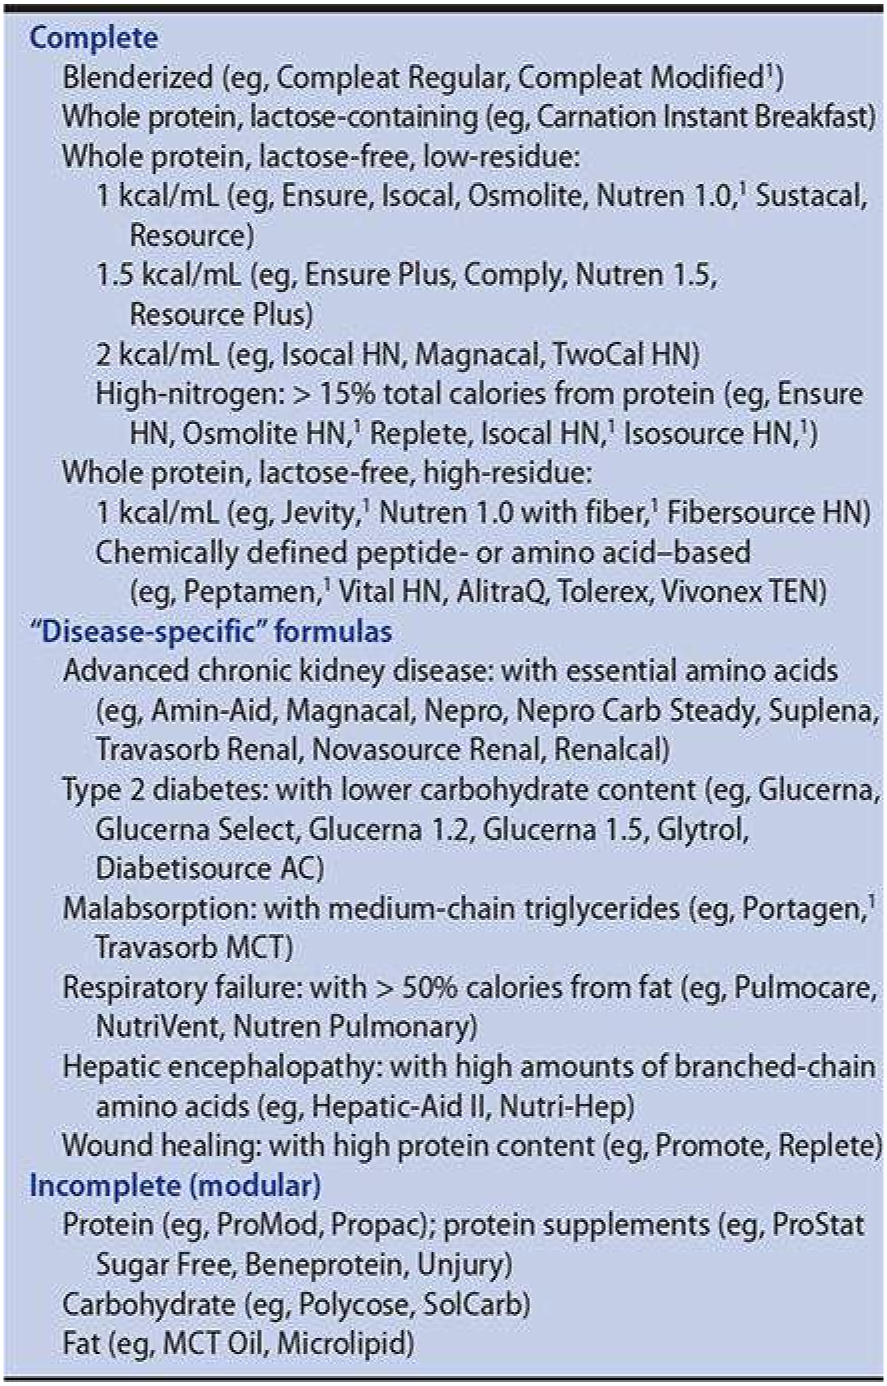
Essential Fatty Acids

Patients receiving nutritional support should be given 2–4% of their total calories as linoleic acid to prevent essential fatty acid deficiency. Most prepared enteral solutions contain adequate linoleic acid. Patients receiving parenteral nutrition should be given at least 250 mL of a 20% intravenous fat (emulsified soybean or safflower oil) about two or three times a week. Intravenous fat can also be used as an energy source in place of dextrose.

ENTERAL NUTRITIONAL SUPPORT SOLUTIONS

Most patients who require enteral nutritional support can be given commercially prepared enteral solutions (Table 29–3). Nutritionally complete solutions have been designed to provide adequate proportions of water, energy, protein, and micronutrients. Nutritionally incomplete solutions are also available to provide specific macronutrients (eg, protein, carbohydrate, and fat) to supplement complete solutions for patients with unusual requirements or to design solutions that are not available commercially.

Table 29–3. Enteral solutions.



Complete

- Blenderized (eg, Compleat Regular, Compleat Modified[1])
- Whole protein, lactose-containing (eg, Carnation Instant Breakfast)
- Whole protein, lactose-free, low-residue:
  - 1 kcal/mL (eg, Ensure, Isocal, Osmolite, Nutren 1.0,[1] Sustacal, Resource)
  - 1.5 kcal/mL (eg, Ensure Plus, Comply, Nutren 1.5, Resource Plus)
  - 2 kcal/mL (eg, Isocal HN, Magnacal, TwoCal HN)
  - High-nitrogen: > 15% total calories from protein (eg, Ensure HN, Osmolite HN,[1] Replete, Isocal HN,[1] Isosource HN,[1])
- Whole protein, lactose-free, high-residue:
  - 1 kcal/mL (eg, Jevity,[1] Nutren 1.0 with fiber,[1] Fibersource HN)
  - Chemically defined peptide- or amino acid–based (eg, Peptamen,[1] Vital HN, AlitraQ, Tolerex, Vivonex TEN)

"Disease-specific" formulas

- Advanced chronic kidney disease: with essential amino acids (eg, Amin-Aid, Magnacal, Nepro, Nepro Carb Steady, Suplena, Travasorb Renal, Novasource Renal, Renalcal)
- Type 2 diabetes: with lower carbohydrate content (eg, Glucerna, Glucerna Select, Glucerna 1.2, Glucerna 1.5, Glytrol, Diabetisource AC)
- Malabsorption: with medium-chain triglycerides (eg, Portagen,[1] Travasorb MCT)
- Respiratory failure: with > 50% calories from fat (eg, Pulmocare, NutriVent, Nutren Pulmonary)
- Hepatic encephalopathy: with high amounts of branched-chain amino acids (eg, Hepatic-Aid II, Nutri-Hep)
- Wound healing: with high protein content (eg, Promote, Replete)

Incomplete (modular)

- Protein (eg, ProMod, Propac); protein supplements (eg, ProStat Sugar Free, Beneprotein, Unjury)
- Carbohydrate (eg, Polycose, SolCarb)
- Fat (eg, MCT Oil, Microlipid)

Nutritionally complete solutions are characterized as follows: (1) by osmolality (isotonic or hypertonic), (2) by lactose content (present or absent), (3) by the molecular form of the protein component (intact proteins; peptides or amino acids), (4) by the quantity of protein and calories provided, and (5) by fiber content (present or absent). For most patients, isotonic solutions containing no lactose or fiber are preferable. Such solutions generally contain moderate amounts of fat and intact protein. Most commercial isotonic solutions contain 1000 kcal and about 37–45 g of protein per liter.

Solutions containing hydrolyzed proteins or crystalline amino acids and with no significant fat content are called elemental solutions, since macronutrients are provided in their most "elemental" form. These solutions have been designed for patients with malabsorption, particularly pancreatic insufficiency and limited fat absorption. Elemental diets are extremely hypertonic and often result in more severe diarrhea. Their use should be limited to patients who cannot tolerate isotonic solutions.

Although formulas have been designed for specific clinical situations—solutions containing primarily essential amino acids (for advanced chronic kidney disease), medium-chain triglycerides (for fat malabsorption), more fat (for respiratory failure and CO_2 retention), and more branched-chain amino acids (for hepatic encephalopathy and severe trauma)—they have not been shown to be superior to standard formulas for most patients.

Enteral solutions should be administered via continuous infusion, preferably with an infusion pump. Isotonic feedings should be started at full strength at about 25–33% of the estimated final infusion rate. Feedings can be advanced by similar amounts every 12 hours as tolerated. Hypertonic feedings should be started at half strength. The strength and the rate can then be advanced every 6 hours as tolerated.

COMPLICATIONS OF ENTERAL NUTRITIONAL SUPPORT

Minor complications of enteral nutritional support occur in 10–15% of patients. Gastrointestinal complications include diarrhea (most common), inadequate gastric emptying, emesis, esophagitis, and occasionally gastrointestinal bleeding. Diarrhea associated with enteral nutritional support may be due to intolerance to the osmotic load or to one of the macronutrients (eg, fat, lactose) in the solution. Patients being fed in this way may also have diarrhea from other causes (as side effects of antibiotics or other drugs, associated with infection, etc), and these possibilities should always be investigated in appropriate circumstances.

Mechanical complications of enteral nutritional support are potentially the most serious. Of particular importance is aspiration. All patients receiving nasogastric tube feedings are at risk for this life-threatening complication. Limiting nasogastric feedings to those patients who can adequately protect their airway and careful monitoring of patients being fed by tube should limit these serious complications to 1–2% of cases. Minor mechanical complications are common and include tube obstruction and dislodgment.

Metabolic complications during enteral nutritional support are common but are easily managed in most cases. The most important problem is hypernatremic dehydration, most commonly seen in elderly patients given excessive protein intake who are unable to respond to thirst. Abnormalities of potassium, glucose, CO_2 production, and acid–base balance may also occur.

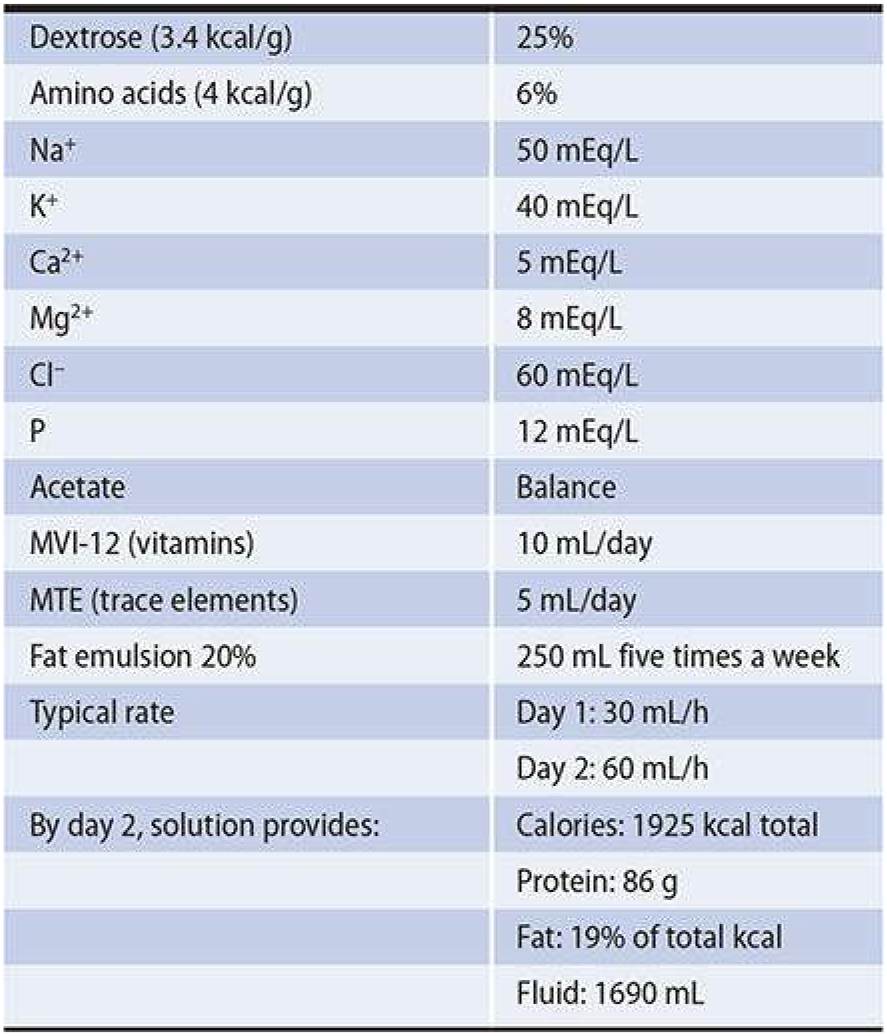
PARENTERAL NUTRITIONAL SUPPORT SOLUTIONS

Parenteral nutritional support solutions can be designed to deliver adequate nutrients to most patients. The basic parenteral solution is composed of dextrose, amino acids, and water. Electrolytes, minerals, trace elements, vitamins, and medications can also be added. Most commercial solutions contain the monohydrate form of dextrose that provides 3.4 kcal/g. Crystalline amino acids are available in a variety of concentrations, so that a broad range of solutions can be made up that will contain specific amounts of dextrose and amino acids as required.

Typical solutions for central vein nutritional support contain 25–35% dextrose and 2.75–6% amino acids depending upon the patient's estimated nutrient and water requirements. These solutions typically have osmolalities in excess of 1800 mOsm/L and require infusion into a central vein. A typical formula for patients without organ failure is shown in Table 29–4.

Table 29–4. Typical parenteral nutrition solution (for stable patients without organ failure).



Dextrose (3.4 kcal/g)	25%
Amino acids (4 kcal/g)	6%
Na^+	50 mEq/L
K^+	40 mEq/L
Ca^{2+}	5 mEq/L
Mg^{2+}	8 mEq/L
Cl^-	60 mEq/L
P	12 mEq/L
Acetate	Balance
MVI-12 (vitamins)	10 mL/day
MTE (trace elements)	5 mL/day
Fat emulsion 20%	250 mL five times a week
Typical rate	Day 1: 30 mL/h
	Day 2: 60 mL/h
By day 2, solution provides:	Calories: 1925 kcal total
	Protein: 86 g
	Fat: 19% of total kcal
	Fluid: 1690 mL

Solutions with lower osmolalities can also be designed for infusion into peripheral veins. Typical solutions for peripheral infusion contain 5–10% dextrose and 2.75–4.25% amino acids. These solutions have osmolalities between 800 and 1200 mOsm/L and result in a high incidence of thrombophlebitis and line infiltration. These solutions will provide adequate protein for most patients but inadequate energy. Additional energy must be provided in the form of emulsified soybean or safflower oil. Such intravenous fat solutions are currently available in 10% and 25% solutions providing 1.1 and 2.2 kcal/mL, respectively. Intravenous fat solutions are isosmotic and well tolerated by peripheral veins.

Typical patients are given 200–500 mL of a 20% solution each day. As much as 60% of total calories can be administered in this manner.

Intravenous fat can also be provided to patients receiving central vein nutritional support. In this instance, dextrose concentrations should be decreased to provide a fixed concentration of energy. Intravenous fat has been shown to be equivalent to intravenous dextrose in providing energy to spare protein. Intravenous fat is associated with less glucose intolerance, less production of carbon dioxide, and less fatty infiltration of the liver and has been increasingly utilized in patients with hyperglycemia, respiratory failure, and liver disease. Intravenous fat has also been increasingly used in patients with large estimated energy requirements. The maximum glucose utilization rate is approximately 5–7 mg/min/kg. Patients who require additional calories can be given them as fat to prevent excess administration of dextrose. Intravenous fat can also be used to prevent essential fatty acid deficiency. The optimal ratio of carbohydrate and fat in parenteral nutritional support has not been determined.

Infusion of parenteral solutions should be started slowly to prevent hyperglycemia and other metabolic complications. Typical solutions are given initially at a rate of 50 mL/h and advanced by about the same amount every 24 hours until the desired final rate is reached.

COMPLICATIONS OF PARENTERAL NUTRITIONAL SUPPORT

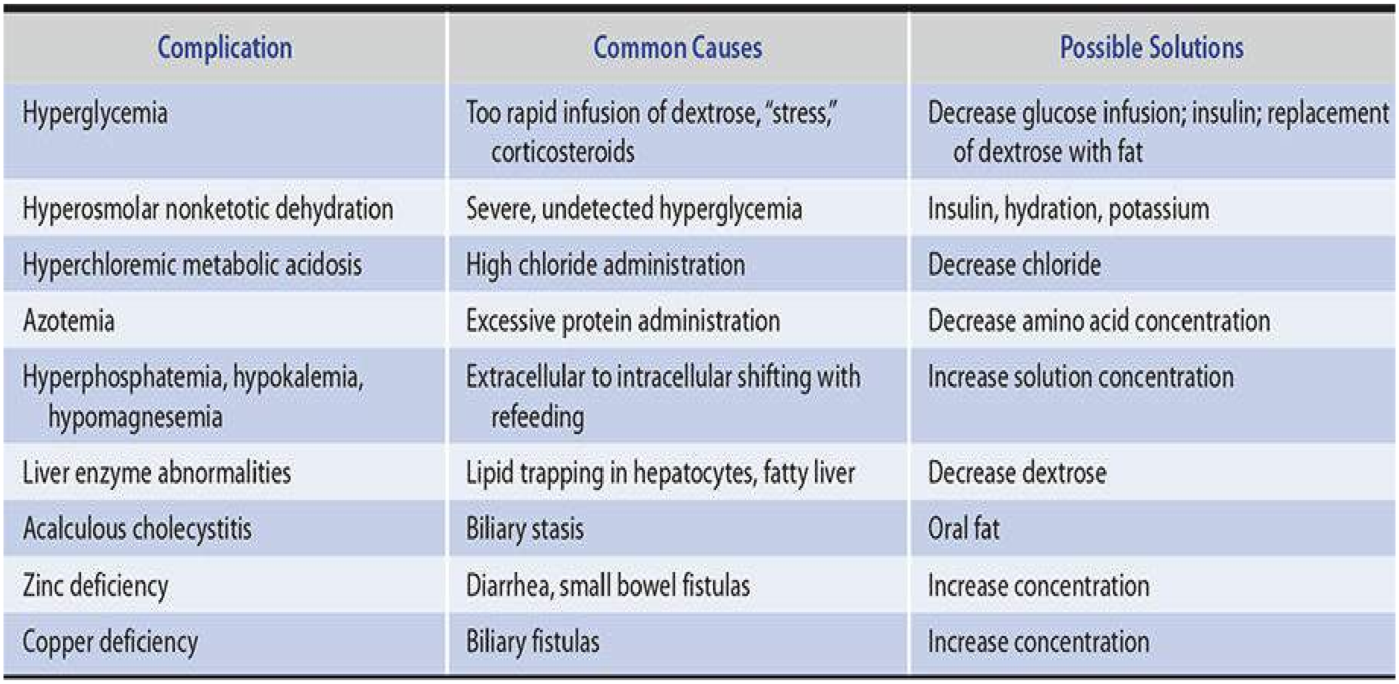
Complications of central vein nutritional support occur in up to 50% of patients. Although most are minor and easily managed, significant complications will develop in about 5% of patients. Complications of central vein nutritional support can be divided into catheter-related complications and metabolic complications.

Catheter-related complications can occur during insertion or while the catheter is in place. Pneumothorax, hemothorax, arterial laceration, air emboli, and brachial plexus injury can occur during catheter placement. The incidence of these complications is inversely related to the experience of the physician performing the procedure but will occur in at least 1–2% of cases even in major medical centers. Each catheter placement should be documented by chest radiograph prior to initiation of nutritional support.

Catheter thrombosis and catheter-related sepsis are the most important complications of indwelling catheters. Patients with indwelling central vein catheters in whom fever develops without an apparent source should have their lines changed over a wire or removed immediately, the tip quantitatively cultured, and antibiotics begun empirically. Quantitative tip cultures and blood cultures will help guide further antibiotic therapy. Catheter-related sepsis occurs in 2–3% of patients even if maximal efforts are made to prevent infection.

Metabolic complications of central vein nutritional support occur in over 50% of patients (Table 29–5). Most are minor and easily managed, and termination of support is seldom necessary.

Table 29–5. Metabolic complications of parenteral nutritional support.



Complication	Common Causes	Possible Solutions
Hyperglycemia	Too rapid infusion of dextrose, "stress," corticosteroids	Decrease glucose infusion; insulin; replacement of dextrose with fat
Hyperosmolar nonketotic dehydration	Severe, undetected hyperglycemia	Insulin, hydration, potassium
Hyperchloremic metabolic acidosis	High chloride administration	Decrease chloride
Azotemia	Excessive protein administration	Decrease amino acid concentration
Hyperphosphatemia, hypokalemia, hypomagnesemia	Extracellular to intracellular shifting with refeeding	Increase solution concentration
Liver enzyme abnormalities	Lipid trapping in hepatocytes, fatty liver	Decrease dextrose
Acalculous cholecystitis	Biliary stasis	Oral fat
Zinc deficiency	Diarrhea, small bowel fistulas	Increase concentration
Copper deficiency	Biliary fistulas	Increase concentration

PATIENT MONITORING DURING NUTRITIONAL SUPPORT

Every patient receiving enteral or parenteral nutritional support should be monitored closely. Formal nutritional support teams composed of a physician, a nurse, a dietitian, and a pharmacist have been shown to decrease the rate of complications.

Patients should be monitored both for the adequacy of treatment and to prevent complications or detect them early when they occur. Because estimates of nutritional requirements are imprecise, frequent reassessment is necessary. Daily intakes should be recorded and compared with estimated requirements. Body weight, hydration status, and overall clinical status should be followed. Patients who do not appear to be responding as anticipated can be evaluated for nitrogen balance by means of the following equation:

$$\text{Nitrogen balance} = \frac{\text{24-hour protein intake (g)}}{6.25} - \text{24-hour urinary nitrogen (g)} + 4$$

Patients with positive nitrogen balances can be continued on their current regimens; patients with negative balances should receive moderate increases in calorie and protein intake and then be reassessed. Monitoring for metabolic complications includes daily measurements of electrolytes; serum glucose, phosphorus, magnesium, calcium, and creatinine; and BUN until the patient is stabilized. Once the patient is stabilized, electrolytes, phosphorus, calcium, magnesium, and glucose should be obtained at least twice weekly. Red blood cell folate, zinc, and copper should be checked at least once a month.

Common Problems in Infectious Diseases & Antimicrobial Therapy

Peter V. Chin-Hong, MD
B. Joseph Guglielmo, PharmD

COMMON PROBLEMS IN INFECTIOUS DISEASES

FEVER OF UNKNOWN ORIGIN (FUO)

ESSENTIALS OF DIAGNOSIS

- Illness of at least 3 weeks in duration.
- Fever over 38.3°C on several occasions.
- Diagnosis has not been made after three outpatient visits or 3 days of hospitalization.

General Considerations

The intervals specified in the criteria for the diagnosis of FUO are arbitrary ones intended to exclude patients with protracted but self-limited viral illnesses and to allow time for the usual radiographic, serologic, and cultural studies to be performed. The criteria for FUO are met when a diagnosis has not been made after three outpatient visits or 3 days of hospitalization.

The recently added categories of FUO include complications of current health care scenarios: (1) **Hospital-associated FUO** refers to the hospitalized patient with fever of 38.3°C or higher on several occasions, due to a process not present or incubating at the time of admission, in whom initial cultures are negative and the diagnosis remains unknown after 3 days of investigation (see Health Care–Associated Infections below); (2) **neutropenic FUO** includes patients with fever of 38.3°C or higher on several occasions with less than 500 neutrophils per microliter in whom initial cultures are negative and the diagnosis remains uncertain after 3 days (see Chapter 2 and Infections in the Immunocompromised Patient, below); (3) **HIV-associated FUO** pertains to HIV-positive patients with fever of 38.3°C or higher who have been febrile for 4 weeks or more as an outpatient or 3 days as an inpatient, in whom the diagnosis remains uncertain after 3 days of investigation with at least 2 days for cultures to incubate (see Chapter 31). Although not usually considered separately, **FUO in solid organ transplant recipients** and **FUO in the returning traveler** are common scenarios, each with a unique differential diagnosis, and are also discussed in this chapter.

For a general discussion of fever, see the section on fever and hyperthermia in Chapter 2.

A. Common Causes

Most cases represent unusual manifestations of common diseases and not rare or exotic diseases—eg, tuberculosis, endocarditis, gallbladder disease, and HIV (primary infection or opportunistic infection) are more common causes of FUO than Whipple disease or familial Mediterranean fever.

B. Age of Patient

In adults, infections (25–40% of cases) and cancer (25–40% of cases) account for the majority of FUOs. In children, infections are the most common cause of FUO (30–50% of cases) and cancer a rare cause (5–10% of cases). Autoimmune disorders occur with equal frequency in adults and children (10–20% of cases), but the diseases differ. Juvenile rheumatoid arthritis is particularly common in children, whereas systemic lupus erythematosus, granulomatosis with polyangiitis (formerly Wegener granulomatosis), and polyarteritis nodosa are more common in adults. Still disease, giant cell arteritis, and polymyalgia rheumatica occur exclusively in adults. In adults over 65 years of age, multisystem immune-mediated diseases such as temporal arteritis, polymyalgia rheumatica, sarcoidosis, rheumatoid arthritis, and granulomatosis with polyangiitis account for 25–30% of all FUOs.

C. Duration of Fever

The cause of FUO changes dramatically in patients who have been febrile for 6 months or longer. Infection, cancer, and autoimmune disorders combined account for only 20% of FUOs in these patients. Instead, other entities such as granulomatous diseases (granulomatous hepatitis, Crohn disease, ulcerative colitis) and factitious fever become important causes. One-fourth of patients who say they have been febrile for 6 months or longer actually have no true fever or underlying disease. Instead, the usual normal circadian variation in temperature (temperature 0.5–1°C higher in the afternoon than in the morning) is interpreted as abnormal. Patients with **episodic** or **recurrent fever** (ie, those who meet the criteria for FUO but have fever-free periods of 2 weeks or longer) are similar to those with **prolonged fever**. Infection, malignancy, and autoimmune disorders account for only 20–25% of such fevers, whereas various miscellaneous diseases (Crohn disease, familial Mediterranean fever, allergic alveolitis) account for another 25%. Approximately 50% of cases remain undiagnosed but have a benign course with eventual resolution of symptoms.

D. Immunologic Status

In the neutropenic patient, fungal infections and occult bacterial infections are important causes of FUO. In the patient taking immunosuppressive medications (particularly organ transplant patients), cytomegalovirus (CMV) infections are a frequent cause of fever, as are fungal infections, nocardiosis, Pneumocystis jirovecii pneumonia, and mycobacterial infections.

E. Classification of Causes of FUO

Most patients with FUO will fit into one of five categories.

1. Infection—Both systemic and localized infections can cause FUO. Tuberculosis and endocarditis are the most common systemic infections associated with FUO, but mycoses, viral diseases (particularly infection with Epstein-Barr virus and CMV), toxoplasmosis, brucellosis, Q fever, cat-scratch disease, salmonellosis, malaria, and many other less common infections have been implicated. Primary infection with HIV or opportunistic infections associated with AIDS—particularly mycobacterial infections—can also present as FUO. The most common form of localized infection causing FUO is an occult abscess. Liver, spleen, kidney, brain, and bone abscesses may be difficult to detect. A collection of pus may form in the peritoneal cavity or in the subdiaphragmatic, subhepatic, paracolic, or other areas. Cholangitis, osteomyelitis, urinary tract infection, dental abscess, or paranasal sinusitis may cause prolonged fever.

2. Neoplasms—Many cancers can present as FUO. The most common are lymphoma (both Hodgkin and non-Hodgkin) and leukemia. Posttransplant lymphoproliferative disorders may also present with fever. Other diseases of lymph nodes, such as angioimmunoblastic lymphoma and Castleman disease, can also cause FUO. Primary and metastatic tumors of the liver are frequently associated with fever, as are renal cell carcinomas. Atrial myxoma is an often forgotten neoplasm that can result in fever. Chronic lymphocytic leukemia and multiple myeloma are rarely associated with fever, and the presence of fever in patients with these diseases should prompt a search for infection.

3. Autoimmune disorders—Still disease, systemic lupus erythematosus, cryoglobulinemia, and polyarteritis nodosa are the most common causes of autoimmune-associated FUO. Giant cell arteritis and polymyalgia rheumatica are seen almost exclusively in patients over 50 years of age and are nearly always associated with an elevated erythrocyte sedimentation rate (greater than 40 mm/h).

4. Miscellaneous causes—Many other conditions have been associated with FUO but less commonly than the foregoing types of illness. Examples include thyroiditis, sarcoidosis, Whipple disease, familial Mediterranean fever, recurrent pulmonary emboli, alcoholic hepatitis, drug fever, and factitious fever.

5. Undiagnosed FUO—Despite extensive evaluation, the diagnosis remains elusive in 15% or more of patients. Of these patients, the fever abates spontaneously in about 75% with no diagnosis; in the remainder, more classic manifestations of the underlying disease appear over time.

Clinical Findings

Because the evaluation of a patient with FUO is costly and time-consuming, it is imperative to first document the presence of fever. This is done by observing the patient while the temperature is being taken to ascertain that fever is not factitious (self-induced). Associated findings that accompany fever include tachycardia, chills, and piloerection. A thorough history—including family, occupational, social (sexual practices, use of injection drugs), dietary (unpasteurized products, raw meat), exposures (animals, chemicals), and travel—may give clues to the diagnosis. Repeated physical examination may reveal subtle, evanescent clinical findings essential to diagnosis.

A. Laboratory Tests

In addition to routine laboratory studies, blood cultures should always be obtained, preferably when the patient has not taken antibiotics for several days, and should be held by the laboratory for 2 weeks to detect slow-growing organisms. Cultures on special media are requested if Legionella, Bartonella, or nutritionally deficient streptococci are possible pathogens. “Screening tests” with immunologic or microbiologic serologies (“febrile agglutinins”) are of low yield and should not be done. If the history or physical examination suggests a specific diagnosis, specific serologic tests with an associated fourfold rise or fall in titer may be useful. Because infection is the most common cause of FUO, other body fluids are usually cultured, ie, urine, sputum, stool, cerebrospinal fluid, and morning gastric aspirates (if one suspects tuberculosis). Direct examination of blood smears may establish a diagnosis of malaria or relapsing fever (Borrelia).

B. Imaging

All patients with FUO should have a chest radiograph. Studies such as sinus CT, upper gastrointestinal series with small bowel follow-through, barium enema, proctosigmoidoscopy, and evaluation of gallbladder function are reserved for patients who have symptoms, signs, or a history that suggest disease in these body regions. CT scan of the abdomen and pelvis is also frequently performed and is particularly useful for looking at the liver, spleen, and retroperitoneum. When the CT scan is abnormal, the findings often lead to a specific diagnosis. A normal CT scan is not quite as useful; more invasive procedures such as biopsy or exploratory laparotomy may be needed. The role of MRI in the investigation of FUO has not been evaluated. In general, however, MRI is better than CT for detecting lesions of the nervous system and is useful in diagnosing various vasculitides. Ultrasound is sensitive for detecting lesions of the kidney, pancreas, and biliary tree. Echocardiography should be used if one is considering endocarditis or atrial myxoma. Transesophageal echocardiography is more sensitive than surface echocardiography for detecting valvular lesions, but even a negative transesophageal study does not exclude endocarditis (10% false-negative rate). The usefulness of radionuclide studies in diagnosing FUO is variable. Some experts use positron emission tomography (PET) in conjunction with CT scans early in the investigation of FUO. However, more studies are needed before this practice can be more fully integrated into clinical practice. Theoretically, a gallium or PET scan would be more helpful than an indium-labeled white blood cell scan because gallium and fluorodeoxyglucose may be useful for detecting infection, inflammation, and neoplasm whereas the indium scan is useful only for detecting infection. Indium-labeled immunoglobulin may prove to be useful in detecting infection and neoplasm and can be used in the neutropenic patient. It is not sensitive for lesions of the liver, kidney, and heart because of high background activity. In general, radionuclide scans are plagued by high rates of false-positive and false-negative results that are not useful when used as screening tests and, if done at all, are limited to those patients whose history or examination suggests local inflammation or infection.

C. Biopsy

Invasive procedures are often required for diagnosis. Any abnormal finding should be aggressively evaluated: Headache calls for lumbar puncture to rule out meningitis; skin rash should be biopsied for cutaneous manifestations of collagen vascular disease or infection; and enlarged lymph nodes should be aspirated or biopsied for neoplasm and sent for culture. Bone marrow aspiration with biopsy is a relatively low-yield procedure (15–25%; except in HIV-positive patients, in whom mycobacterial infection is a common cause of FUO), but the risk is low and the procedure should be done if other less invasive tests have not yielded a diagnosis, particularly in persons with hematologic abnormalities. Liver biopsy will yield a specific diagnosis in 10–15% of patients with FUO and should be considered in any patient with abnormal liver tests even if the liver is normal in size. CT scanning and MRI have decreased the need for exploratory laparotomy; however, surgical visualization and biopsies should be considered when there is continued deterioration or lack of diagnosis.

Treatment

Although an empiric course of antimicrobials is sometimes considered for FUO, it is rarely helpful and may impact infectious diseases diagnoses (eg, by reducing the sensitivity of blood cultures).

When to Refer

- Any patient with FUO and progressive weight loss and other constitutional signs.
- Any immunocompromised patient (eg, transplant recipients and HIV-infected patients).
- Infectious diseases specialists may also be able to coordinate and interpret specialized testing (eg, Q fever serologies) with outside agencies, such as the US Centers for Disease Control and Prevention.

When to Admit

- Any patient who is rapidly declining with weight loss where hospital admission may expedite workup.
- If FUO is present in immunocompromised patients, such as those who are neutropenic from recent chemotherapy or those who have undergone transplantation (particularly in the previous 6 months).

origin: A cohort study. Medicine (Baltimore). 2018 Jun;97(24):e10986. [PMID: 29901588]

INFECTIONS IN THE IMMUNOCOMPROMISED PATIENT

ESSENTIALS OF DIAGNOSIS

- Fever and other symptoms may be blunted because of immunosuppression.
- A contaminating organism in an immunocompetent individual may be a pathogen in an immunocompromised one.
- The interval since transplantation and the degree of immunosuppression can narrow the differential diagnosis.
- Empiric broad-spectrum antibiotics may be appropriate in high-risk patients whether or not symptoms are localized.

General Considerations

Immunocompromised patients have defects in their natural defense mechanisms resulting in an increased risk for infection. In addition, infection is often severe, rapidly progressive, and life threatening. Organisms that are not usually problematic in the immunocompetent person may be important pathogens in the compromised patient (eg, Staphylococcus epidermidis, Corynebacterium jeikeium, Propionibacterium acnes, Bacillus species). Therefore, culture results must be interpreted with caution, and isolates should not be disregarded as solely contaminants. Although the type of immunodeficiency is associated with specific infectious disease syndromes, any pathogen can cause infection in any immunosuppressed patient at any time. Thus, a systematic evaluation is required to identify a specific organism.

A. Impaired Humoral Immunity

Defects in humoral immunity are often congenital, although hypogammaglobulinemia can occur in multiple myeloma, chronic lymphocytic leukemia, small lymphocyte lymphoma, and in patients who have undergone splenectomy. Patients with ineffective humoral immunity lack opsonizing antibodies and are at particular risk for infection with encapsulated organisms, such as Haemophilus influenzae, Neisseria meningitides, and Streptococcus pneumoniae. Although rituximab is normally thought of as being linked to impaired cellular immunity, it has been associated with the development of

Pneumocystis jirovecii infection and progressive multifocal leukoencephalopathy (PML) as well as with hepatitis B reactivation.

B. Granulocytopenia (Neutropenia)

Granulocytopenia is common following hematopoietic cell transplantation ("stem cell transplantation") and among patients with solid tumors—as a result of myelosuppressive chemotherapy—and in acute leukemias. The risk of infection begins to increase when the absolute granulocyte count falls below 1000/mcL, with a dramatic increase in frequency and severity when the granulocyte count falls below 100/mcL. The infection risk is also increased with a rapid rate of decline of neutrophils and with a prolonged period of neutropenia. The granulocytopenic patient is particularly susceptible to infections with gram-negative enteric organisms, Pseudomonas, gram-positive cocci (particularly Staphylococcus aureus, S epidermidis, and viridans streptococci), Candida, Aspergillus, and other fungi that have recently emerged as pathogens such as Trichosporon, Scedosporium, Fusarium, and the mucormycoses.

C. Impaired Cellular Immunity

Patients with cellular immune deficiency encompass a large and heterogeneous group, including patients with HIV infection (see Chapter 31); patients with lymphoreticular malignancies, such as Hodgkin disease; and patients receiving immunosuppressive medications, such as corticosteroids, cyclosporine, tacrolimus, and other cytotoxic medications. This latter group—those who are immunosuppressed as a result of medications—includes patients who have undergone solid organ transplantation, many patients receiving therapy for solid tumors, and patients receiving prolonged high-dose corticosteroid treatment (eg, for asthma, temporal arteritis, systemic lupus erythematosus). Patients taking tumor necrosis factor (TNF) inhibitors, such as etanercept and infliximab, are also included in this category. Patients with cellular immune dysfunction are susceptible to infections by a large number of organisms, particularly ones that replicate intracellularly. Examples include bacteria, such as Listeria, Legionella, Salmonella, and Mycobacterium; viruses, such as herpes simplex, varicella, and CMV; fungi, such as Cryptococcus, Coccidioides, Histoplasma, and Pneumocystis; and protozoa, such as Toxoplasma.

D. Hematopoietic Cell Transplant Recipients

The length of time it takes for complications to occur in hematopoietic cell transplant recipients can be helpful in determining the etiologic agent. In the **early (preengraftment) posttransplant period (days 1–21),** patients will become severely neutropenic for 7–21 days. Patients are at risk for gram-positive (particularly catheter-related) and gram-negative bacterial infections, as well as herpes simplex virus, respiratory syncytial virus, and fungal infections. In contrast to solid organ transplant recipients, the source of fever is unknown in 60–70% of hematopoietic cell transplant patients. **Between 3 weeks and 3 months posttransplant,** infections with CMV, adenovirus, Aspergillus, and Candida are most common. P jirovecii pneumonia is possible, particularly in patients who receive additional immunosuppression for treatment of graft-versus-host disease. Patients continue to be at risk for infectious complications **beyond 3 months following transplantation,** particularly those who have received allogeneic transplantation and those who are taking immunosuppressive therapy for chronic graft-versus-host disease. Varicella-zoster is common, and Aspergillus and CMV infections are increasingly seen in this period as well.

E. Solid Organ Transplant Recipients

The length of time it takes for infection to occur following solid organ transplantation can also be helpful in determining the infectious origin. **Immediate postoperative infections** often involve the transplanted organ. Following lung transplantation, pneumonia and mediastinitis are particularly common; following liver transplantation, intra-abdominal abscess, cholangitis, and peritonitis may be seen; after kidney transplantation, urinary tract infections, perinephric abscesses, and infected lymphoceles can occur.

Most infections that occur in the **first 2–4 weeks posttransplant** are related to the operative procedure and to hospitalization itself (wound infection, intravenous catheter infection, urinary tract infection from a Foley catheter) or are related to the transplanted organ. In rare instances, donor-derived infections (eg, West Nile virus, tuberculosis) may present during this time period. Compensated organ transplants obtained abroad through “medical tourism” can introduce additional risk of infections, which vary by country and by transplant setting. Infections that occur **between the first and sixth months** are often related to immunosuppression. During this period, reactivation of viruses, such as herpes simplex, varicella-zoster, and CMV is quite common. Opportunistic infections with fungi (eg, Candida, Aspergillus, Cryptococcus, Pneumocystis), Listeria monocytogenes, Nocardia, and Toxoplasma are also common. **After 6 months,** if immunosuppression has been reduced to maintenance levels, infections that would be expected in any population occur. Patients with poorly functioning allografts receiving long-term immunosuppression therapy continue to be at risk for opportunistic infections.

F. Tumor Necrosis Factor Inhibitor Recipients

Patients taking TNF inhibitors have specific defects that increase risk of bacterial, mycobacterial (particularly tuberculosis), viral (HBV reactivation and HCV progression), and fungal infections (Pneumocystis, molds, and endemic mycoses). Infection risk may be highest shortly after therapy is initiated (within the first 3 months) and with a higher dose of medications.

G. Recipients of Other Biologics

In addition to TNF inhibitors, other biologics target a variety of immunologic pathways that are involved in immunologic mediated disease and in cancer replication. Disruption of these pathways include, but are not limited to impact on B cells, T cells, complement and leukocytes. This may result in not only serious infections, but the development of autoimmune disease and malignancies as well. Some medications have been observed to have specific associations with opportunistic infections (eg, natalizumab and PML, or eculizumab and meningococcal disease). Other biologics such as chimeric antigen receptor T cells may have unintended infectious risks that are currently unknown, or may have adverse effects that mimic infection (eg, cytokine release syndrome). As more biologics are developed and used, clinicians must remain vigilant for the possibility of serious infectious disease risk.

H. Other Immunocompromised States

A large group of patients who are not specifically immunodeficient are at increased risk for infection due to debilitating injury (eg, burns or severe trauma), invasive procedures (eg, chronic central intravenous catheters, Foley catheters, dialysis catheters), central nervous system dysfunction (which predisposes patients to aspiration pneumonia and decubitus ulcers), obstructing lesions (eg, pneumonia due to an obstructed bronchus, pyelonephritis due to nephrolithiasis, cholangitis secondary to cholelithiasis), and use of broad-spectrum antibiotics. Patients with diabetes mellitus have alterations in cellular immunity, resulting in mucormycosis, emphysematous pyelonephritis, and foot infections.

Clinical Findings

A. Laboratory Findings

Routine evaluation includes complete blood count with differential, chest radiograph, and blood cultures; urine and respiratory cultures should be obtained if indicated clinically or radiographically. Any focal complaints (localized pain, headache, rash) should prompt imaging and cultures appropriate to the site.

Patients who remain febrile without an obvious source should be evaluated for viral infection (serum CMV antigen test or polymerase chain reaction), abscesses (which usually occur near previous operative sites), candidiasis involving the liver or spleen, or aspergillosis. Serologic evaluation may be helpful if toxoplasmosis or an endemic fungal infection (coccidioidomycosis, histoplasmosis) is a possible cause. Antigen-based assays may be useful for the diagnosis of aspergillosis (detected by galactomannan level in serum or bronchoalveolar lavage fluid), or other invasive fungal disease, including Pneumocystis infection (serum [1 → 3]-beta-D-glucan level).

B. Special Diagnostic Procedures

Special diagnostic procedures should also be considered. The cause of pulmonary infiltrates can be easily determined with simple techniques in some situations—eg, induced sputum yields a diagnosis of Pneumocystis pneumonia in 50–80% of AIDS patients with this infection. In other situations, more invasive procedures may be required (bronchoalveolar lavage, transbronchial biopsy, open lung biopsy). Skin, liver, or bone marrow biopsy may be helpful in establishing a diagnosis. Next generation DNA-sequencing analysis is an increasingly used and validated option for diagnosis of infectious diseases in immunocompromised persons.

Differential Diagnosis

Transplant rejection, organ ischemia and necrosis, thrombophlebitis, and lymphoma (posttransplant lymphoproliferative disease) may all present as fever and must be considered in the differential diagnosis.

Prevention

While prophylactic antimicrobial medications are used commonly, the optimal medications or dosage regimens are debated. Hand washing is the simplest and most effective means of decreasing hospital-associated infections, especially in the compromised patient. Invasive devices such as central and peripheral lines and Foley catheters are potential sources of infection. Some centers use laminar airflow isolation or high-efficiency particulate air (HEPA) filtering in hematopoietic cell transplant patients. Rates of infection and episodes of febrile neutropenia, but not mortality, are decreased if colony-stimulating factors are used (typically in situations where the risk of febrile neutropenia is 20% or higher) during chemotherapy or during stem-cell transplantation.

A. Pneumocystis & Herpes Simplex Infections

Trimethoprim-sulfamethoxazole (TMP-SMZ), one double-strength tablet orally three times a week, one double-strength tablet twice daily on weekends, or one single-strength tablet daily for 3–6 months, is frequently used to prevent Pneumocystis infections in transplant patients. In patients allergic to TMP-SMZ, dapsone, 50 mg orally daily or 100 mg three times weekly, is recommended. Glucose-6-phosphate dehydrogenase (G6PD) levels should be assessed before dapsone is instituted. Acyclovir prevents herpes simplex infections in bone marrow and solid organ transplant recipients and is given to seropositive patients who are not receiving ganciclovir or valganciclovir for CMV prophylaxis. The usual dose is 200 mg orally three times daily for 4 weeks (hematopoietic cell transplants) to 12 weeks (other solid organ transplants).

B. CMV

No uniformly accepted approach has been adopted for prevention of CMV. Prevention strategies often depend on the serologic status of the donor and recipient and the organ transplanted, which determines the level of immunosuppression after transplant. In solid organ transplants (liver, kidney, heart, lung), the greatest risk of developing CMV disease is in seronegative recipients who receive organs from seropositive donors. These high-risk patients usually receive oral valganciclovir, 900 mg daily for 3–6 months (longer in lung transplant recipients). Other solid organ transplant recipients (seropositive recipients) are at lower risk for developing CMV disease, but still usually receive oral valganciclovir for 3 months. The lowest-risk group for the development of CMV disease is in seronegative patients who receive organs from seronegative donors. Typically, no CMV prophylaxis is used in this group. Ganciclovir and valganciclovir also prevent herpes virus reactivation. Because immunosuppression is increased during periods of rejection, patients treated for rejection usually receive CMV prophylaxis during rejection therapy. Alternatively, in a preemptive approach, patients can be monitored without specific prophylaxis by having blood sampled weekly to look for CMV by polymerase chain reaction techniques. If CMV is detected, then therapy is instituted with oral valganciclovir, 900 mg orally twice daily for a minimum of 2–3 weeks.

Recipients of hematopoietic cell transplants are more severely immunosuppressed than recipients of solid organ transplants, are at greater risk for developing serious CMV infection (usually CMV reactivation), and thus usually receive more aggressive prophylaxis. Like in solid organ transplant recipients, two approaches have been used: universal prophylaxis or preemptive therapy. In the former, all high-risk patients (seropositive patients who receive allogeneic transplants) may receive oral valganciclovir, 900 mg daily to day 100. However, valganciclovir is associated with significant bone marrow toxicity. Letermovir is being used increasingly, and it is not associated with bone marrow toxicity. Universal prophylaxis may be costly. Because of the possibility of bone marrow toxicity and the expense, many clinicians traditionally preferred the preemptive approach over the universal prophylaxis approach for recipients of hematopoietic stem cell transplants. However, while this preemptive approach is effective, it does miss a small number of patients in whom CMV disease would have been prevented had prophylaxis been used. Other preventive strategies include use of CMV-negative or leukocyte-depleted blood products for CMV-seronegative recipients.

C. Other Organisms

Routine decontamination of the gastrointestinal tract to prevent bacteremia in the neutropenic patient is not recommended. The use of prophylactic antibiotics in the afebrile, asymptomatic neutropenic patient is debated, although many centers have adopted this strategy. Rates of bacteremia are decreased, but overall mortality is not affected and emergence of resistant organisms takes place. Use of intravenous immunoglobulin is reserved for the small number of patients with severe hypogammaglobulinemia following hematopoietic stem cell transplantation and should not be routinely administered to all transplant patients.

Prophylaxis with antifungal agents to prevent invasive mold (primarily Aspergillus) and yeast (primarily Candida) infections is routinely used, but the optimal agent, dose, and duration are also debated. Lipid-based preparations of amphotericin B, aerosolized amphotericin B, intravenous and oral fluconazole or voriconazole, and oral posaconazole solution and tablets are all prophylactic options in the neutropenic patient. Because voriconazole is superior to amphotericin for documented Aspergillus infections and because posaconazole prophylaxis (compared with fluconazole) has been shown to result in fewer cases of invasive aspergillosis among allogeneic stem cell transplant recipients with graft-versus-host disease, one approach to prophylaxis is to use oral fluconazole (400 mg/day) for patients at low risk for developing fungal infections (those who receive autologous stem cell transplants) and oral voriconazole (200 mg twice daily) or oral posaconazole (200 mg suspension three times daily or 300 mg [three 100-mg tablets] sustained-release tablets once daily) for those at high risk (allogeneic transplants, graft-versus-host disease) at least until engraftment (usually 30 days). In solid organ transplant recipients, the risk of invasive fungal infection varies considerably (1–2% in liver, pancreas, and kidney transplants and 6–8% in heart and lung transplants). Whether universal prophylaxis or observation with preemptive therapy is the best approach has not been determined. Although fluconazole is effective in preventing yeast infections, emergence of fluconazole-resistant Candida and molds (Fusarium, Aspergillus, Mucor) has raised concerns about its routine use as a prophylactic agent in the general solid organ transplant population. However, liver transplant recipients with additional risk factors, such as having undergone a choledochojejunostomy, having had a high transfusion requirement or having developed kidney disease, may benefit from abbreviated postoperative Candida prophylaxis.

Given the high risk of reactivation of tuberculosis in patients taking TNF inhibitors, all patients should be screened for latent tuberculosis infection (LTBI) with a tuberculin skin test or an interferon-gamma release assay prior to the start of therapy. If LTBI is diagnosed, treatment with the TNF inhibitors should be delayed until treatment for LTBI is completed. There is also a marked risk of reactivation of hepatitis B and hepatitis C in patients taking TNF inhibitors; patients should also be screened for these viruses when TNF inhibitor treatment is being considered. Providers should also ensure that patients' vaccinations are up-to-date before starting TNF inhibitors therapy.

Treatment

A. General Measures

Because infections in the immunocompromised patient can be rapidly progressive and life-threatening, diagnostic procedures must be performed promptly, and empiric therapy is usually instituted.

While reduction or discontinuation of immunosuppressive medication may jeopardize the viability of the transplanted organ, this measure may be necessary if the infection is life-threatening. Hematopoietic growth factors (granulocyte and granulocyte-macrophage colony-stimulating factors) stimulate proliferation of bone marrow stem cells, resulting in an increase in peripheral leukocytes. These agents shorten the period of neutropenia and have been associated with reduction in infection.

B. Specific Measures

Antimicrobial medication therapy ultimately should be tailored to culture results. While combinations of antimicrobials are used with the intent of providing synergy or preventing resistance, the primary reason for empiric combination therapy is broad-spectrum coverage of all likely pathogens.

Empiric therapy is often instituted at the earliest sign of infection in the immunosuppressed patient because prompt therapy favorably affects outcome. The antibiotic or combination of antibiotics used depends on the degree of immune compromise and the site of infection. For example, in the febrile neutropenic patient, an algorithmic approach to therapy is often used. Febrile neutropenic patients should be empirically treated with broad-spectrum agents active against selected gram-positive bacteria, Pseudomonas aeruginosa, and other aerobic gram-negative bacilli (such as cefepime 2 g every 8 hours intravenously). The addition of vancomycin, 10–15 mg/kg/dose intravenously every 12 hours, should be considered in those patients with suspected infection due to methicillin-resistant Staphylococcus aureus (MRSA), S epidermidis, enterococcus, and resistant viridans streptococci. Continued neutropenic fever necessitates broadening of antibacterial coverage from cefepime to agents such as imipenem 500 mg every 6 hours or meropenem 1 g every 8 hours intravenously with or without tobramycin 5–7 mg/kg intravenously every 24 hours. Antifungal agents (such as voriconazole, 200 mg intravenously or orally every 12 hours, or caspofungin, 50 mg daily intravenously) should be added if fevers continue after 5–7 days of broad-spectrum antibacterial therapy. Regardless of whether the patient becomes afebrile, therapy is continued until resolution of neutropenia. Failure to continue antibiotics through the period of neutropenia has been associated with increased morbidity and mortality.

Patients with fever and low-risk neutropenia (neutropenia expected to persist for less than 10 days, no comorbid complications requiring hospitalization, and cancer adequately treated) can be treated with oral antibiotic regimens, such as ciprofloxacin, 750 mg every 12 hours, plus amoxicillin-clavulanic acid, 500 mg every 8 hours. Antibiotics are continued as long as the patient is neutropenic even if a source is not identified. In the organ transplant patient with interstitial infiltrates, the main concern is infection with Pneumocystis or Legionella species, so that empiric treatment with a macrolide or fluoroquinolone (Legionella) and TMP-SMZ, 15 mg/kg/day orally or intravenously, based on trimethoprim component (Pneumocystis) would be reasonable in those patients not receiving TMP-SMZ prophylaxis. If the patient does not respond to empiric treatment, a decision must be made to add more antimicrobial agents or perform invasive procedures (see above) to make a specific diagnosis. By making a definite diagnosis, therapy can be specific, thereby reducing selection pressure for resistance and superinfection.

When to Refer

- Any immunocompromised patient with an opportunistic infection.
- Patients with potential drug toxicities and drug interactions related to antimicrobials where alternative agents are sought.
- Patients with latent tuberculosis, HBV, and HCV infection in whom therapy with TNF inhibitors is planned.

When to Admit

Immunocompromised patients who are febrile, or those without fevers in whom an infection is suspected, particularly in the following groups: solid-organ or hematopoietic stem cell transplant recipient (particularly in the first 6 months), neutropenic patients, patients receiving TNF inhibitors, and transplant recipients who have had recent rejection episodes (including graft-versus-host disease).

HEALTH CARE–ASSOCIATED INFECTIONS

ESSENTIALS OF DIAGNOSIS

- Health care–associated infections are acquired during the course of receiving health care treatment for other conditions.

- Hospital-associated infections are a subset of health care–associated infections defined as those not present or incubating at the time of hospital admission and developing 48 hours or more after admission.
- Most health care–associated infections are preventable.
- Hand washing is the most effective means of preventing health care–associated infections and should be done routinely even when gloves are worn.

General Considerations

Worldwide, approximately 10% of patients acquire a health care–associated infection, resulting in prolongation of the hospital stay, increase in cost of care, and significant morbidity and mortality. The most common infections are urinary tract infections, usually associated with Foley catheters or urologic procedures; bloodstream infections, most commonly from indwelling catheters but also from secondary sites, such as surgical wounds, abscesses, pneumonia, the genitourinary tract, and the gastrointestinal tract; pneumonia in intubated patients or those with altered levels of consciousness; surgical wound infections; MRSA infections; and Clostridioides difficile colitis.

Some general principles are helpful in preventing, diagnosing, and treating health care–associated infections:

1. Many infections are a direct result of the use of invasive devices for monitoring or therapy, such as intravenous catheters, Foley catheters, shunts, surgical drains, catheters placed by interventional radiology for drainage, nasogastric tubes, and orotracheal or nasotracheal tubes for ventilatory support. Early removal of such devices reduces the possibility of infection.
2. Patients in whom health care–associated infections develop are often critically ill, have been hospitalized for extended periods, and have received several courses of broad-spectrum antibiotic therapy. As a result, health care–associated infections are often due to multidrug resistant pathogens and differ from those encountered in community-acquired infections. For example, S aureus and S epidermidis (a frequent cause of prosthetic device infection) are often resistant to methicillin and most cephalosporins (ceftaroline is active against MRSA) and require vancomycin for therapy; Enterococcus faecium resistant to ampicillin and vancomycin; gram-negative infections caused by Pseudomonas, Citrobacter, Enterobacter, Acinetobacter, Stenotrophomonas, extended-spectrum beta-lactamases (ESBL)–producing E coli, and Klebsiella may be resistant to most antibacterials. When choosing antibiotics to treat the seriously ill patient with a health care–associated

infection, antimicrobial history and the “local ecology” must be considered. In the most seriously ill patients, broad-spectrum coverage with vancomycin and a carbapenem with or without an aminoglycoside is recommended. Once a pathogen is isolated and susceptibilities are known, the most narrow-spectrum, least toxic, most cost-effective regimen should be used.

Widespread use of antimicrobial medications contributes to the selection of drug-resistant organisms; thus, every effort should be made to limit the spectrum of coverage and unnecessary duration. All too often, unreliable or uninterpretable specimens are obtained for culture that result in unnecessary use of antibiotics. The best example of this principle is the diagnosis of line-related or bloodstream infection in the febrile patient. To avoid unnecessary use of antibiotics, thoughtful consideration of culture results is mandatory. A positive wound culture without signs of inflammation or infection, a positive sputum culture without pulmonary infiltrates on chest radiograph, or a positive urine culture in a catheterized patient without symptoms or signs of pyelonephritis are all likely to represent colonization, not infection.

Clinical Findings

A. Symptoms and Signs

Catheter-associated infections have a variable presentation, depending on the type of catheter used (peripheral or central venous catheters, nontunneled or tunneled). Local signs of infection may be present at the insertion site, with pain, erythema, and purulence. Fever is often absent in uncomplicated infections and if present, may indicate more disseminated disease such as bacteremia, cellulitis and septic thrombophlebitis. Often signs of infection at the insertion site are absent.

1. Fever in an intensive care unit patient—Fever complicates up to 70% of patients in intensive care units, and the etiology of the fever may be infectious or noninfectious. Common infectious causes include catheter-associated infections, hospital-acquired and ventilator-associated pneumonia (see Chapter 9), surgical site infections, urinary tract infections, and sepsis. Clinically relevant sinusitis is relatively uncommon in the patient in the intensive care unit.

An important noninfectious cause is thromboembolic disease. Fever in conjunction with refractory hypotension and shock may suggest sepsis; however, adrenal insufficiency, thyroid storm, and transfusion reaction may have a similar clinical presentation. Drug fever is difficult to diagnose and is usually a diagnosis of exclusion unless there are other signs of hypersensitivity, such as a typical maculopapular rash (most common with beta-lactams).

2. Fever in the postoperative patient—Postoperative fever is very common and noninfectious fever resolves spontaneously. Timing of the onset of the fever in relation to the surgical procedure may be of diagnostic benefit.

A. IMMEDIATE FEVER (IN THE FIRST FEW HOURS AFTER SURGERY)—Immediate fever can be due to medications that were given perioperatively, to surgical trauma, or to infections that were present before surgery. Necrotizing fasciitis due to group A streptococci or mixed organisms may present in this period. Malignant hyperthermia is rare and presents 30 minutes to several hours following inhalational anesthesia and is characterized by extreme hyperthermia, muscle rigidity, rhabdomyolysis, electrolyte abnormalities, and hypotension. Aggressive cooling and dantrolene are the mainstays of therapy. Aspiration of acidic gastric contents during surgery can result in a chemical pneumonitis (**Mendelson syndrome**) that develops rapidly, is transient, and does not require antibiotics. Fever due to surgical trauma usually resolves in 2–3 days; however, it may be longer in more complicated operative cases and in patients with head trauma.

B. ACUTE FEVER (WITHIN 1 WEEK OF SURGERY)—Acute fever is usually due to common causes of hospital-associated infections, such as ventilator-associated pneumonia (including aspiration pneumonia in patients with decreased gag reflex) and line infections. Noninfectious causes include alcohol withdrawal, gout, pulmonary embolism, and pancreatitis. Atelectasis following surgery is commonly invoked as a cause of postoperative fever but there is no good evidence to support a causal association between the presence or degree of atelectasis and fever.

C. SUBACUTE FEVER (AT LEAST 1 WEEK AFTER SURGERY)—Surgical site infections commonly present at least 1 week after surgery. The type of surgery that was performed predicts specific infectious etiologies. Patients undergoing cardiothoracic surgery may be at higher risk for pneumonia and deep and superficial sternal wound infections. Meningitis without typical signs of meningismus may complicate neurosurgical procedures. Postoperative deep abdominal abscesses may require drainage.

B. Laboratory Findings

Blood cultures are universally recommended, and chest radiographs are frequently obtained. A properly prepared sputum Gram stain and semi-quantitative sputum cultures may be useful in selected patients where there is a high pretest probability of pneumonia but multiple exclusion criteria probably limit generalizability in most patients, such as immunocompromised patients and those with drug resistance. Other diagnostic strategies will be dictated by the clinical context (eg, transesophageal echocardiogram in a patient with S aureus bacteremia).

Any fever in a patient with a central venous catheter should prompt the collection of blood. The best method to evaluate bacteremia is to gather at least two peripherally obtained blood cultures. Blood cultures from unidentified sites, a single blood culture from any site, or a blood culture through an existing line will often be positive for coagulase-positive staphylococci, particularly S epidermidis, often resulting in the inappropriate use of vancomycin. Unless two separate venipuncture cultures are obtained—not through catheters—interpretation of results is impossible, and unnecessary therapy often results. Each "pseudobacteremia" increases laboratory costs, antibiotic use, and length of stay. Microbiologic evaluation of the removed catheter can sometimes be helpful, but only in addition to (not instead of) blood cultures drawn from peripheral sites. The **differential time to positivity** measures the difference in time that cultures simultaneously drawn through a catheter and a peripheral site become positive. A positive test (at least 120 minutes' difference in time) supports a catheter-related bloodstream infection, while a negative test suggests catheters may be retained.

Complications

Complications such as septic thrombophlebitis, endocarditis, or metastatic foci of infection (particularly with S aureus) may be suspected in patients with persistent bacteremia and fever despite removal of the infected catheter. Additional studies such as venous Doppler studies, transesophageal echocardiogram, and chest radiographs may be indicated, and 4–6 weeks of antibiotics may be needed. In the case of septic thrombophlebitis, anticoagulation with heparin is also recommended if there are no contraindications.

Differential Diagnosis

Although most fevers are due to infections, about 25% of patients will have fever of noninfectious origin, including drug fever, nonspecific postoperative fevers (tissue damage or necrosis), hematoma, pancreatitis, pulmonary embolism, myocardial infarction, and ischemic bowel disease.

Prevention

The concept of universal precautions emphasizes that all patients are treated as though they have a potential blood-borne transmissible disease, and thus all body secretions are handled with care to prevent spread of disease. Body substance isolation requires use of gloves whenever a health care worker anticipates contact with blood or other body secretions. Even though gloves are worn, health care workers should routinely wash their hands, since it is the easiest and most effective means of preventing hospital-associated infections. Application of a rapid drying, alcohol-based antiseptic is simple, takes less time than traditional hand washing with soap and water, is more effective at reducing hand colonization, and promotes compliance with hand decontamination. For prevention of transmission of C difficile infection, hand washing is more effective than alcohol-based antiseptics. Consequently, even after removing gloves, providers should always wash hands in cases of proven or suspected C difficile infection.

Peripheral intravenous lines should be replaced no more frequently than every 3–4 days. Some clinicians replace only when clinically indicated or if the line was put in emergently. Arterial lines and lines in the central venous circulation (including those placed peripherally) can be left in place indefinitely and are changed or removed when they are clinically suspected of being infected, when they are nonfunctional, or when they are no longer needed. Using sterile barrier precautions (including cap, mask, gown, gloves, and drape) is recommended while inserting central venous catheters. Antibiotic-impregnated (minocycline plus rifampin or chlorhexidine plus silver sulfadiazine) venous catheters reduce line infections. Silver alloy–impregnated Foley catheters reduce the incidence of catheter-associated bacteriuria, but not consistently catheter-associated urinary tract infections. Best practices to prevent ventilator-associated pneumonia include avoiding intubation if possible, minimizing and daily interruption of sedation, pooling/draining of subglottic secretions above the tube cuff, and elevating the head of the bed. Silver-coated endotracheal tubes may reduce the incidence of ventilator-associated pneumonia but has limited impact on hospital stay duration or mortality, so they are not generally recommended. Catheter-related urinary tract infections and intravenous catheter-associated infections are not Medicare-reimbursable conditions in the United States. Preoperative skin preparation with chlorhexidine and alcohol (versus povidone-iodine) reduces the incidence of infection following surgery. Another strategy that can prevent surgical-site infections is the identification and treatment of S aureus nasal carriers with 2% mupirocin nasal ointment and chlorhexidine soap. Daily bathing of ICU patients with chlorhexidine-impregnated washcloths versus soap and water results in lower incidence of health care–associated infections and colonization. Selective decontamination of the digestive tract with nonabsorbable or parenteral antibiotics, or both, may prevent hospital-acquired pneumonia and decrease mortality but is in limited use because of the concern of the development of antibiotic resistance. Prevention bundles (implementing more than one intervention concomitantly) are commonly used as a practical strategy to enhance care in the healthcare setting.

Attentive nursing care (positioning to prevent pressure injuries, wound care, elevating the head during tube feedings to prevent aspiration) is critical in preventing hospital-associated infections. In addition, monitoring of high-risk areas by hospital epidemiologists is critical in the prevention of infection. Some guidelines advocate rapid screening (active surveillance cultures) for MRSA on admission to acute care facilities among certain subpopulations of patients (eg, those recently hospitalized, admission to the intensive care unit, patients undergoing hemodialysis). However, outside the setting of an MRSA outbreak, it is not clear whether this strategy decreases the incidence of hospital-associated MRSA infections.

Vaccines, including hepatitis A, hepatitis B, and the varicella, pneumococcal, and influenza vaccinations, are important adjuncts. (See section below titled Immunization Against Infectious Diseases.)

Treatment

A. Fever in an Intensive Care Unit Patient

Unless the patient has a central neurologic injury with elevated intracranial pressure or has a temperature higher than 41°C, there is less physiologic need to maintain euthermia. Empiric broad-spectrum antibiotics (see Table 30–5) are recommended for neutropenic and other immunocompromised patients and in patients who are clinically unstable.

B. Catheter-Associated Infections

Factors that inform treatment decisions include the type of catheter, the causative pathogen, the availability of alternate catheter access sites, the need for ongoing intravascular access, and the severity of disease.

In general, catheters should be removed if there is purulence at the exit site; if the organism is S aureus, gram-negative rods, or Candida species; if there is persistent bacteremia (more than 48 hours while receiving antibiotics); or if complications, such as septic thrombophlebitis, endocarditis, or other metastatic disease exist. Central venous catheters may be exchanged over a guidewire provided there is no erythema or purulence at the exit site and the patient does not appear to be septic. Methicillin-resistant, coagulase-negative staphylococci are the most common pathogens; thus, empiric therapy with vancomycin, 15 mg/kg/dose intravenously twice daily, should be given assuming normal kidney function. Empiric gram-negative coverage should be used in patients who are immunocompromised or who are critically ill (see Table 30–5).

Antibiotic treatment duration depends on the pathogen and the extent of disease. For uncomplicated bacteremia, 5–7 days of therapy is usually sufficient for coagulase-negative staphylococci, even if the original catheter is retained. Fourteen days of therapy is generally recommended for uncomplicated bacteremia caused by gram-negative rods, Candida species, and S aureus. **Antibiotic lock therapy** involves the instillation of supratherapeutic concentrations of antibiotics with heparin in the lumen of catheters. The purpose is to achieve adequate concentrations of antibiotics to kill microbes in the biofilm. Antibiotic lock therapy can be used for catheter-related bloodstream infections caused by both gram-positive and gram-negative bacterial pathogens and when the catheter is being retained in a salvage situation.

When to Refer

- Any patient with multidrug-resistant infection.
- Any patient with fungemia or persistent bacteremia.
- Patients with multisite infections.
- Patients with impaired or fluctuating kidney function for assistance with dosing of antimicrobials.
- Patients with refractory or recurrent C difficile colitis.

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

ESSENTIALS OF DIAGNOSIS

- Central nervous system infection is a medical emergency.
- Symptoms and signs common to all central nervous system infections include headache, fever, sensorial disturbances, neck and back stiffness, positive Kernig and Brudzinski signs, and cerebrospinal fluid abnormalities.

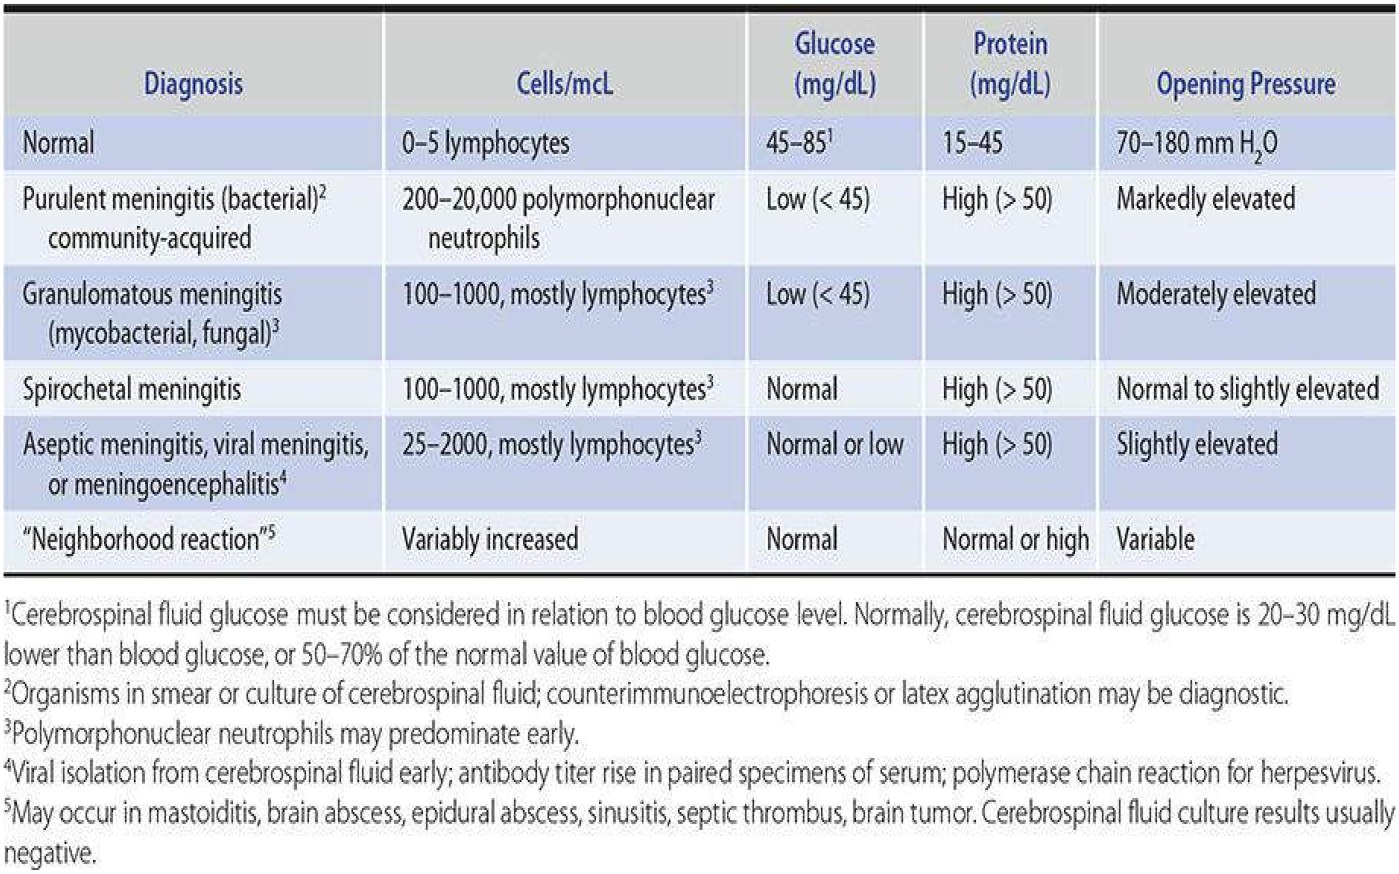
General Considerations

Infections of the central nervous system can be caused by almost any infectious agent, including bacteria, mycobacteria, fungi, spirochetes, protozoa, helminths, and viruses.

Etiologic Classification

Central nervous system infections can be divided into several categories that usually can be readily distinguished from each other by cerebrospinal fluid examination as the first step toward etiologic diagnosis (Table 30–1).

Table 30–1. Typical cerebrospinal fluid findings in various central nervous system diseases.



Diagnosis	Cells/mcL	Glucose (mg/dL)	Protein (mg/dL)	Opening Pressure
Normal	0–5 lymphocytes	45–85[1]	15–45	70–180 mm H_2O
Purulent meningitis (bacterial)[2] community-acquired	200–20,000 polymorphonuclear neutrophils	Low (< 45)	High (> 50)	Markedly elevated
Granulomatous meningitis (mycobacterial, fungal)[3]	100–1000, mostly lymphocytes[3]	Low (< 45)	High (> 50)	Moderately elevated
Spirochetal meningitis	100–1000, mostly lymphocytes[3]	Normal	High (> 50)	Normal to slightly elevated
Aseptic meningitis, viral meningitis, or meningoencephalitis[4]	25–2000, mostly lymphocytes[3]	Normal or low	High (> 50)	Slightly elevated
"Neighborhood reaction"[5]	Variably increased	Normal	Normal or high	Variable

[1] Cerebrospinal fluid glucose must be considered in relation to blood glucose level. Normally, cerebrospinal fluid glucose is 20–30 mg/dL lower than blood glucose, or 50–70% of the normal value of blood glucose.

[2] Organisms in smear or culture of cerebrospinal fluid; counterimmunoelectrophoresis or latex agglutination may be diagnostic.

[3] Polymorphonuclear neutrophils may predominate early.

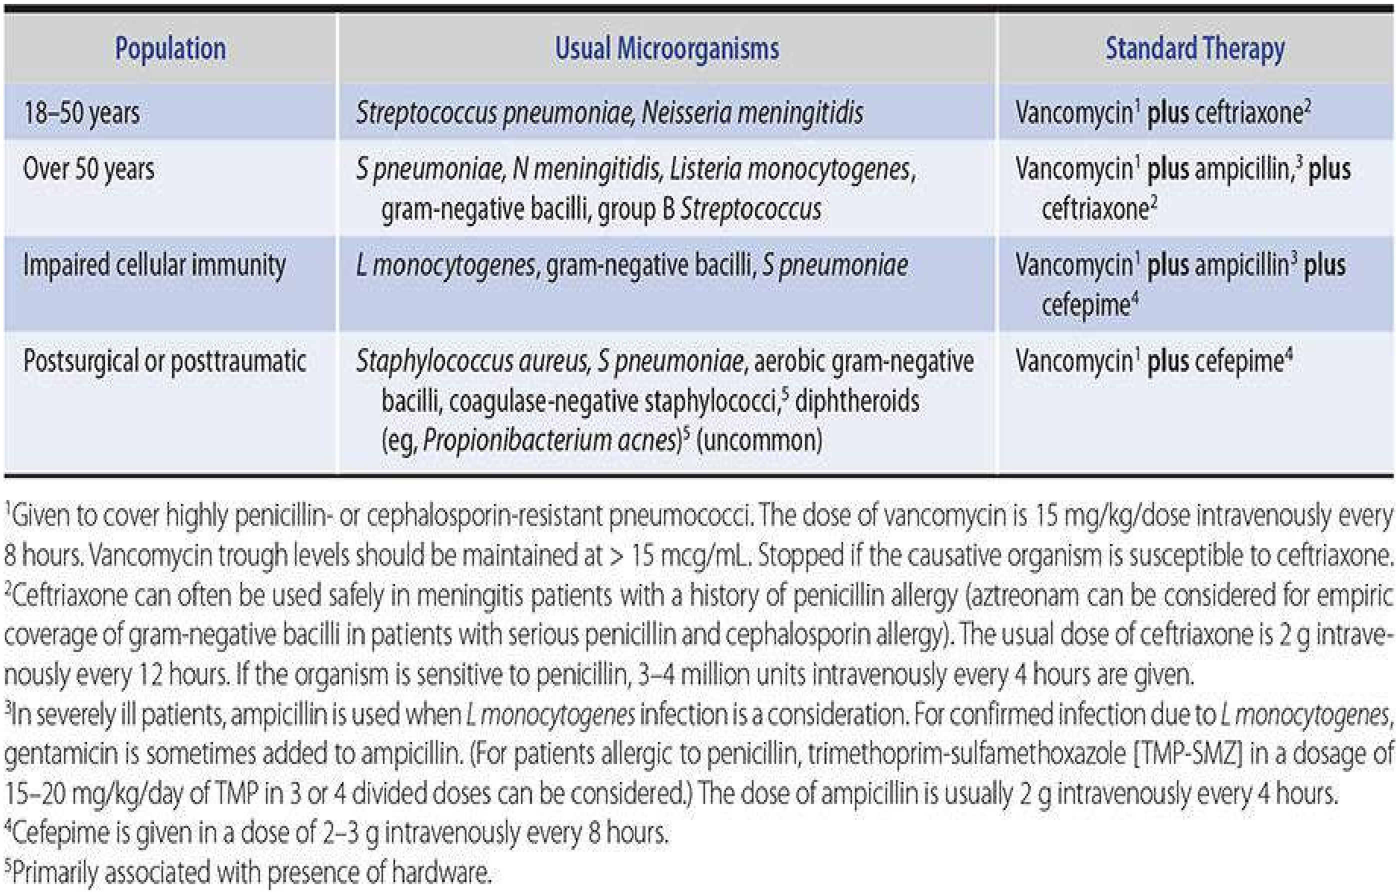
[4] Viral isolation from cerebrospinal fluid early; antibody titer rise in paired specimens of serum; polymerase chain reaction for herpesvirus.

[5] May occur in mastoiditis, brain abscess, epidural abscess, sinusitis, septic thrombus, brain tumor. Cerebrospinal fluid culture results usually negative.

A. Purulent Meningitis

Patients with bacterial meningitis usually seek medical attention within hours or 1–2 days after onset of symptoms. The organisms responsible depend primarily on the age of the patient as summarized in Table 30–2. The diagnosis is usually based on the Gram-stained smear (positive in 60–90%) or culture (positive in over 90%) of the cerebrospinal fluid.

Table 30–2. Initial antimicrobial therapy for purulent meningitis of unknown cause.



Population	Usual Microorganisms	Standard Therapy
18–50 years	*Streptococcus pneumoniae, Neisseria meningitidis*	Vancomycin[1] **plus** ceftriaxone[2]
Over 50 years	*S pneumoniae, N meningitidis, Listeria monocytogenes*, gram-negative bacilli, group B *Streptococcus*	Vancomycin[1] **plus** ampicillin,[3] **plus** ceftriaxone[2]
Impaired cellular immunity	*L monocytogenes*, gram-negative bacilli, *S pneumoniae*	Vancomycin[1] **plus** ampicillin[3] **plus** cefepime[4]
Postsurgical or posttraumatic	*Staphylococcus aureus, S pneumoniae*, aerobic gram-negative bacilli, coagulase-negative staphylococci,[5] diphtheroids (eg, *Propionibacterium acnes*)[5] (uncommon)	Vancomycin[1] **plus** cefepime[4]

[1] Given to cover highly penicillin- or cephalosporin-resistant pneumococci. The dose of vancomycin is 15 mg/kg/dose intravenously every 8 hours. Vancomycin trough levels should be maintained at > 15 mcg/mL. Stopped if the causative organism is susceptible to ceftriaxone.

[2] Ceftriaxone can often be used safely in meningitis patients with a history of penicillin allergy (aztreonam can be considered for empiric coverage of gram-negative bacilli in patients with serious penicillin and cephalosporin allergy). The usual dose of ceftriaxone is 2 g intravenously every 12 hours. If the organism is sensitive to penicillin, 3–4 million units intravenously every 4 hours are given.

[3] In severely ill patients, ampicillin is used when *L monocytogenes* infection is a consideration. For confirmed infection due to *L monocytogenes*, gentamicin is sometimes added to ampicillin. (For patients allergic to penicillin, trimethoprim-sulfamethoxazole [TMP-SMZ] in a dosage of 15–20 mg/kg/day of TMP in 3 or 4 divided doses can be considered.) The dose of ampicillin is usually 2 g intravenously every 4 hours.

[4] Cefepime is given in a dose of 2–3 g intravenously every 8 hours.

[5] Primarily associated with presence of hardware.

B. Chronic Meningitis

The presentation of chronic meningitis is less acute than purulent meningitis. Patients with chronic meningitis usually have a history of symptoms lasting weeks to months. The most common pathogens are Mycobacterium tuberculosis, atypical mycobacteria, fungi (Cryptococcus, Coccidioides, Histoplasma), and spirochetes (Treponema pallidum and Borrelia burgdorferi). The diagnosis is made by culture or in some cases by serologic tests (cryptococcosis, coccidioidomycosis, syphilis, Lyme disease).

C. Aseptic Meningitis

Aseptic meningitis—a much more benign and self-limited syndrome than purulent meningitis—is caused principally by viruses, especially herpes simplex virus and the enterovirus group (including coxsackieviruses and echoviruses). Infectious mononucleosis may be accompanied by aseptic meningitis. Leptospiral infection is also usually placed in the aseptic group because of the lymphocytic cellular response and its relatively benign course. This type of meningitis also occurs during secondary syphilis and disseminated Lyme disease. Prior to the routine administration of measles-mumps-rubella (MMR) vaccines, mumps was the most common cause of viral meningitis. Drug-induced aseptic meningitis has been reported with nonsteroidal anti-inflammatory drugs, sulfonamides, and certain monoclonal antibodies.

D. Encephalitis

Encephalitis (due to herpesviruses, arboviruses, rabies virus, flaviviruses [West Nile encephalitis, Japanese encephalitis], and many others) produces disturbances of the sensorium, seizures, and many other manifestations. Patients are more ill than those with aseptic meningitis. Cerebrospinal fluid may be entirely normal or may show some lymphocytes and, in some instances, (eg, herpes simplex) red cells as well. Influenza has been associated with encephalitis, but the relationship is not clear. An autoimmune form of encephalitis associated with N-methyl-D-aspartate receptor antibodies should be suspected in younger patients with encephalitis and associated seizures, movement disorders, and psychosis.

E. Partially Treated Bacterial Meningitis

Previous effective antibiotic therapy given for 12–24 hours will decrease the rate of positive cerebrospinal fluid Gram stain results by 20% and culture by 30–40% but will have little effect on cell count, protein, or glucose. Occasionally, previous antibiotic therapy will change a predominantly polymorphonuclear response to a lymphocytic pleocytosis, and some of the cerebrospinal fluid findings may be similar to those seen in aseptic meningitis.

F. Neighborhood Reaction

As noted in Table 30–1, this term denotes a purulent infectious process in close proximity to the central nervous system that spills some of the products of the inflammatory process—white blood cells or protein—into the cerebrospinal fluid. Such an infection might be a brain abscess, osteomyelitis of the vertebrae, epidural abscess, subdural empyema, or bacterial sinusitis or mastoiditis.

G. Noninfectious Meningeal Irritation

Carcinomatous meningitis, sarcoidosis, systemic lupus erythematosus, chemical meningitis, and certain medications—nonsteroidal anti-inflammatory drugs, OKT3, TMP-SMZ, and others—can also produce symptoms and signs of meningeal irritation with associated cerebrospinal fluid pleocytosis, increased protein, and low or normal glucose. Meningismus with normal cerebrospinal fluid findings occurs in the presence of other infections such as pneumonia and shigellosis.

H. Brain Abscess

Brain abscess presents as a space-occupying lesion; symptoms may include vomiting, fever, change of mental status, or focal neurologic manifestations. When brain abscess is suspected, a CT scan should be performed. If positive, lumbar puncture should not be performed since results rarely provide clinically useful information and herniation can occur. The bacteriology of brain abscess is usually polymicrobial and includes S aureus, gram-negative bacilli, streptococci, and mouth anaerobes (including anaerobic streptococci and Prevotella species).

I. Health Care–Associated Meningitis

This infection may arise as a result of invasive neurosurgical procedures (eg, craniotomy, internal or external ventricular catheters, external lumbar catheters), complicated head trauma, or hospital-acquired bloodstream infections. Outbreaks have been associated with contaminated epidural or paraspinal corticosteroid injections. In general, the microbiology is distinct from community-acquired meningitis, with gram-negative organisms (eg, Pseudomonas), S aureus, and coagulase-negative staphylococci and, in the outbreaks associated with contaminated corticosteroids, mold and fungi (Exserohilum rostratum and Aspergillus fumigatus) playing a larger role.

Clinical Findings

A. Symptoms and Signs

The classic triad of fever, stiff neck, and altered mental status has a low sensitivity (44%) for bacterial meningitis. However, nearly all patients with bacterial meningitis have at least two of the following symptoms—fever, headache, stiff neck, or altered mental status.

B. Laboratory Tests

Evaluation of a patient with suspected meningitis includes a blood count, blood culture, lumbar puncture followed by careful study and culture of the cerebrospinal fluid, and a chest film. The fluid must be examined for cell count, glucose, and protein, and a smear stained for bacteria (and acid-fast organisms when appropriate) and cultured for pyogenic organisms and for mycobacteria and fungi when indicated. Latex agglutination tests can detect antigens of encapsulated organisms (S pneumoniae, H influenzae, N meningitidis, and Cryptococcus neoformans) but are rarely used except for detection of Cryptococcus or in partially treated patients. Polymerase chain reaction (PCR) testing of cerebrospinal fluid has been used to detect bacteria (S pneumoniae, H influenzae, N meningitidis, M tuberculosis, B burgdorferi, and Tropheryma whipplei) and viruses (herpes simplex, varicella-zoster, CMV, Epstein-Barr virus, and enteroviruses) in patients with meningitis. The greatest experience is with PCR for herpes simplex, varicella-zoster, and JC virus. These tests are very sensitive (greater than 95%) and specific. In addition to its use in meningitis, molecular methods such as PCR and next-generation sequencing are being used increasingly for the diagnosis of encephalitis, transverse myelitis, and brain abscess. In general, molecular diagnostic tests may provide a more sensitive and rapid alternative to traditional culture and serology methods. However, it is difficult to ascertain the true sensitivity of many molecular tests for CNS infections given the absence of a gold standard. In some cases, tests to detect several organisms may not be any more sensitive than culture (or serology), but the real value is the rapidity with which results are available, ie, hours compared with days or weeks.

C. Lumbar Puncture and Imaging

Since performing a lumbar puncture in the presence of a space-occupying lesion (brain abscess, subdural hematoma, subdural empyema, necrotic temporal lobe from herpes encephalitis) may result in brainstem herniation, a CT scan is performed prior to lumbar puncture if a space-occupying lesion is suspected on the basis of papilledema, seizures, or focal neurologic findings. Other indications for CT scan are an immunocompromised patient or moderately to severely impaired level of consciousness. If delays are encountered in obtaining a CT scan and bacterial meningitis is suspected, blood cultures should be drawn and antibiotics and corticosteroids administered even before cerebrospinal fluid is obtained for culture to avoid delay in treatment (Table 30–1). Antibiotics given within 4 hours before obtaining cerebrospinal fluid probably do not affect culture results. MRI with contrast of the epidural injection site and surrounding areas is recommended (sometimes repeatedly) for those with symptoms following a possibly contaminated corticosteroid injection to exclude epidural abscess, phlegmon, vertebral osteomyelitis, discitis, or arachnoiditis.

Treatment

Although it is difficult to prove with existing clinical data that early antibiotic therapy improves outcome in bacterial meningitis, prompt therapy is still recommended. In purulent meningitis, the identity of the causative microorganism may remain unknown or doubtful for a few days and initial antibiotic treatment as set forth in Table 30–2 should be directed against the microorganisms most common for each age group.

The duration of therapy for bacterial meningitis varies depending on the etiologic agent: H influenzae, 7 days; N meningitidis, 3–7 days; S pneumoniae, 10–14 days; L monocytogenes, 14–21 days; and gram-negative bacilli, 21 days.

For adults with pneumococcal meningitis, dexamethasone 10 mg administered intravenously 15–20 minutes before or simultaneously with the first dose of antibiotics and continued every 6 hours for 4 days decreases morbidity and mortality. Patients most likely to benefit from corticosteroids are those infected with gram-positive organisms (Streptococcus pneumoniae or S suis), and those who are HIV negative. It is unknown whether patients with meningitis due to N meningitidis and other bacterial pathogens benefit from the use of adjunctive corticosteroids. Increased intracranial pressure due to brain edema often requires therapeutic attention. Hyperventilation, mannitol (25–50 g intravenously as a bolus), and even drainage of cerebrospinal fluid by repeated lumbar punctures or by placement of intraventricular catheters have been used to control cerebral edema and increased intracranial pressure. Dexamethasone (4 mg intravenously every 4–6 hours) may also decrease cerebral edema.

Therapy of brain abscess consists of drainage (excision or aspiration) in addition to 3–4 weeks of systemic antibiotics directed against organisms isolated. An empiric regimen often includes metronidazole, 500 mg intravenously or orally every 8 hours, plus ceftriaxone, 2 g intravenously every 12 hours, with or without vancomycin, 10–15 mg/kg/dose intravenously every 12 hours. Vancomycin trough serum levels should be greater than 15 mcg/mL in such patients. In cases where abscesses are smaller than 2 cm, where there are multiple abscesses that cannot be drained, or if an abscess is located in an area where significant neurologic sequelae would result from drainage, antibiotics for 6–8 weeks can be used without drainage.

In addition to antibiotics, in cases of health care–associated meningitis associated with an external intraventricular catheter, the probability of cure is increased if the catheter is removed. In infections associated with internal ventricular catheters, removal of the internal components and insertion of an external drain is recommended. After collecting cerebrospinal fluid, epidural aspirate, or other specimens for culture, empiric antifungal therapy with voriconazole as well as routine empiric treatment for other pathogens (as above) is recommended until the specific cause of the patient’s central nervous system or parameningeal infection has been identified. In addition, early consultation with a neurosurgeon is recommended for those found to have an epidural abscess, phlegmon, vertebral osteomyelitis, discitis, or arachnoiditis to discuss possible surgical management (eg, debridement).

Therapy of other types of meningitis is discussed elsewhere in this book (fungal meningitis, Chapter 36; syphilis and Lyme borreliosis, Chapter 34; tuberculous meningitis, Chapter 33; herpes encephalitis, Chapter 32).

When to Refer

- Patients with acute meningitis, particularly if culture negative or atypical (eg, fungi, syphilis, Lyme disease, M tuberculosis), or if the patient is immunosuppressed.
- Patients with chronic meningitis.

- All patients with brain abscesses and encephalitis.
- Patients with suspected hospital-acquired meningitis (eg, in patients who have undergone recent neurosurgery or epidural or paraspinal corticosteroid injection).
- Patients with recurrent meningitis.

When to Admit

- Patients with suspected acute meningitis, encephalitis, and brain or paraspinous abscess should be admitted for urgent evaluation and treatment.
- There is less urgency to admit patients with chronic meningitis; these patients may be admitted to expedite diagnostic procedures and coordinate care, particularly if no diagnosis has been made in the outpatient setting.

ANIMAL & HUMAN BITE WOUNDS

ESSENTIALS OF DIAGNOSIS

- Cat and human bites have higher rates of infection than dog bites.
- Hand bites are particularly concerning for the possibility of closed-space infection.
- Antibiotic prophylaxis indicated for noninfected bites of the hand and hospitalization required for infected hand bites.
- All infected wounds need to be cultured to direct therapy.

General Considerations

About 1000 dog bite injuries require emergency department attention each day in the United States, most often in urban areas. Dog bites occur most commonly in the summer months. Biting animals are usually known by their victims, and most biting incidents are provoked (ie, bites occur while playing with the animal or after surprising the animal while eating or waking it abruptly from sleep). Failure to elicit a history of provocation is important, because an unprovoked attack raises the possibility of rabies. Human bites are usually inflicted by children while playing or fighting; in adults, bites are associated with alcohol use and closed-fist injuries that occur during fights.

The animal inflicting the bite, the location of the bite, and the type of injury inflicted are all important determinants of whether they become infected. Cat bites are more likely to become infected than human bites—between 30% and 50% of all cat bites become infected. Infections following human bites are variable. Bites inflicted by children rarely become infected because they are superficial, and bites by adults become infected in 15–30% of cases, with a particularly high rate of infection in closed-fist injuries. Dog bites, for unclear reasons, become infected only 5% of the time. Bites of the head, face, and neck are less likely to become infected than bites on the extremities. “Through and through” bites (eg, involving the mucosa and the skin) have an infection rate similar to closed-fist injuries. Puncture wounds become infected more frequently than lacerations, probably because the latter are easier to irrigate and debride.

The bacteriology of bite infections is polymicrobial. Following dog and cat bites, over 50% of infections are caused by aerobes and anaerobes and 36% are due to aerobes alone. Pure anaerobic infections are rare. Pasteurella species are the single most common isolate (75% of infections caused by cat bites and 50% of infections caused by dog bites). Other common aerobic isolates include streptococci, staphylococci, Moraxella, and Neisseria; the most common anaerobes are Fusobacterium, Bacteroides, Porphyromonas, and Prevotella. The median number of isolates following human bites is four (three aerobes and one anaerobe). Like dog and cat bites, infections caused by most human bites are a mixture of aerobes and anaerobes (54%) or are due to aerobes alone (44%). Streptococci and S aureus are the most common aerobes. Eikenella corrodens (found in up to 30% of patients), Prevotella, and Fusobacterium are the most common anaerobes. Although the organisms noted are the most common, innumerable others have been isolated—including Capnocytophaga (dog and cat), Pseudomonas, and Haemophilus—emphasizing the point that all infected bites should be cultured to define the microbiology.

HIV can be transmitted from bites (either from biting or receiving a bite from an HIV-infected patient) but has rarely been reported.

Treatment

A. Local Care

Vigorous cleansing and irrigation of the wound as well as debridement of necrotic material are the most important factors in decreasing the incidence of infections. Radiographs should be obtained to look for fractures and the presence of foreign bodies. Careful examination to assess the extent of the injury (tendon laceration, joint space penetration) is critical to appropriate care.

B. Suturing

If wounds require closure for cosmetic or mechanical reasons, suturing can be done. However, one should never suture an infected wound, and wounds of the hand should generally not be sutured since a closed-space infection of the hand can result in loss of function.

C. Prophylactic Antibiotics

Prophylaxis is indicated in high-risk bites and in high-risk patients. Cat bites in any location and hand bites by any animal, including humans, should receive prophylaxis. Individuals with certain comorbidities (diabetes, liver disease) are at increased risk for severe complications and should receive prophylaxis even for low-risk bites, as should patients without functional spleens who are at increased risk for overwhelming sepsis (primarily with Capnocytophaga species). Amoxicillin-clavulanate (Augmentin) 500 mg orally three times daily for 5–7 days is the regimen of choice. For patients with serious allergy to penicillin, a combination of clindamycin 300 mg orally three times daily together with one of the following is recommended for 5–7 days: doxycycline 100 mg orally twice daily, or double-strength TMP-SMZ orally twice daily, or a fluoroquinolone (ciprofloxacin 500 mg orally twice daily or levofloxacin 500–750 mg orally once daily). Moxifloxacin, a fluoroquinolone with good aerobic and anaerobic activity, may be suitable as monotherapy at 400 mg orally once daily for 5–7 days. Agents such as dicloxacillin, cephalexin, macrolides, and clindamycin should not be used alone because they lack activity against Pasteurella species. TMP-SMZ has poor activity against anaerobes and should only be used in combination with clindamycin.

Because the risk of HIV transmission is so low following a bite, routine postexposure prophylaxis is not recommended. Each case should be evaluated individually and consideration for prophylaxis should be given to those who present within 72 hours of the incident, the source is known to be HIV infected, and the exposure is high risk.

D. Antibiotics for Documented Infection

For wounds that are infected, antibiotics are clearly indicated. How they are given (orally or intravenously) and the need for hospitalization are individualized clinical decisions. The most commonly encountered pathogens require treatment with ampicillin-sulbactam (Unasyn), 1.5–3.0 g intravenously every 6–8 hours; or amoxicillin-clavulanate (Augmentin), 500 mg orally three times daily; or with ertapenem, 1 g intravenously daily. For the patient with severe penicillin allergy, a combination of clindamycin 600–900 mg intravenously every 8 hours plus a fluoroquinolone (ciprofloxacin, 400 mg intravenously every 12 hours; levofloxacin, 500–750 mg intravenously once daily) or TMP-SMZ (10 mg/kg of trimethoprim daily in two or three divided doses) is indicated. Duration of therapy is usually 2–3 weeks unless complications such as septic arthritis or osteomyelitis is present; if these complications are present, therapy should be extended to 4 and 6 weeks, respectively.

E. Tetanus and Rabies

All patients must be evaluated for the need for tetanus (see Chapter 33) and rabies (see Chapter 32) prophylaxis.

When to Refer

- If septic arthritis or osteomyelitis is suspected.
- For exposure to bites by dogs, cats, reptiles, amphibians, and rodents.
- When rabies is a possibility.

When to Admit

- Patients with infected hand bites.
- Deep bites, particularly if over joints.

SEXUALLY TRANSMITTED DISEASES

ESSENTIALS OF DIAGNOSIS

- All sexually transmitted diseases (STDs) have subclinical or latent periods, and patients may be asymptomatic.
- Simultaneous infection with several organisms is common.
- All patients who seek STD testing should be screened for syphilis and HIV.
- Partner notification and treatment are important to prevent further transmission and reinfection of the index case.

General Considerations

The most common STDs are gonorrhea,[*] syphilis,[*] human papillomavirus (HPV)–associated condyloma acuminatum, chlamydial genital infections,[*] herpesvirus genital infections, trichomonas vaginitis, chancroid,[*] granuloma inguinale, scabies, louse infestation, and bacterial vaginosis (among women who have sex with women). However, shigellosis[*]; hepatitis A, B, and C[*]; amebiasis; giardiasis[*]; cryptosporidiosis[*]; salmonellosis[*]; and campylobacteriosis may also be transmitted by sexual (oral-anal) contact, especially in men who have sex with men. Ebola virus and Zika virus have both been associated with sexual transmission. Both homosexual and heterosexual contact are risk factors for the transmission of HIV (see Chapter 31). All STDs have subclinical or latent phases that play an important role in long-term persistence of the infection or in its transmission from infected (but largely asymptomatic) persons to other contacts. Simultaneous infection by several different agents is common.

Infections typically present in one of several ways, each of which has a defined differential diagnosis, which should prompt appropriate diagnostic tests.

A. Genital Ulcers

Common etiologies include herpes simplex virus, primary syphilis, and chancroid. Other possibilities include lymphogranuloma venereum (see Chapter 33), granuloma inguinale caused by Klebsiella granulomatis (see Chapter 33), as well as lesions caused by infection with Epstein-Barr virus and HIV. Noninfectious causes are Behçet disease (see Chapter 20), neoplasm, trauma, drugs, and irritants.

B. Urethritis With or Without Urethral Discharge

The most common infections causing urethral discharge are Neisseria gonorrhoeae and Chlamydia trachomatis. N gonorrhoeae and C trachomatis are also frequent causes of prostatitis among sexually active men. Other sexually transmitted infections that can cause urethritis include Mycoplasma genitalium and, less commonly, Ureaplasma urealyticum and Trichomonas vaginalis. Noninfectious causes of urethritis include reactive arthritis with associated urethritis.

C. Vaginal Discharge

Common causes of vaginitis are bacterial vaginosis (caused by overgrowth of anaerobes such as Gardnerella vaginalis), candidiasis, and T vaginalis (see Chapter 18). Less common infectious causes of vaginitis include HPV-associated condylomata acuminata and group A streptococcus. Noninfectious causes are physiologic changes related to the menstrual cycle, irritants, and lichen planus. Even though N gonorrhoeae and C trachomatis are frequent causes of cervicitis, they rarely produce vaginal discharge.

Screening & Prevention

All persons who seek STD testing should undergo routine screening for HIV infection, using rapid HIV testing (if patients may not follow up for results obtained by standard methods) or nucleic acid amplification followed by confirmatory serology (if primary HIV infection may be a possibility) as indicated. Patients in whom certain STDs have been diagnosed and treated (chlamydia or gonorrhea, and trichomonas in women) are at a high risk for reinfection and should be encouraged to be rescreened for STDs at 3 months following the initial STD diagnosis.

Asymptomatic patients often request STD screening at the time of initiating a new sexual relationship. Routine HIV testing and hepatitis B serology testing should be offered to all such patients. In sexually active women who have not been recently screened, cervical Papanicolaou testing and nucleic acid amplification testing of a urine specimen for gonorrhea and chlamydia are recommended. Among men who have sex with men, additional screening is recommended for syphilis; hepatitis A; urethral, pharyngeal, and rectal gonorrhea; as well as urethral and rectal chlamydia. Nucleic acid amplification testing is recommended for gonorrhea or chlamydia. There are no recommendations to screen heterosexual men for urethral chlamydia, but this could be considered in STD clinics, adolescent clinics, or correctional facilities. The periodicity of screening thereafter depends on sexual risk, but most screening should be offered at least annually to sexually active adults (particularly to those 25 years old and under). Clinicians should also evaluate transgender men and women for STD screening, based on current anatomy and behaviors practiced. If not immune, hepatitis B vaccination is recommended for all sexually active adults, and hepatitis A vaccination in men who have sex with men. Persons between the ages of 9 and 26 should be routinely offered vaccination against HPV (9-valent).

The risk of developing an STD following a sexual assault is difficult to accurately ascertain given high rates of baseline infections and poor follow-up. Victims of assault have a high baseline rate of infection (N gonorrhoeae, 6%; C trachomatis, 10%; T vaginalis, 15%; and bacterial vaginosis, 34%), and the risk of acquiring infection as a result of the assault is significant, but is often lower than the preexisting rate (N gonorrhoeae, 6–12%; C trachomatis, 4–17%; T vaginalis, 12%; syphilis, 0.5–3%; and bacterial vaginosis, 19%). Victims should be evaluated within 24 hours after the assault, and nucleic acid amplification tests for N gonorrhoeae and C trachomatis should be performed. Vaginal secretions are obtained for Trichomonas wet mount and culture, or point-of-care testing. If a discharge is present, if there is itching, or if secretions are malodorous, a wet mount should be examined for Candida and bacterial vaginosis. In addition, a blood sample should be obtained for immediate serologic testing for syphilis, hepatitis B, and HIV. Follow-up examination for STDs should be repeated within 1–2 weeks, since concentrations of infecting organisms may not have been sufficient to produce a positive test at the time of initial examination. If prophylactic treatment was given (may include postexposure hepatitis B vaccination without hepatitis B immune globulin; treatment for chlamydial, gonorrheal, or trichomonal infection; and emergency contraception), tests should be repeated only if the victim has symptoms. If prophylaxis was not administered, the individual should be seen in 1 week so that any positive tests can be treated. Follow-up serologic testing for syphilis and HIV infection should be performed in 6, 12, and 24 weeks if the initial tests are negative. The usefulness of presumptive therapy is controversial, with some feeling that all patients should receive it and others that it should be limited to those in whom follow-up cannot be ensured or to patients who request it.

Although seroconversion to HIV has been reported following sexual assault when this was the only known risk, this risk is believed to be low. The likelihood of HIV transmission from vaginal or anal receptive intercourse when the source is known to be HIV positive is 1 per 1000 and 5 per 1000, respectively. Although prophylactic antiretroviral therapy has not been studied in this setting, the Department of Health and Human Services recommends the prompt institution of postexposure prophylaxis with antiretroviral therapy if the person seeks care within 72 hours of the assault, the source is known to be HIV positive, and the exposure presents a substantial risk of transmission.

In addition to screening asymptomatic patients with STDs, other strategies for preventing further transmission include evaluating sex partners and administering preexposure vaccination of preventable STDs to individuals at risk; other strategies include the consistent use of male and female condoms and male circumcision. Adult male circumcision has been shown to decrease the transmission of HIV by 50%, and of herpes simplex virus and HPV by 30% in heterosexual couples in sub-Saharan Africa. For each patient, there are one or more sexual contacts who require diagnosis and treatment. Prompt treatment of contacts by giving antibiotics to the index case to distribute to all sexual contacts (**patient-delivered therapy**) is an important strategy for preventing further transmission and to prevent reinfection of the index case.

Note that vaginal spermicides and condoms containing nonoxynol-9 provide no additional protection against STDs. Early initiation of antiretroviral therapy in HIV-infected individuals can prevent HIV acquisition in an uninfected sex partner. Also, preexposure prophylaxis with a once-daily pill containing emtricitabine plus tenofovir disoproxil fumarate (TDF) has been shown to be effective in preventing HIV infection among high-risk men who have sex with men, heterosexual women and men, transgender women, and persons who inject drugs.

When to Refer

- Patients with a new diagnosis of HIV.
- Patients with persistent, refractory, or recurrent STDs, particularly when drug resistance is suspected.

INFECTIONS IN PERSONS WHO INJECT DRUGS

ESSENTIALS OF DIAGNOSIS

- Common infections that occur with greater frequency in persons who inject drugs include:
  - Skin infections, aspiration pneumonia, tuberculosis.
  - Hepatitis A, B, C, D; STDs; HIV/AIDS.
  - Pulmonary septic emboli, infective endocarditis.
  - Osteomyelitis and septic arthritis.

General Considerations

There is a high incidence of infection among drug users, particularly among people who inject drugs. Increased risk of infection is likely associated with poor hygiene and colonization with potentially pathogenic organisms, contamination of drugs and equipment, increased sexual risk behaviors, and impaired immune defenses. The use of parenterally administered recreational drugs has increased enormously in recent years, fueled in part by an epidemic of prescription opioid misuse and abuse. More than 2 million persons in North America are estimated to have used injection drugs in the past year.

Skin infections are associated with poor hygiene and use of nonsterile technique when injecting drugs. S aureus (including community-acquired methicillin-resistant strains) and oral flora (streptococci, Eikenella, Fusobacterium, Peptostreptococcus) are the most common organisms, with enteric gram-negatives generally more likely seen in those who inject into the groin. Cellulitis and subcutaneous abscesses occur most commonly, particularly in association with subcutaneous (“skin-popping”) or intramuscular injections and the use of cocaine and heroin mixtures (probably due to ischemia). Myositis, clostridial myonecrosis, and necrotizing fasciitis occur infrequently but are life-threatening. Wound botulism in association with black tar heroin occurs sporadically but often in clusters.

Aspiration pneumonia and its complications (lung abscess, empyema, brain abscess) result from altered consciousness associated with drug use. Mixed aerobic and anaerobic mouth flora are usually involved.

Tuberculosis also occurs in persons who use drugs, and infection with HIV has fostered the spread of tuberculosis in this population. Morbidity and mortality rates are increased in HIV-infected individuals with tuberculosis. Classic radiographic findings are often absent; tuberculosis is suspected in any patient with infiltrates who does not respond to antibiotics.

Hepatitis is very common among persons who inject drugs and is transmissible both by the parenteral (hepatitis B, C, and D) and by the fecal-oral route (hepatitis A). Multiple episodes of hepatitis with different agents can occur.

Pulmonary septic emboli may originate from venous thrombi or right-sided endocarditis.

STDs are not directly related to drug use, but the practice of exchanging sex for drugs has resulted in an increased frequency of STDs. Syphilis, gonorrhea, and chancroid are the most common.

HIV/AIDS has a high incidence among persons who inject drugs and their sexual contacts and among the offspring of infected women (see Chapter 31).

Infective endocarditis in persons who inject drugs is most commonly caused by S aureus, Candida (usually C albicans or C parapsilosis), Enterococcus faecalis, other streptococci, and gram-negative bacteria (especially Pseudomonas and Serratia marcescens). See Chapter 33.

Other vascular infections include septic thrombophlebitis and mycotic aneurysms. Mycotic aneurysms resulting from direct trauma to a vessel with secondary infection most commonly occur in femoral arteries and less commonly in arteries of the neck. Aneurysms resulting from hematogenous spread of organisms frequently involve intracerebral vessels and thus are seen in association with endocarditis.

Osteomyelitis and **septic arthritis** involving vertebral bodies, sternoclavicular joints, the pubic symphysis, the sacroiliac joints, and other sites usually results from hematogenous distribution of injected organisms or septic venous thrombi. Pain and fever precede radiographic changes, sometimes by several weeks. While S aureus—often methicillin-resistant—is most common, Serratia, Pseudomonas, Candida (often not C albicans), and other pathogens rarely encountered in spontaneous bone or joint disease are found in persons who inject drugs.

Treatment

A common and difficult clinical problem is management of a person known to inject drugs who presents with fever. In general, after obtaining appropriate cultures (blood, urine, and sputum if the chest radiograph is abnormal), empiric therapy is begun. If the chest radiograph is suggestive of a community-acquired pneumonia (consolidation), therapy for outpatient pneumonia is begun with ceftriaxone, 1 g intravenously every 24 hours, plus either azithromycin (500 mg orally or intravenously every 24 hours) or doxycycline (100 mg orally or intravenously twice daily). If the chest radiograph is suggestive of septic emboli (nodular infiltrates), therapy for presumed endocarditis is initiated, usually with vancomycin 15 mg/kg/dose every 12 hours intravenously (due to the high prevalence of MRSA and the possibility of enterococcus). If the chest radiograph is normal and no focal site of infection can be found, endocarditis is presumed. While awaiting the results of blood cultures, empiric treatment with vancomycin is started. If blood cultures are positive for organisms that frequently cause endocarditis in drug users (see above), endocarditis is presumed to be present and treated accordingly. If blood cultures are positive for an organism that is an unusual cause of endocarditis, evaluation for an occult source of infection should go forward. In this setting, a transesophageal echocardiogram may be quite helpful since it is 90% sensitive in detecting vegetations and a negative study is strong evidence against endocarditis. If blood cultures are negative and the patient responds to antibiotics, therapy should be continued for 7–14 days (oral therapy can be given once an initial response has occurred). In every patient, careful examination for an occult source of infection (eg, genitourinary, dental, sinus, gallbladder) should be done. Given the intersecting epidemics of opioid use disorder and the infectious complications that arise, clinicians must also be prepared to integrate treatment of opioid use disorder whenever possible.

When to Refer

- Any patient with suspected or proven infective endocarditis.
- Patients with persistent bacteremia.

When to Admit

- Persons who inject drugs with fever.
- Patients with abscesses or progressive skin and soft tissue infection that require debridement.

ACUTE INFECTIOUS DIARRHEA

ESSENTIALS OF DIAGNOSIS

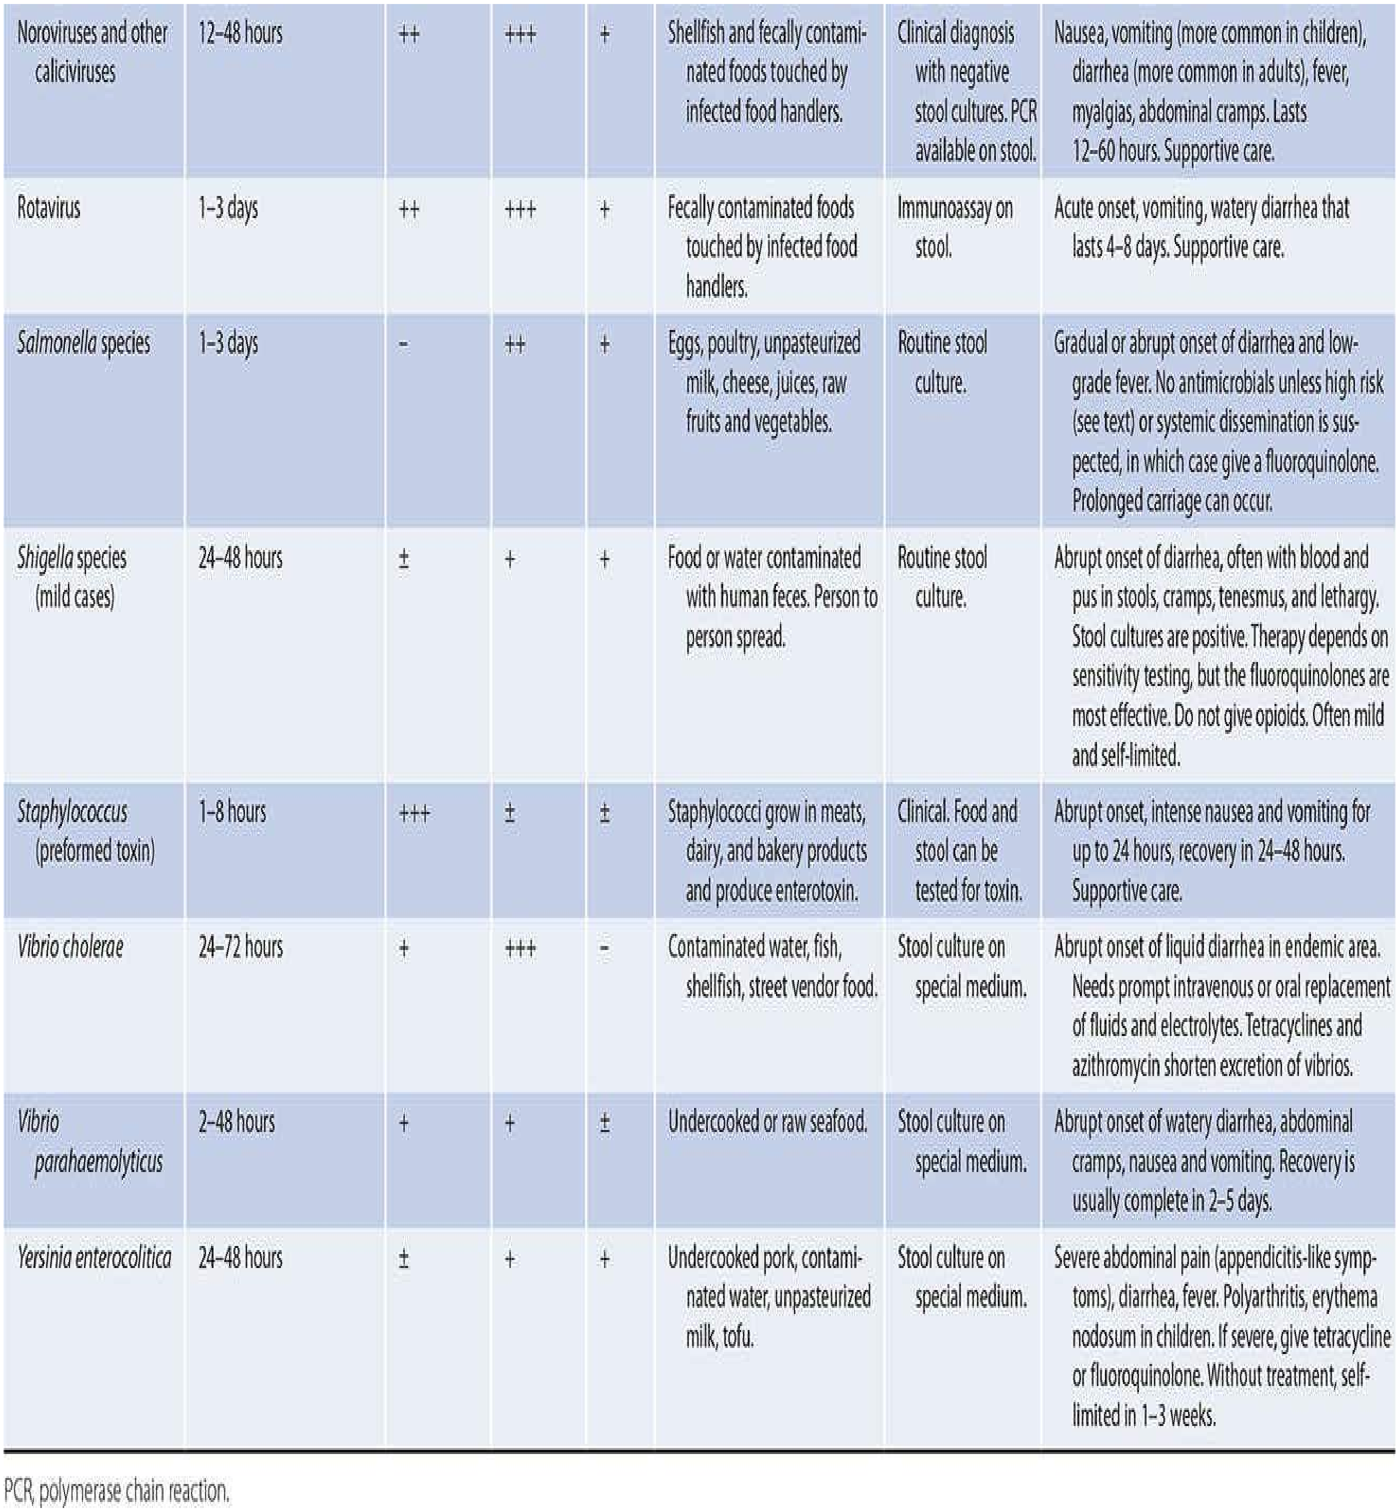
- **Acute diarrhea:** lasts less than 2 weeks
- **Chronic diarrhea:** lasts longer than 2 weeks.
- **Mild diarrhea:** 3 or fewer stools per day.
- **Moderate diarrhea:** 4 or more stools per day with local symptoms (abdominal cramps, nausea, tenesmus).
- **Severe diarrhea:** 4 or more stools per day with systemic symptoms (fever, chills, dehydration).

General Considerations

Acute diarrhea can be caused by a number of different factors, including emotional stress, food intolerance, inorganic agents (eg, sodium nitrite), organic substances (eg, mushrooms, shellfish), medications, and infectious agents (including viruses, bacteria, and protozoa) (Table 30–3). From a diagnostic and therapeutic standpoint, it is helpful to classify infectious diarrhea into syndromes that produce inflammatory or bloody diarrhea and those that are noninflammatory, nonbloody, or watery. In general, the term "**inflammatory diarrhea**" suggests colonic involvement by invasive bacteria or parasites or by toxin production. Patients complain of frequent bloody, small-volume stools, often associated with fever, abdominal cramps, tenesmus, and fecal urgency. Common causes of this syndrome include Shigella, Salmonella, Campylobacter, Yersinia, invasive strains of Escherichia coli, and other Shiga-toxin–producing strains of E coli (STEC), Entamoeba histolytica, and C difficile. Tests for fecal leukocytes or the neutrophil marker lactoferrin are frequently positive, and definitive etiologic diagnosis requires stool culture. **Noninflammatory diarrhea** is generally milder and is caused by viruses or toxins that affect the small intestine and interfere with salt and water balance, resulting in large-volume watery diarrhea, often with nausea, vomiting, and cramps. Common causes of this syndrome include viruses (eg, rotavirus, norovirus, astrovirus, enteric adenoviruses), vibriones (Vibrio cholerae, Vibrio parahaemolyticus), enterotoxin-producing E coli, Giardia lamblia, cryptosporidia, and agents that can cause food-borne gastroenteritis. In developed countries, viruses (particularly norovirus) are an important cause of hospitalizations due to acute gastroenteritis among adults.

Table 30–3. Acute bacterial diarrheas and "food poisoning" (listed in alphabetical order).

Organism	Incubation Period	Vomiting	Diarrhea	Fever	Associated Foods	Diagnosis	Clinical Features and Treatment
Bacillus cereus (diarrheal toxin)	10–16 hours	±	+++	–	Toxin in meats, stews, and gravy.	Clinical. Food and stool can be tested for toxin.	Abdominal cramps, watery diarrhea, and nausea lasting 24–48 hours. Supportive care.
Bacillus cereus (preformed toxin)	1–8 hours	+++	±	–	Reheated fried rice causes vomiting or diarrhea.	Clinical. Food and stool can be tested for toxin.	Acute onset, severe nausea and vomiting lasting 24 hours. Supportive care.
Campylobacter jejuni	2–5 days	±	+++	+	Raw or undercooked poultry, unpasteurized milk, water.	Stool culture on special medium.	Fever, diarrhea that can be bloody, cramps. Usually self-limited in 2–10 days. Treat with azithromycin or fluoroquinolones for severe disease. May be associated with Guillain-Barré syndrome.
Clostridium botulinum	12–72 hours	±	–	–	Clostridia grow in anaerobic acidic environment eg, canned foods, fermented fish, foods held warm for extended periods.	Stool, serum, and food can be tested for toxin. Stool and food can be cultured.	Diplopia, dysphagia, dysphonia, respiratory embarrassment. Treatment requires clear airway, ventilation, and intravenous polyvalent antitoxin (see text). Symptoms can last for days to months.
Clostridioides difficile	Usually occurs after 7–10 days of antibiotics. Can occur after a single dose or several weeks after completion of antibiotics.	–	+++	++	Associated with antibacterial drugs; clindamycin and beta-lactams most commonly implicated. Fluoroquinolones associated with hypervirulent strains.	Stool tested for toxin.	Abrupt onset of diarrhea that may be bloody; fever. Vancomycin 125 mg orally four times per day or fidaxomicin 200 mg twice daily for 10 days recommended over metronidazole.
Clostridium perfringens	8–16 hours	±	+++	–	Clostridia grow in rewarmed meat and poultry dishes and produce an enterotoxin.	Stools can be tested for enterotoxin or cultured.	Abrupt onset of profuse diarrhea, abdominal cramps, nausea; vomiting occasionally. Recovery usual without treatment in 24–48 hours. Supportive care; antibiotics not needed.
Enterohemorrhagic *Escherichia coli*, including Shiga-toxin–producing *E coli* strains (STEC)	1–8 days	+	+++	–	Undercooked beef, especially hamburger; unpasteurized milk and juice; raw fruits and vegetables.	Shiga-toxin–producing *E coli* can be cultured on special medium. Other toxins can be detected in stool.	Usually abrupt onset of diarrhea, often bloody; abdominal pain. In adults, it is usually self-limited to 5–10 days. In children, it is associated with hemolytic-uremic syndrome (HUS). Antibiotic therapy may increase risk of HUS. Plasma exchange may help patients with STEC-associated HUS.
Enterotoxigenic *E coli* (ETEC)	1–3 days	±	+++	±	Water, food contaminated with feces.	Stool culture. Special tests required to identify toxin-producing strains.	Watery diarrhea and abdominal cramps, usually lasting 3–7 days. In travelers, fluoroquinolones shorten disease.



Noroviruses and other caliciviruses	12–48 hours	++	+++	+	Shellfish and fecally contaminated foods touched by infected food handlers.	Clinical diagnosis with negative stool cultures. PCR available on stool.	Nausea, vomiting (more common in children), diarrhea (more common in adults), fever, myalgias, abdominal cramps. Lasts 12–60 hours. Supportive care.
Rotavirus	1–3 days	++	+++	+	Fecally contaminated foods touched by infected food handlers.	Immunoassay on stool.	Acute onset, vomiting, watery diarrhea that lasts 4–8 days. Supportive care.
Salmonella species	1–3 days	–	++	+	Eggs, poultry, unpasteurized milk, cheese, juices, raw fruits and vegetables.	Routine stool culture.	Gradual or abrupt onset of diarrhea and low-grade fever. No antimicrobials unless high risk (see text) or systemic dissemination is suspected, in which case give a fluoroquinolone. Prolonged carriage can occur.
Shigella species (mild cases)	24–48 hours	±	+	+	Food or water contaminated with human feces. Person to person spread.	Routine stool culture.	Abrupt onset of diarrhea, often with blood and pus in stools, cramps, tenesmus, and lethargy. Stool cultures are positive. Therapy depends on sensitivity testing, but the fluoroquinolones are most effective. Do not give opioids. Often mild and self-limited.
Staphylococcus (preformed toxin)	1–8 hours	+++	±	±	Staphylococci grow in meats, dairy, and bakery products and produce enterotoxin.	Clinical. Food and stool can be tested for toxin.	Abrupt onset, intense nausea and vomiting for up to 24 hours, recovery in 24–48 hours. Supportive care.
Vibrio cholerae	24–72 hours	+	+++	–	Contaminated water, fish, shellfish, street vendor food.	Stool culture on special medium.	Abrupt onset of liquid diarrhea in endemic area. Needs prompt intravenous or oral replacement of fluids and electrolytes. Tetracyclines and azithromycin shorten excretion of vibrios.
Vibrio parahaemolyticus	2–48 hours	+	+	±	Undercooked or raw seafood.	Stool culture on special medium.	Abrupt onset of watery diarrhea, abdominal cramps, nausea and vomiting. Recovery is usually complete in 2–5 days.
Yersinia enterocolitica	24–48 hours	±	+	+	Undercooked pork, contaminated water, unpasteurized milk, tofu.	Stool culture on special medium.	Severe abdominal pain (appendicitis-like symptoms), diarrhea, fever. Polyarthritis, erythema nodosum in children. If severe, give tetracycline or fluoroquinolone. Without treatment, self-limited in 1–3 weeks.

PCR, polymerase chain reaction.

The term "food poisoning" denotes diseases caused by toxins present in consumed foods. When the incubation period is short (1–6 hours after consumption), the toxin is usually preformed. Vomiting is usually a major complaint, and fever is usually absent. Examples include intoxication from S aureus or Bacillus cereus, and toxin can be detected in the food. When the incubation period is longer—between 8 hours and 16 hours—the organism is present in the food and produces toxin after being ingested.

Vomiting is less prominent, abdominal cramping is frequent, and fever is often absent. The best example of this disease is that due to Clostridium perfringens. Toxin can be detected in food or stool specimens.

The inflammatory and noninflammatory diarrheas discussed above can also be transmitted by food and water and usually have incubation periods between 12 and 72 hours. Cyclospora, cryptosporidia, and Isospora are protozoans capable of causing disease in both immunocompetent and immunocompromised patients. Characteristics of disease include profuse watery diarrhea that is prolonged but usually self-limited (1–2 weeks) in the immunocompetent patient but can be chronic in the compromised host. Epidemiologic features may be helpful in determining etiology. Recent hospitalization or antibiotic use suggests C difficile; recent foreign travel suggests Salmonella, Shigella, Campylobacter, E coli, or V cholerae; undercooked hamburger suggests STEC; outbreak in long-term care facility, school, or cruise ship suggests norovirus (including newly identified strains, eg, GII.4 Sydney); and fried rice consumption is associated with B cereus toxin. Prominent features of some of these causes of diarrhea are listed in Table 30–3.

Treatment

A. General Measures

In general, most cases of acute gastroenteritis are self-limited and do not require therapy other than supportive measures. Treatment usually consists of replacement of fluids and electrolytes and, very rarely, management of hypovolemic shock and respiratory compromise. In mild diarrhea, increasing ingestion of juices and clear soups is adequate. In more severe cases of dehydration (postural light-headedness, decreased urination), oral glucose-based rehydration solutions can be used (Ceralyte, Pedialyte).

B. Specific Measures

In immunocompetent adults, empiric antimicrobial therapy for bloody diarrhea while waiting for results is recommended only with the following circumstances: (1) documented fever, abdominal pain, bloody diarrhea, and bacillary dysentery (frequent scant bloody stools, fever, abdominal cramps, tenesmus) presumptively due to Shigella; and (2) returning travelers with a temperature of at least 38.5°C or signs of sepsis.

Either a fluoroquinolone or azithromycin should be used as empiric antimicrobial therapy for bloody diarrhea. Empiric antibacterial treatment should be considered in immunocompromised people with severe illness and bloody diarrhea. Loperamide may be given to immunocompetent adults with acute watery diarrhea, but should be avoided with Shigella infection or in suspected or proven toxic megacolon. Therapeutic recommendations for specific agents can be found elsewhere in this book.

INFECTIOUS DISEASES IN THE RETURNING TRAVELER

ESSENTIALS OF DIAGNOSIS

- Most infections are common and self-limited.
- Identify patients with transmissible diseases that require isolation.
- The incubation period may be helpful in diagnosis.
- Less than 3 weeks following exposure may suggest dengue, leptospirosis, and yellow fever; more than 3 weeks suggest typhoid fever, malaria, and tuberculosis.

General Considerations

The differential diagnosis of fever in the returning traveler is broad, ranging from self-limited viral infections to life-threatening illness. The evaluation is best done by identifying whether a particular syndrome is present, then refining the differential diagnosis based on an exposure history. The travel history should include directed questions regarding geography (rural versus urban, specific country visited), time of year, animal or arthropod contact, unprotected sexual intercourse, ingestion of untreated water or raw foods, historical or pretravel immunizations, and adherence to malaria prophylaxis.

Etiologies

The most common infectious causes of fever—excluding simple causes such as upper respiratory infections, bacterial pneumonia and urinary tract infections—in returning travelers are malaria (see Chapter 35), diarrhea (see next section), and dengue (see Chapter 32). Others include mononucleosis (associated with Epstein-Barr virus or cytomegalovirus), respiratory infections, including seasonal influenza, influenza A/H1N1 "swine" influenza, and influenza A/H5N1 or A/H7N9 "avian" influenza (see Chapter 32); leptospirosis (see Chapter 34); typhoid fever (see Chapter 33); and rickettsial infections (see Chapter 32). Foreign travel is increasingly recognized as a risk factor for colonization and disease with resistant pathogens, such as ESBL-producing gram-negative organisms. Systemic febrile illnesses without a diagnosis also occur commonly, particularly in travelers returning from sub-Saharan Africa or Southeast Asia.

A. Fever and Rash

Potential etiologies include dengue, Ebola, Chikungunya, and Zika viruses, viral hemorrhagic fever, leptospirosis, meningococcemia, yellow fever, typhus, Salmonella typhi, and acute HIV infection.

B. Pulmonary Infiltrates

Tuberculosis, ascaris, Paragonimus, and Strongyloides can all cause pulmonary infiltrates.

C. Meningoencephalitis

Etiologies include N meningitidis, leptospirosis, arboviruses, rabies, and (cerebral) malaria.

D. Jaundice

Consider hepatitis A, yellow fever, hemorrhagic fever, leptospirosis, and malaria.

E. Fever Without Localizing Symptoms or Signs

Malaria, typhoid fever, acute HIV infection, rickettsial illness, visceral leishmaniasis, trypanosomiasis, and dengue are possible etiologies.

F. Traveler's Diarrhea

See next section.

Clinical Findings

Fever and rash in the returning traveler should prompt blood cultures and serologic tests based on the exposure history. The workup of a pulmonary infiltrate should include the placement of a PPD or use of an interferon-gamma release assay, examination of sputum for acid-fast bacilli and possibly for ova and parasites. Patients with evidence of meningoencephalitis should receive lumbar puncture, blood cultures, thick/thin smears of peripheral blood, history-guided serologies, and a nape biopsy (if rabies is suspected). Jaundice in a returning traveler should be evaluated for hemolysis (for malaria), and the following tests should be performed: liver biochemical tests, thick/thin smears of peripheral blood, and directed serologic testing. The workup of traveler’s diarrhea is presented in the following section. Finally, patients with fever but no localizing signs or symptoms should have blood cultures performed. Routine laboratory studies usually include complete blood count with differential, electrolytes, liver biochemical tests, urinalysis, and blood cultures. Thick and thin peripheral blood smears should be done (and repeated in 12–24 hours if clinical suspicion remains high) for malaria if there has been travel to endemic areas. Other studies are directed by the results of history, physical examination, and initial laboratory tests. They may include stool for ova and parasites, chest radiograph, HIV test, and specific serologies (eg, dengue, leptospirosis, rickettsial disease, schistosomiasis, Strongyloides). Bone marrow biopsy to diagnose typhoid fever could be helpful in the appropriate patient.

When to Refer

Travelers with fever, particularly if immunocompromised.

When to Admit

Any evidence of hemorrhage, respiratory distress, hemodynamic instability, and neurologic deficits.

TRAVELER’S DIARRHEA

ESSENTIALS OF DIAGNOSIS

- Usually a benign, self-limited disease occurring about 1 week into travel.
- Prophylaxis not recommended unless there is a comorbid disease (inflammatory bowel syndrome, HIV, immunosuppressive medication).
- Single-dose therapy of a fluoroquinolone usually effective if significant symptoms develop.

General Considerations

Whenever a person travels from one country to another—particularly if the change involves a marked difference in climate, social conditions, or sanitation standards and facilities—diarrhea may develop within 2–10 days. Bacteria cause 80% of cases of traveler’s diarrhea, with enterotoxigenic E coli, Shigella species, and Campylobacter jejuni being the most common pathogens. Less common are Aeromonas, Salmonella, noncholera vibriones, E histolytica, and G lamblia. Contributory causes include unusual food and drink, change in living habits, occasional viral infections (adenoviruses or rotaviruses), and change in bowel flora. Chronic watery diarrhea may be due to amebiasis or giardiasis or, rarely, tropical sprue.

Clinical Findings

A. Symptoms and Signs

There may be up to ten or even more loose stools per day, often accompanied by abdominal cramps and nausea, occasionally by vomiting, and rarely by fever. The stools are usually watery and not associated with fever when caused by enterotoxigenic E coli. With invasive bacterial pathogens (Shigella, Campylobacter, Salmonella), stools can be bloody and fever may be present. The illness usually subsides spontaneously within 1–5 days, although 10% remain symptomatic for 1 week or longer, and symptoms persist for longer than 1 month in 2%. Traveler's diarrhea is also a significant risk factor for developing irritable bowel syndrome.

B. Laboratory Findings

In patients with fever and bloody diarrhea, stool culture is indicated, but in most cases, cultures are reserved for those who do not respond to antibiotics.

Prevention

A. General Measures

Avoidance of fresh foods and water sources that are likely to be contaminated is recommended for travelers to developing countries, where infectious diarrheal illnesses are endemic.

B. Specific Measures

Because not all travelers will have diarrhea and because most episodes are brief and self-limited, the currently recommended approach is to provide the traveler with a supply of antimicrobials. Prophylaxis is recommended for those with significant underlying disease (inflammatory bowel disease, AIDS, diabetes mellitus, heart disease in older adults, conditions requiring immunosuppressive medications) and for those whose full activity status during the trip is so essential that even short periods of diarrhea would be unacceptable.

Prophylaxis is started upon entry into the destination country and is continued for 1 or 2 days after leaving. For stays of more than 3 weeks, prophylaxis is not recommended because of the cost and increased toxicity. For prophylaxis, several oral antimicrobial once-daily regimens are effective, such as ciprofloxacin, 500 mg, or rifaximin, 200 mg. Bismuth subsalicylate is effective but turns the tongue and the stools black and can interfere with doxycycline absorption, which may be needed for malaria prophylaxis; it is rarely used.

Treatment

For most individuals, the affliction is short-lived, and symptomatic therapy with loperamide is all that is required, provided the patient is not systemically ill (fever 39°C or higher) and does not have dysentery (bloody stools), in which case antimotility agents should be avoided. Packages of oral rehydration salts to treat dehydration are available over the counter in the United States (Infalyte, Pedialyte, others) and in many foreign countries.

When treatment is necessary, in areas where toxin-producing bacteria are the major cause of diarrhea (Latin America and Africa), loperamide (4 mg oral loading dose, then 2 mg after each loose stool to a maximum of 16 mg/day) with a single oral dose of ciprofloxacin (750 mg), levofloxacin (500 mg), or ofloxacin (200 mg), cures most cases of traveler's diarrhea. If diarrhea is associated with bloody stools or persists despite a single dose of a fluoroquinolone, 1000 mg of azithromycin should be taken. In pregnant women and in areas where invasive bacteria more commonly cause diarrhea (Indian subcontinent, Asia, especially Thailand where fluoroquinolone-resistant Campylobacter is prevalent), azithromycin is the medication of choice. Rifaximin, a nonabsorbable agent, is also approved for therapy of traveler's diarrhea at a dose of 200 mg orally three times per day or 400 mg twice a day for 3 days. Because luminal concentrations are high, but tissue levels are insufficient, it should not be used in situations where there is a high likelihood of invasive disease (eg, fever, systemic toxicity, or bloody stools).

When to Refer

- Cases refractory to treatment.
- Persistent infection.
- Immunocompromised patient.

When to Admit

Patients who are severely dehydrated or hemodynamically unstable should be admitted to the hospital.

Giddings SL et al. Traveler's diarrhea. Med Clin North Am. 2016 Mar;100(2):317–30. [PMID: 26900116]

ANTIMICROBIAL THERAPY

SELECTED PRINCIPLES OF ANTIMICROBIAL THERAPY

Specific steps (outlined below) are required when considering antibiotic therapy for patients. Medications within classes, medications of first choice, and alternative medications are presented in Table 30–4.

Table 30–4. Medication of choice for suspected or documented microbial pathogens (listed in alphabetical order, within classes).

Suspected or Proved Etiologic Agent	Medication(s) of First Choice	Alternative Medication(s)
Gram-Negative Cocci		
Moraxella catarrhalis	Cefuroxime, amoxicillin-clavulanic acid	Ceftriaxone, cefuroxime axetil, a fluoroquinolone,[1] a macrolide,[2] a tetracycline,[3] TMP-SMZ[4]
Neisseria gonorrhoeae (gonococcus)	Ceftriaxone + azithromycin or doxycycline	Cefixime + azithromycin or doxycycline[5]
Neisseria meningitidis (meningococcus)	Penicillin[6]	Ceftriaxone, ampicillin
Gram-Positive Cocci		
Enterococcus faecalis	Ampicillin ± gentamicin[7]	Vancomycin ± gentamicin
Enterococcus faecium	Vancomycin ± gentamicin[7]	Linezolid,[8] quinupristin-dalfopristin,[8] daptomycin,[8] tigecycline,[8] tedizolid,[8] oritavancin[8]
Streptococcus, hemolytic, groups A, B, C, G	Penicillin[6]	Macrolide,[2] a cephalosporin,[9] vancomycin, clindamycin
Staphylococcus, methicillin-resistant	Vancomycin	TMP-SMZ,[4] doxycycline, minocycline, linezolid,[8] tedizolid,[8] daptomycin,[8] televancin,[8] dalbavancin,[8] oritavancin,[8] ceftaroline, delafloxacin
Staphylococcus, methicillin-susceptible	Penicillinase-resistant penicillin[10]	Vancomycin, a cephalosporin,[9] clindamycin, amoxicillin-clavulanic acid, ampicillin-sulbactam
Streptococcus pneumoniae[11] (pneumococcus)	Penicillin[6]	Macrolide,[2] a cephalosporin,[9] vancomycin, clindamycin, a tetracycline,[3] respiratory fluoroquinolones[1]
Viridans streptococci	Penicillin[6]	Cephalosporin,[9] vancomycin
Gram-Negative Rods		
Acinetobacter	Imipenem, meropenem	Tigecycline, minocycline, doxycycline, aminoglycosides,[12] colistin
Bacteroides, gastrointestinal strains	Metronidazole	Ampicillin-sulbactam, piperacillin-tazobactam, ertapenem
Brucella	Doxycycline + rifampin[3]	TMP-SMZ[4] ± gentamicin; ciprofloxacin + rifampin
Burkholderia mallei (glanders)	Streptomycin + tetracycline[3]	Chloramphenicol + streptomycin

Gram-Negative Rods (cont.)		
Burkholderia pseudomallei (melioidosis)	Ceftazidime	Tetracycline,[3] TMP-SMZ,[4] amoxicillin-clavulanic acid, imipenem or meropenem
Campylobacter jejuni	Azithromycin	A fluoroquinolone[1]
Enterobacter	Ertapenem, imipenem, meropenem, cefepime	Aminoglycoside, a fluoroquinolone,[1] TMP-SMZ[4]
Escherichia coli (uncomplicated outpatient urinary infection)	Nitrofurantoin, fosfomycin	Fluoroquinolones,[1] TMP-SMZ,[4] oral cephalosporin
Escherichia coli (sepsis)[13]	Cefotaxime, ceftriaxone	Ertapenem[13] imipenem[13] or meropenem,[13] aminoglycosides,[12] aztreonam, ticarcillin-clavulanate, piperacillin-tazobactam, ceftazidime-avibactam,[13] ceftolozane-tazobactam,[13,14] meropenem/vaborbactam[15]
Haemophilus (respiratory infections, otitis)	Ampicillin-clavulanate	Doxycycline, azithromycin, ceftriaxone, cefuroxime, cefuroxime axetil, TMP-SMZ[4]
Haemophilus (serious infection)	Ceftriaxone	Aztreonam
Helicobacter pylori	Proton pump inhibitor (PPI), clarithromycin, amoxicillin, and metronidazole	PPI, clarithromycin, and amoxicillin **or** metronidazole
Klebsiella[13]	Ceftriaxone	TMP-SMZ,[4] aminoglycoside,[12] ertapenem,[13] imipenem[13] or meropenem,[13] a fluoroquinolone,[1] aztreonam, ticarcillin-clavulanate, piperacillin-tazobactam, ceftazidime-avibactam,[13] ceftolozane-tazobactam,[13,14] meropenem/vaborbactam[15]
Legionella species (pneumonia)	Azithromycin, or fluoroquinolones[1] ± rifampin	Doxycycline ± rifampin
Prevotella, oropharyngeal strains	Clindamycin	Metronidazole
Proteus mirabilis	Ampicillin	An aminoglycoside,[12] TMP-SMZ,[4] a fluoroquinolone,[1] a cephalosporin[9]
Proteus vulgaris and other species *(Morganella, Providencia)*	Ceftriaxone	Aminoglycoside,[12] ertapenem, imipenem or meropenem, TMP-SMZ,[4] a fluoroquinolone[1]
Pseudomonas aeruginosa	Piperacillin-tazobactam or ceftazidime or cefepime, or imipenem or meropenem or doripenem or aztreonam ± aminoglycoside[12]	Ciprofloxacin (or levofloxacin) ± piperacillin-tazobactam; ciprofloxacin (or levofloxacin) ± ceftazidime; ciprofloxacin (or levofloxacin) ± cefepime; ceftazidime-avibactam[13]; ceftolozane-tazobactam[13]
Salmonella (bacteremia)	Ceftriaxone	A fluoroquinolone[1]
Serratia	Carbapenem	TMP-SMZ,[4] aminoglycosides,[12] a fluoroquinolone,[1] ceftriaxone
Shigella	Azithromycin, ciprofloxacin, or ceftriaxone	TMP-SMZ[4]
Vibrio (cholera, sepsis)	A tetracycline[3]	TMP-SMZ,[4] a fluoroquinolone[1]
Yersinia pestis (plague)	Streptomycin ± a tetracycline[3]	Chloramphenicol, TMP-SMZ[5]
Gram-Positive Rods		
Actinomyces	Penicillin[6]	Tetracycline,[3] clindamycin
Bacillus (including anthrax)	Penicillin[6]	A macrolide,[2] a fluoroquinolone[1]
Clostridium (eg, gas gangrene, tetanus)	Penicillin[6]	Metronidazole, clindamycin, imipenem, or meropenem
Corynebacterium diphtheria	Macrolide[2]	Penicillin[6]
Corynebacterium jeikeium	Vancomycin	Linezolid
Listeria	Ampicillin ± aminoglycoside[12]	TMP-SMZ[4]

Acid-Fast Rods		
Mycobacterium avium complex	Clarithromycin or azithromycin + ethambutol, ± rifabutin	Amikacin, ciprofloxacin
Mycobacterium fortuitum-chelonei	Cefoxitin + clarithromycin	Amikacin, rifampin, sulfonamide, doxycycline, linezolid
Mycobacterium kansasii	INH + rifampin ± ethambutol	Clarithromycin, azithromycin, ethionamide, cycloserine
Mycobacterium leprae	Dapsone + rifampin ± clofazimine	Minocycline, ofloxacin, clarithromycin
Mycobacterium tuberculosis[16]	Isoniazid (INH) + rifampin + pyrazinamide ± ethambutol	Other antituberculous drugs (see Tables 9–14 and 9–15)
Nocardia	TMP-SMZ[4]	Minocycline, imipenem or meropenem, linezolid
Spirochetes		
Borrelia burgdorferi (Lyme disease)	Doxycycline, amoxicillin, cefuroxime axetil	Ceftriaxone, penicillin, azithromycin
Borrelia recurrentis (relapsing fever)	Doxycycline[3]	Penicillin[6]
Leptospira	Penicillin[6]	Doxycycline,[3] ceftriaxone
Treponema pallidum (syphilis)	Penicillin[6]	Doxycycline, ceftriaxone
Treponema pertenue (yaws)	Penicillin[6]	Doxycycline
Mycoplasmas	Azithromycin or doxycycline	A fluoroquinolone[1]
Chlamydiae		
C pneumoniae	Doxycycline[3]	Azithromycin, a fluoroquinolone[1,17]
C psittaci	Doxycycline	Chloramphenicol
C trachomatis (urethritis or pelvic inflammatory disease)	Doxycycline or azithromycin	Levofloxacin, ofloxacin
Rickettsiae	Doxycycline[3]	Chloramphenicol, a fluoroquinolone[1]

---

[1] Fluoroquinolones include ciprofloxacin, levofloxacin, moxifloxacin, and others. Gemifloxacin, levofloxacin, and moxifloxacin, the so-called respiratory fluoroquinolones, demonstrate the most reliable activity against penicillin-resistant *S pneumoniae* and other respiratory infection pathogens. Delafloxacin is predictably active against methicillin-resistant *S aureus* (MRSA).

[2] Azithromycin is the preferred macrolide due to increased safety profile and minimal drug interaction potential.

[3] All tetracyclines have similar activity against most microorganisms. Minocycline (the most active tetracycline) and doxycycline are more active than tetracycline against *S aureus*.

[4] TMP-SMZ is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.

[5] Test of cure required if ceftriaxone not used.

[6] Penicillin G is preferred for parenteral injection; penicillin V for oral administration.

[7] Addition of gentamicin indicated only for severe enterococcal infections (eg, endocarditis, meningitis).

[8] Linezolid, tedizolid, daptomycin, televancin, dalbavancin, and oritavancin should be reserved for the treatment of vancomycin-resistant isolates or in patients intolerant of vancomycin.

[9] Most intravenous cephalosporins (with the exception of ceftazidime) are active against streptococci and staphylococci.

[10] Parenteral nafcillin or oxacillin; oral dicloxacillin, cloxacillin, or oxacillin.

[11] Infections caused by isolates with intermediate resistance may respond to high dose penicillin or ceftriaxone or the respiratory fluoroquinolones (gemifloxacin, levofloxacin, and moxifloxacin). Infections caused by highly penicillin-resistant isolates should be treated with vancomycin. Penicillin-resistant pneumococci are often resistant to macrolides, tetracyclines, and TMP-SMZ.

[12] Aminoglycosides—gentamicin, tobramycin, amikacin, netilmicin—should be chosen on the basis of local patterns of susceptibility.

[13] Extended beta-lactamase–producing (ESBL) isolates should be treated with a carbapenem. If a carbapenem cannot be used, ceftazidime-avibactam or possibly ceftolozane-tazobactam can be considered.

[14] Ceftolozane-tazobactam and occasionally ceftazidime-avibactam may be active against multidrug-resistant *P aeruginosa*.

[15] Consider in cases of infection due to carbapenemase-producing Enterobacteriaceae.

[16] Resistance is common and susceptibility testing must be performed.

[17] Ciprofloxacin has inferior antichlamydial activity compared with levofloxacin or ofloxacin.

±, alone or combined with.

A. Etiologic Diagnosis

Based on the organ system involved, the organism causing infection can often be predicted. See Tables 30–5 and 30–6.

Table 30–5. Examples of initial antimicrobial therapy for acutely ill, hospitalized adults pending identification of causative organism (in alphabetical order).

Suspected Clinical Diagnosis	Likely Etiologic Diagnosis	Medication of Choice
Brain abscess	Mixed anaerobes, pneumococci, streptococci	Ceftriaxone, 2 g intravenously every 12 hours **plus** metronidazole, 500 mg orally every 8 hours **plus** vancomycin, 15 mg/kg intravenously every 8 hours
Endocarditis, acute (including injection drug user)	*S aureus*, *E faecalis*, viridans streptococci	Vancomycin, 15 mg/kg/dose intravenously every 12 hours
Fever in neutropenic patient receiving cancer chemotherapy	*S aureus*, *Pseudomonas*, *Klebsiella*, *E coli*	Cefepime, 2 g intravenously every 8 hours
Intra-abdominal sepsis (eg, postoperative, peritonitis, cholecystitis)	Gram-negative bacteria, *Bacteroides*, anaerobic bacteria, enterococcus	Piperacillin-tazobactam, 4.5 g intravenously every 6 hours, **or** ertapenem, 1 g every 24 hours
Meningitis, bacterial, age > 50, community-acquired	Pneumococcus, meningococcus, *Listeria monocytogenes*,[1] gram-negative bacilli, group B *Streptococcus*	Ampicillin, 2 g intravenously every 4 hours, **plus** ceftriaxone, 2 g intravenously every 12 hours, **plus** vancomycin, 15 mg/kg intravenously every 8 hours
Meningitis, bacterial, community-acquired	*Streptococcus pneumoniae* (pneumococcus),[2] *Neisseria meningitidis* (meningococcus)	Ceftriaxone, 2 g intravenously every 12 hours,[1] **plus** vancomycin, 15 mg/kg intravenously every 8 hours
Meningitis, postoperative (or posttraumatic)	*S aureus*, gram-negative bacilli, coagulase-negative staphylococci, diphtheroids (eg, *Propionibacterium acnes*) (uncommon) pneumococcus (in posttraumatic)	Vancomycin, 15 mg/kg intravenously every 8 hours, **plus** cefepime, 3 g intravenously every 8 hours[3]
Osteomyelitis	*S aureus*, secondarily gram-negative aerobes	Vancomycin 15 mg/kg intravenously every 8 hours **plus** ceftriaxone 2 g intravenously every 24 hours
Pneumonia, acute, community-acquired, non-ICU hospital admission	Pneumococci, *M pneumoniae*, *Legionella*, *C pneumoniae*	Ceftriaxone, 1 g intravenously every 24 hours or ampicillin, 2 g intravenously every 6 hours) **plus** azithromycin, 500 mg intravenously every 24 hours; **or** a respiratory fluoroquinolone[4] alone
Pneumonia, postoperative or nosocomial	*S aureus*, mixed anaerobes, gram-negative bacilli	Cefepime, 2 g intravenously every 8 hours; **or** ceftazidime, 2 g intravenously every 8 hours; **or** piperacillin-tazobactam, 4.5 g intravenously every 6–8 hours; **or** imipenem, 500 mg intravenously every 6 hours; **or** meropenem, 1 g intravenously every 8 hours **plus** tobramycin, 5–7 mg/kg intravenously every 24 hours; **or** ciprofloxacin, 400 mg intravenously every 12 hours; **or** levofloxacin, 500 mg intravenously every 24 hours **plus** vancomycin, 15 mg/kg/dose intravenously every 12 hours
Pyelonephritis with flank pain and fever (recurrent urinary tract infection)	*E coli*, *Klebsiella*, *Enterobacter*, *Pseudomonas*	Ceftriaxone, 1 g intravenously every 24 hours; **or** if culture results confirm susceptibility, ciprofloxacin, 400 mg intravenously every 12 hours (500 mg orally); **or** levofloxacin, 500 mg once daily (intravenously/orally)
Septic arthritis	*S aureus*, *N gonorrhoeae*	Ceftriaxone, 1–2 g intravenously every 24 hours
Septic thrombophlebitis (eg, IV tubing, IV shunts)	*S aureus*, gram-negative aerobic bacteria	Vancomycin, 15 mg/kg/dose intravenously every 12 hours, **plus** ceftriaxone, 1 g intravenously every 24 hours

---

[1] TMP-SMZ can be used to treat *Listeria monocytogenes* in patients allergic to penicillin in a dosage of 15–20 mg/kg/day of TMP in three or four divided doses.

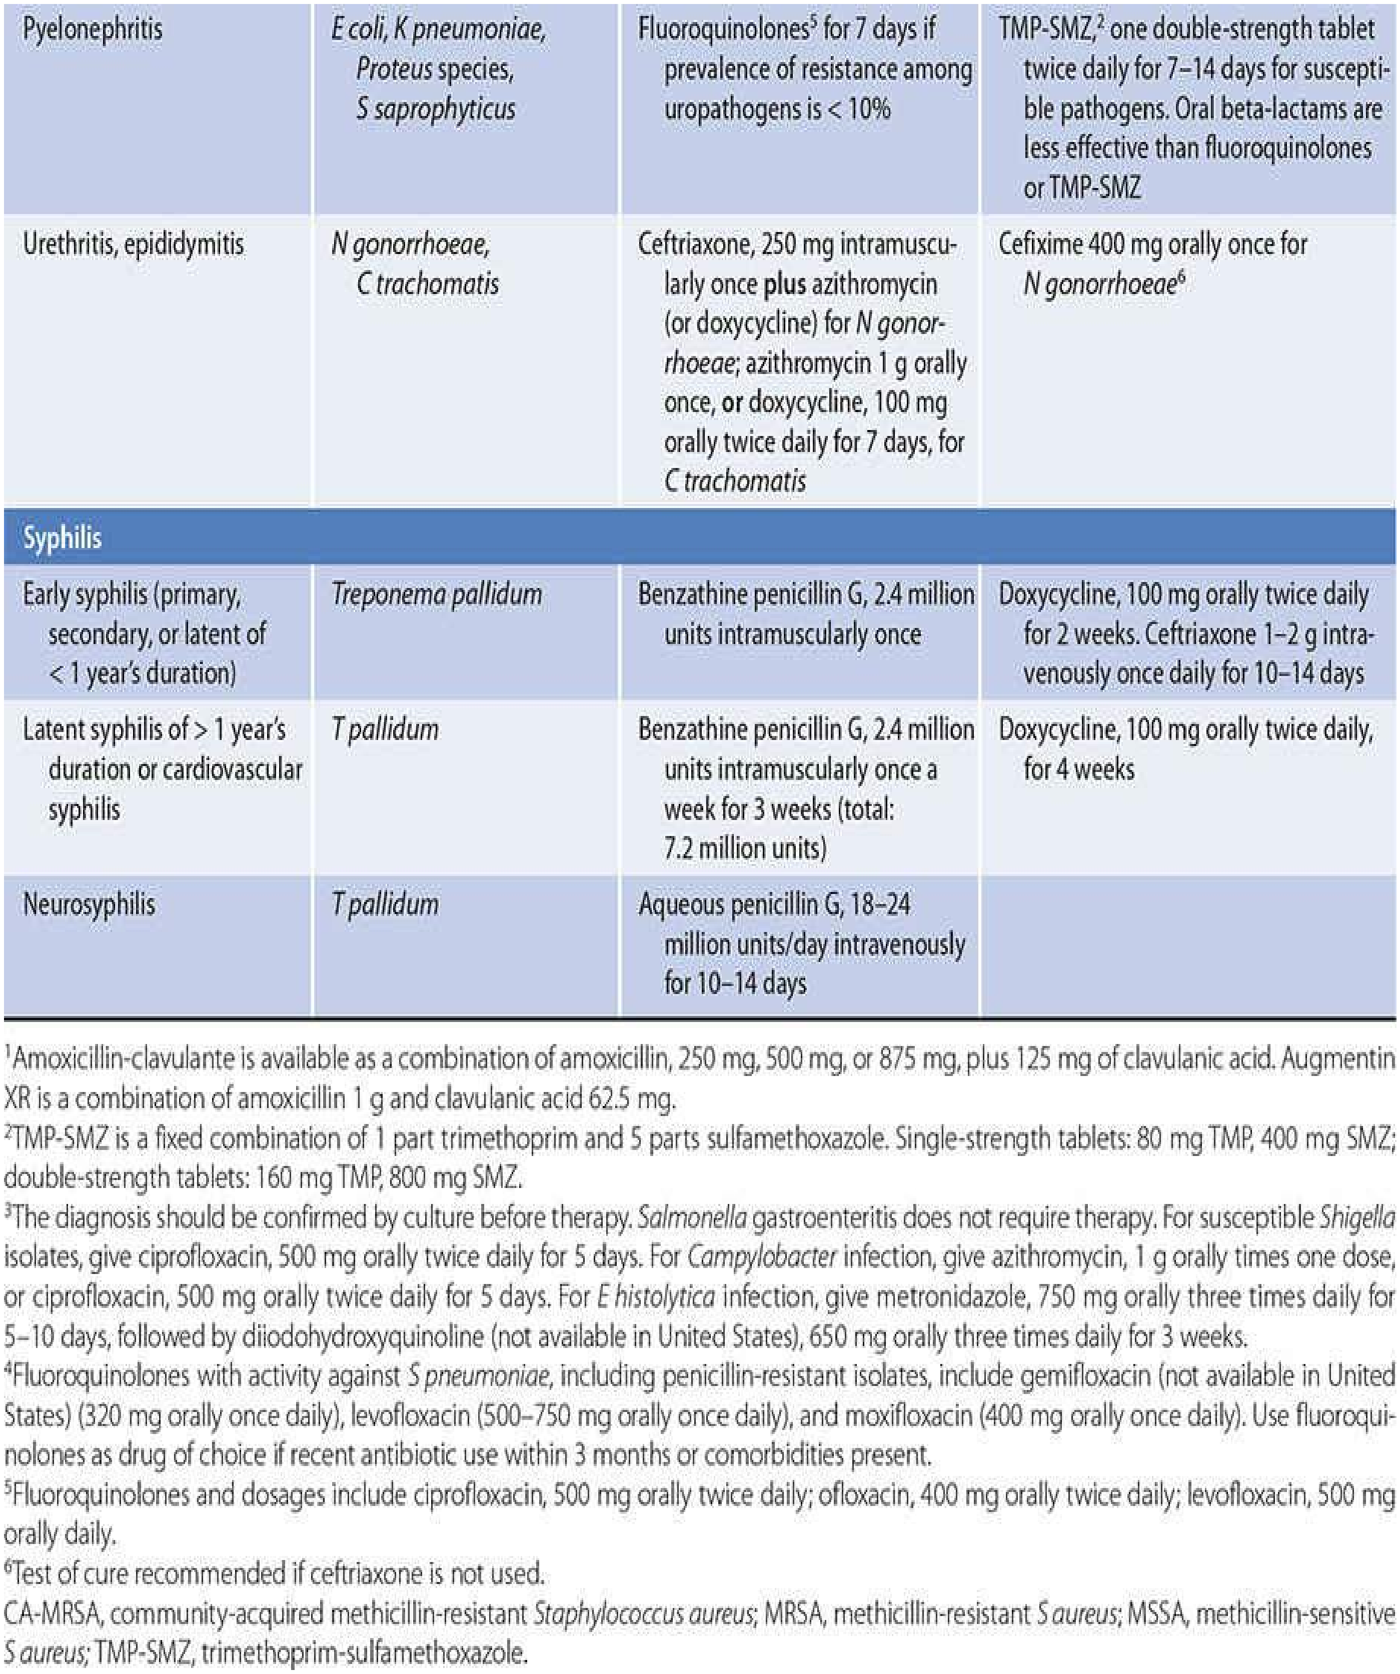
[2] Including penicillin nonsusceptible isolates.

[3] Cefepime 3 g is a higher dose than sometimes recommended in order to optimize treatment of *Pseudomonas* and *Enterobacter*.

[4] Levofloxacin 750 mg/day, moxifloxacin 400 mg/day.

Table 30–6. Examples of empiric choices of antimicrobials for adult outpatient infections (in alphabetical order).

Suspected Clinical Diagnosis	Likely Etiologic Agents	Medications of Choice	Alternative Medications
Acute sinusitis	*Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis*	Augmentin,[1] 875 mg orally twice daily for 10 days	For patients allergic to penicillin, doxycycline, 100 mg twice daily for 10 days
Aspiration pneumonia	Mixed oropharyngeal flora, including anaerobes	Clindamycin, 300 mg orally four times daily for 10–14 days	Amoxicillin 500 mg orally three times daily for 10–14 days
Cystitis	*Escherichia coli, Staphylococcus saprophyticus, Klebsiella pneumoniae, Proteus* species, other gram-negative rods or enterococci	Nitrofurantoin monohydrate macrocrystals 100 mg twice daily for 5–7 days (unless pregnant); fosfomycin 3 g orally as a single dose	Cephalexin, 500 mg orally four times daily for 7 days, for uncomplicated cystitis. Due to increasing bacterial resistance, TMP-SMZ and fluoroquinolones are **not** recommended as first-line therapy for empiric treatment
Erysipelas, impetigo, cellulitis, ascending lymphangitis	Group A *Streptococcus*	Penicillin V, 500 mg orally four times daily for 7–10 days	Cephalexin, 500 mg orally four times daily for 7–10 days; **or** azithromycin, 500 mg on day 1 and 250 mg on days 2–5
Furuncle with surrounding cellulitis	*Staphylococcus aureus*	Dicloxacillin, 500 mg orally four times daily for 7–10 days for MSSA. For CA-MRSA: TMP-SMZ[2] one double-strength tablet twice daily for 7–10 days; **or** clindamycin 300 mg orally three times daily for 7–10 days	Cephalexin, 500 mg orally four times daily for 7–10 days for MSSA. For CA-MRSA, doxycycline is a reasonable alternative
Gastroenteritis	*Salmonella, Shigella, Campylobacter, Entamoeba histolytica*	See footnote 3	
Otitis media	*S pneumoniae, H influenzae, M catarrhalis*	Amoxicillin, 500 mg–1 g orally three times daily for 10 days	Amoxicillin-clavulanate,[1] 875 mg orally twice daily; **or** cefuroxime, 500 mg orally twice daily; **or** cefpodoxime, 200–400 mg daily; **or** doxycycline, 100 mg twice daily
Pelvic inflammatory disease	*Neisseria gonorrhoeae, Chlamydia trachomatis,* anaerobes, gram-negative rods	Ceftriaxone 250 mg intramuscularly once plus doxycycline 100 mg orally twice daily for 14 days +/– metronidazole 500 mg orally twice daily for 14 days; **or** cefoxitin 2 g intramuscularly once plus probenecid 1 g orally once, plus doxycycline 100 mg orally twice daily for 14 days +/– metronidazole 500 mg orally twice daily for 14 days	
Pharyngitis	Group A *Streptococcus*	Penicillin V, 500 mg orally four times daily, **or** amoxicillin, 500 mg–1 g orally three times daily, for 10 days	For patients with history of mild penicillin allergy, cephalexin, 500 mg orally four times daily for 10 days; for patients with IgE-mediated reaction, clindamycin, 300 mg orally four times daily for 10 days; **or** azithromycin, 500 mg on day 1 and 250 mg on days 2–5
Pneumonia	*S pneumoniae, Mycoplasma pneumoniae, Legionella pneumophila, Chlamydophila pneumoniae*	Doxycycline, 100 mg orally twice daily	Amoxicillin, 1.0 g orally three times daily plus azithromycin 500 mg orally on day 1 and 250 mg on days 2–5. A respiratory fluoroquinolone[4] for patients at high risk for infection due to resistant pneumococci



Pyelonephritis	*E coli, K pneumoniae, Proteus* species, *S saprophyticus*	Fluoroquinolones[5] for 7 days if prevalence of resistance among uropathogens is < 10%	TMP-SMZ,[2] one double-strength tablet twice daily for 7–14 days for susceptible pathogens. Oral beta-lactams are less effective than fluoroquinolones or TMP-SMZ
Urethritis, epididymitis	*N gonorrhoeae, C trachomatis*	Ceftriaxone, 250 mg intramuscularly once **plus** azithromycin (or doxycycline) for *N gonorrhoeae*; azithromycin 1 g orally once, **or** doxycycline, 100 mg orally twice daily for 7 days, for *C trachomatis*	Cefixime 400 mg orally once for *N gonorrhoeae*[6]
Syphilis			
Early syphilis (primary, secondary, or latent of < 1 year's duration)	*Treponema pallidum*	Benzathine penicillin G, 2.4 million units intramuscularly once	Doxycycline, 100 mg orally twice daily for 2 weeks. Ceftriaxone 1–2 g intravenously once daily for 10–14 days
Latent syphilis of > 1 year's duration or cardiovascular syphilis	*T pallidum*	Benzathine penicillin G, 2.4 million units intramuscularly once a week for 3 weeks (total: 7.2 million units)	Doxycycline, 100 mg orally twice daily, for 4 weeks
Neurosyphilis	*T pallidum*	Aqueous penicillin G, 18–24 million units/day intravenously for 10–14 days	

---

[1] Amoxicillin-clavulante is available as a combination of amoxicillin, 250 mg, 500 mg, or 875 mg, plus 125 mg of clavulanic acid. Augmentin XR is a combination of amoxicillin 1 g and clavulanic acid 62.5 mg.

[2] TMP-SMZ is a fixed combination of 1 part trimethoprim and 5 parts sulfamethoxazole. Single-strength tablets: 80 mg TMP, 400 mg SMZ; double-strength tablets: 160 mg TMP, 800 mg SMZ.

[3] The diagnosis should be confirmed by culture before therapy. *Salmonella* gastroenteritis does not require therapy. For susceptible *Shigella* isolates, give ciprofloxacin, 500 mg orally twice daily for 5 days. For *Campylobacter* infection, give azithromycin, 1 g orally times one dose, or ciprofloxacin, 500 mg orally twice daily for 5 days. For *E histolytica* infection, give metronidazole, 750 mg orally three times daily for 5–10 days, followed by diiodohydroxyquinoline (not available in United States), 650 mg orally three times daily for 3 weeks.

[4] Fluoroquinolones with activity against *S pneumoniae*, including penicillin-resistant isolates, include gemifloxacin (not available in United States) (320 mg orally once daily), levofloxacin (500–750 mg orally once daily), and moxifloxacin (400 mg orally once daily). Use fluoroquinolones as drug of choice if recent antibiotic use within 3 months or comorbidities present.

[5] Fluoroquinolones and dosages include ciprofloxacin, 500 mg orally twice daily; ofloxacin, 400 mg orally twice daily; levofloxacin, 500 mg orally daily.

[6] Test of cure recommended if ceftriaxone is not used.

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; MRSA, methicillin-resistant *S aureus*; MSSA, methicillin-sensitive *S aureus;* TMP-SMZ, trimethoprim-sulfamethoxazole.

B. “Best Guess”

Select an empiric regimen that is likely to be effective against the suspected pathogens.

C. Laboratory Control

Specimens for laboratory examination should be obtained before institution of therapy to determine susceptibility.

D. Clinical Response

Based on clinical response and other data, the laboratory reports are evaluated and then the desirability of changing the regimen is considered. If the specimen was obtained from a normally sterile site (eg, blood, cerebrospinal fluid, pleural fluid, joint fluid), the recovery of a microorganism in significant amounts is meaningful even if the organism recovered is different from the clinically suspected agent, and this may force a change in treatment. Isolation of unexpected microorganisms from the respiratory tract, gastrointestinal tract, or surface lesions (sites that have a complex flora) may represent colonization or contamination, and cultures must be critically evaluated before medications are abandoned that were judiciously selected on a "best guess" basis.

E. Drug Susceptibility Tests

Some microorganisms are predictably inhibited by certain medications; if such organisms are isolated, they need not be tested for drug susceptibility. For example, all group A hemolytic streptococci are inhibited by penicillin. Other organisms (eg, enteric gram-negative rods) are variably susceptible and generally require susceptibility testing whenever they are isolated. Organisms that once had predictable susceptibility patterns are now associated with resistance and require testing. Examples include the pneumococci, which may be resistant to multiple medications (including penicillin, macrolides, and TMP-SMZ); the enterococci, which may be resistant to penicillin, aminoglycosides, and vancomycin; and ESBL producing–E coli resistant to third-generation cephalosporins and fluoroquinolones.

When culture and susceptibility results have been finalized, clinicians must use the most narrow-spectrum agent and the shortest duration possible to decrease the selection pressure for antibacterial resistance.

Antimicrobial drug susceptibility tests may be performed on solid media as disk diffusion tests, in broth, in tubes, in wells of microdilution plates, or as E-tests (strips with increasing concentration of antibiotic). The latter three methods yield results expressed as MIC (minimal inhibitory concentration). In most infections, the MIC is the appropriate in vitro test to guide selection of an antibacterial agent. When there appear to be marked discrepancies between susceptibility testing and clinical response, the following possibilities must be considered:

1. Selection of an inappropriate medication, medication dosage, or route of

administration.

2. Failure to drain a collection of pus or to remove a foreign body.
3. Failure of a poorly diffusing drug to reach the site of infection (eg, central nervous system) or to reach intracellular phagocytosed bacteria.
4. Superinfection in the course of prolonged chemotherapy.
5. Emergence of drug resistance in the original pathogen or superinfection with a new more resistant organism.
6. Participation of two or more microorganisms in the infectious process, of which only one was originally detected and used for medication selection.
7. Inadequate host defenses, including immunodeficiencies and diabetes mellitus.
8. Noninfectious causes, including drug fever, malignancy, and autoimmune disease.

F. Promptness of Response

Response depends on a number of factors, including the patient (immunocompromised patients respond slower than immunocompetent patients), the site of infection (deep-seated infections such as osteomyelitis and endocarditis respond more slowly than superficial infections such as cystitis or cellulitis), the pathogen (virulent organisms such as S aureus respond more slowly than viridans streptococci; mycobacterial and fungal infections respond slower than bacterial infections), and the duration of illness (in general, the longer the symptoms are present, the longer it takes to respond). Thus, depending on the clinical situation, persistent fever and leukocytosis several days after initiation of therapy may not indicate improper choice of antibiotics but may be due to the natural history of the disease being treated. In most infections, either a bacteriostatic or a bactericidal agent can be used. In some infections (eg, infective endocarditis and meningitis), a bactericidal agent should be used. When potentially toxic medications (eg, aminoglycosides, flucytosine) are used, serum levels of the medication are measured to minimize toxicity and ensure appropriate dosage. In patients with altered renal or hepatic clearance of medications, the dosage or frequency of administration must be adjusted; it is best to measure levels in older adults, in morbidly obese patients, or in those with altered kidney function when possible and adjust therapy accordingly.

G. Duration of Antimicrobial Therapy

Generally, effective antimicrobial treatment results in reversal of the clinical and laboratory parameters of active infection and marked clinical improvement. However, varying periods of treatment may be required for cure. Key factors include (1) the type of infecting organism (bacterial infections generally can be cured more rapidly than fungal or mycobacterial ones), (2) the location of the process (eg, endocarditis and osteomyelitis require prolonged therapy), and (3) the immunocompetence of the patient.

H. Adverse Reactions and Toxicity

These include hypersensitivity reactions, direct toxicity, superinfection by drug-resistant microorganisms, and drug interactions. If the infection is life-threatening and treatment cannot be stopped, the reactions are managed symptomatically or another medication is chosen that does not cross-react with the offending one (Table 30–4). If the infection is less serious, it may be possible to stop all antimicrobials and monitor the patient closely.

I. Route of Administration

Intravenous therapy is preferred for acutely ill patients with serious infections (eg, endocarditis, meningitis, sepsis, severe pneumonia) when dependable levels of antibiotics are required for successful therapy. Certain medications (eg, doxycycline, fluconazole, voriconazole, rifampin, metronidazole, TMP-SMZ, and fluoroquinolones) are so well absorbed that they generally can be administered orally in seriously ill—but not hemodynamically unstable—patients.

Food does not significantly influence the bioavailability of most oral antimicrobial agents. However, the tetracyclines (particularly tetracycline) and the quinolones chelate multivalent cations resulting in decreased oral bioavailability. Posaconazole suspension should always be administered with food.

A major complication of intravenous antibiotic therapy is infection due to the manipulation of the intravenous catheter. Peripheral catheters are changed every 48–72 hours to decrease the likelihood of catheter-associated infection, and antimicrobial-coated central venous catheters (minocycline and rifampin, chlorhexidine and sulfadiazine) have been associated with a decreased incidence of these infections. Most of these infections present with local signs of infection (erythema, tenderness) at the insertion site. In a patient with fever who is receiving intravenous therapy, the catheter must always be considered a potential source. Small-gauge (20–23F) peripherally inserted silicone or polyurethane catheters (Per Q Cath, A-Cath, Ven-A-Cath, and others) are associated with a low infection rate and can be maintained for 3–6 months without replacement. Such catheters are ideal for long-term outpatient antibiotic therapy.

J. Cost of Antibiotics

The cost of these agents can be substantial. In addition to acquisition costs and monitoring costs (drug levels, liver biochemical tests, electrolytes, etc), the cost of treating adverse reactions, the cost of treatment failure and superinfection, and the costs associated with drug administration must be considered.

Chua KP et al. Appropriateness of outpatient antibiotic prescribing among privately insured US patients: ICD-10-CM based cross sectional study. BMJ. 2019 Jan 16;364:k5092. [PMID: 30651273]

Tamma PD et al. Association of adverse events with antibiotic use in hospitalized patients. JAMA Intern Med. 2017 Sep 1;177(9):1308–15. [PMID: 28604925]

HYPERSENSITIVITY

Penicillin Allergy

All penicillins are cross-sensitizing and cross-reacting. Skin tests using penicilloyl-polylysine and undegraded penicillin can identify most individuals with IgE-mediated reactions (hives, bronchospasm). In those patients with positive reaction to skin tests, the incidence of subsequent immediate severe reactions associated with penicillin administration is high. A history of a penicillin reaction in the past is often not reliable. Only a small proportion (less than 5%) of patients with a stated history of penicillin allergy experience an adverse reaction when challenged with the medication. The decision to administer penicillin or related medications (other beta-lactams) to patients with an allergic history depends on the severity of the reported reaction, the severity of the infection being treated, and the availability of alternative medications. For patients with a history of severe reaction (anaphylaxis), alternative medications should be used. In the rare situations when there is a strong indication for using penicillin (eg, syphilis in pregnancy) in allergic patients, desensitization can be performed. If the reaction is mild (nonurticarial rash), the patient may be rechallenged with penicillin or may be given another beta-lactam antibiotic.

Allergic reactions include anaphylaxis, serum sickness (urticaria, fever, joint swelling, angioedema 7–12 days after exposure), skin rashes, fever, interstitial nephritis, eosinophilia, hemolytic anemia, other hematologic disturbances, and vasculitis. The incidence of hypersensitivity to penicillin is estimated to be 1–5% among adults in the United States. Life-threatening anaphylactic reactions are very rare (0.05%). Ampicillin produces maculopapular skin rashes more frequently than other penicillins, but many ampicillin (and other beta-lactam) rashes are not allergic in origin. The nonallergic ampicillin rash usually occurs after 3–4 days of therapy, is maculopapular, is more common in patients with coexisting viral illness (especially Epstein-Barr infection), and resolves with continued therapy. The maculopapular rash may or may not reappear with rechallenge. Beta-lactams can induce nephritis with primary tubular lesions associated with anti-basement membrane antibodies.

If the intradermal test described below is negative, desensitization is not necessary, and a full dose of the penicillin may be given. If the test is positive, alternative medications should be strongly considered. If that is not feasible, desensitization is necessary.

Patients with a history of allergy to penicillin are also at an increased risk for having a reaction to cephalosporins or carbapenems. A common approach to these patients is to assess the severity of the reaction. If an IgE-mediated reaction to penicillin can be excluded by history, a cephalosporin can be administered. When the history justifies concern about an immediate-type reaction, penicillin skin testing should be performed. If the test is negative, the cephalosporin or carbapenem can be given. If the test is positive, there is a 5–10% chance of cross reactivity with cephalosporins, and the decision whether to use cephalosporins depends on the availability of alternative agents and the severity of the infection. While carbapenems historically have been considered highly cross reactive with penicillins, the cross reactivity appears to be minimal (1%).

IMMUNIZATION AGAINST INFECTIOUS DISEASES

RECOMMENDED IMMUNIZATION FOR ADULTS

Immunization is one of the most important tools (along with sanitation) used to prevent morbidity and mortality from infectious diseases. In general, the administration of most vaccinations induces a durable antibody response (**active immunity**). In contrast, **passive immunization** occurs when preformed antibodies are given (eg, immune globulin from pooled serum), resulting in temporary protection which is a less durable response. The two variants of active immunization are **live attenuated vaccines** (which are believed to result in an immunologic response more like natural infection), and **inactivated or killed vaccines.**

The schedule of vaccinations varies based on the risk of the disease being prevented by vaccination, whether a vaccine has been given previously, the immune status of the patient (probability of responding to vaccine) and safety of the vaccine (live versus killed product, as well as implications for the fetus in pregnant women). Recommendations for healthy adults as well as special populations based on medical conditions are summarized in Table 30–7, which can be accessed online at https://www.cdc.gov/vaccines/schedules.

Table 30–7. Recommended adult immunization schedule—United States, 2019.

Recommended Adult Immunization Schedule by Age Group United States, 2019

Vaccine	19–21 years	22–26 years	27–49 years	50–64 years	≥65 years
Influenza inactivated (IIV) or **Influenza recombinant** (RIV)	🟨 1 dose annually	🟨	🟨	🟨	🟨

🟨 Recommended vaccination for adults who meet age requirement, lack documentation of vaccination, or lack evidence of past infection

🟪 Recommended vaccination for adults with an additional risk factor or another indication

🟧 Precaution—vaccine might be indicated if benefit of protection outweighs risk of adverse reaction

◼ Delay vaccination until after pregnancy if vaccine is indicated

🟥 Contraindicated—vaccine should not be administered because of risk for serious adverse reaction

⬜ No recommendation

1. Precaution for LAIV does not apply to alcoholism. **2.** See notes for influenza; hepatitis B; measles, mumps, and rubella; and varicella vaccinations. **3.** Hematopoietic stem cell transplant.

NOTES

***Haemophilus influenzae* type b vaccination**

Special situations

- **Anatomical or functional asplenia (including sickle cell disease):** 1 dose Hib if previously did not receive Hib; if elective splenectomy, 1 dose Hib, preferably at least 14 days before splenectomy
- **Hematopoietic stem cell transplant (HSCT):** 3-dose series Hib 4 weeks apart starting 6–12 months after successful transplant, regardless of Hib vaccination history

Hepatitis A vaccination

Routine vaccination

- **Not at risk but want protection from hepatitis A** (identification of risk factor not required): 2-dose series HepA (Havrix 6–12 months apart or Vaqta 6–18 months apart [minimum interval: 6 months]) or 3-dose series HepA-HepB (Twinrix at 0, 1, 6 months [minimum intervals: 4 weeks between doses 1 and 2, 5 months between doses 2 and 3])

Special situations

- **At risk for hepatitis A virus infection:** 2-dose series HepA or 3-dose series HepA-HepB as above
  - -Chronic liver disease
  - -Clotting factor disorders
  - -Men who have sex with men
  - -Injection or non-injection drug use
  - -Homelessness
  - -**Work with hepatitis A virus** in research laboratory or nonhuman primates with hepatitis A virus infection
  - -Travel in countries with high or intermediate endemic hepatitis A
  - -**Close personal contact with international adoptee** (e.g., household, regular babysitting) in first 60 days after arrival from country with high or intermediate endemic hepatitis A (administer dose 1 as soon as adoption is planned, at least 2 weeks before adoptee's arrival)

Hepatitis B vaccination

Routine vaccination

- **Not at risk but want protection from hepatitis B** (identification of risk factor not required): 2- or 3-dose series HepB (2-dose series Heplisav-B at least 4 weeks apart [2-dose series HepB only applies when 2 doses of Heplisav-B are used at least 4 weeks apart] or 3-dose series Engerix-B or Recombivax HB at 0, 1, 6 months [minimum intervals: 4 weeks between doses 1 and 2, 8 weeks between doses 2 and 3, 16 weeks between doses 1 and 3]) or 3-dose series HepA-HepB (Twinrix at 0, 1, 6 months [minimum intervals: 4 weeks between doses 1 and 2, 5 months between doses 2 and 3])

Special situations

- **At risk for hepatitis B virus infection:** 2-dose (Heplisav-B) or 3-dose (Engerix-B, Recombivax HB) series HepB, or 3-dose series HepA-HepB as above
  - -Hepatitis C virus infection
  - -**Chronic liver disease** (e.g., cirrhosis, fatty liver disease, alcoholic liver disease, autoimmune hepatitis, alanine aminotransferase [ALT] or aspartate aminotransferase [AST] level greater than twice upper limit of normal)
  - -HIV infection
  - -**Sexual exposure risk** (e.g., sex partners of hepatitis B surface antigen (HBsAg)-positive persons; sexually active persons not in mutually monogamous relationships, persons seeking evaluation or treatment for a sexually transmitted infection, men who have sex with men)
  - -Current or recent injection drug use
  - -**Percutaneous or mucosal risk for exposure to blood** (e.g., household contacts of HBsAg-positive persons; residents and staff of facilities for developmentally disabled persons; health care and public safety personnel with reasonably anticipated risk for exposure to blood or blood-contaminated body fluids; hemodialysis, peritoneal dialysis, home dialysis, and predialysis patients; persons with diabetes mellitus age younger than 60 years and, at discretion of treating clinician, those age 60 years or older)
  - -Incarcerated persons
  - -Travel in countries with high or intermediate endemic hepatitis B

Human papillomavirus vaccination

Routine vaccination

- **Females through age 26 years and males through age 21 years:** 2- or 3-dose series HPV vaccine depending on age at initial vaccination; males age 22 through 26 years may be vaccinated based on individual clinical decision (HPV vaccination routinely recommended at age 11–12 years)
- **Age 15 years or older at initial vaccination:** 3-dose series HPV vaccine at 0, 1–2, 6 months (minimum intervals: 4 weeks between doses 1 and 2, 12 weeks between doses 2 and 3, 5 months between doses 1 and 3; repeat dose if administered too soon)

- **Age 9 through 14 years at initial vaccination and received 1 dose, or 2 doses less than 5 months apart:** 1 dose HPV vaccine
- **Age 9 through 14 years at initial vaccination and received 2 doses at least 5 months apart:** HPV vaccination complete, no additional dose needed
- If completed valid vaccination series with any HPV vaccine, no additional doses needed

Special situations

- **Immunocompromising conditions (including HIV infection) through age 26 years:** 3-dose series HPV vaccine at 0, 1–2, 6 months as above
- **Men who have sex with men and transgender persons through age 26 years:** 2- or 3-dose series HPV vaccine depending on age at initial vaccination as above
- **Pregnancy through age 26 years:** HPV vaccination not recommended until after pregnancy; no intervention needed if vaccinated while pregnant; pregnancy testing not needed before vaccination

Influenza vaccination

Routine vaccination

- **Persons age 6 months or older:** 1 dose IIV, RIV, or LAIV appropriate for age and health status annually
- For additional guidance, see www.cdc.gov/flu/professionals/index.htm

Special situations

- **Egg allergy, hives only:** 1 dose IIV, RIV, or LAIV appropriate for age and health status annually
- **Egg allergy more severe than hives** (e.g., angioedema, respiratory distress): 1 dose IIV, RIV, or LAIV appropriate for age and health status annually in medical setting under supervision of health care provider who can recognize and manage severe allergic conditions
- **Immunocompromising conditions (including HIV infection), anatomical or functional asplenia, pregnant women, close contacts and caregivers of severely immunocompromised persons in protected environment, use of influenza antiviral medications in previous 48 hours, with cerebrospinal fluid leak or cochlear implant:** 1 dose IIV or RIV annually (LAIV not recommended)
- **History of Guillain-Barré syndrome within 6 weeks of previous dose of influenza vaccine:** Generally should not be vaccinated

Measles, mumps, and rubella vaccination

Routine vaccination

- **No evidence of immunity to measles, mumps, or rubella:** 1 dose MMR
  - Evidence of immunity: Born before 1957 (except health care personnel [see below]), documentation of receipt of MMR, laboratory evidence of immunity or disease (diagnosis of disease without laboratory confirmation is not evidence of immunity)

Special situations

- **Pregnancy with no evidence of immunity to rubella:** MMR contraindicated during pregnancy; after pregnancy (before discharge from health care facility), 1 dose MMR
- **Non-pregnant women of childbearing age with no evidence of immunity to rubella:** 1 dose MMR
- **HIV infection with CD4 count ≥200 cells/μL for at least 6 months and no evidence of immunity to measles, mumps, or rubella:** 2-dose series MMR at least 4 weeks apart; MMR contraindicated in HIV infection with CD4 count <200 cells/μL
- **Severe immunocompromising conditions:** MMR contraindicated
- **Students in postsecondary educational institutions, international travelers, and household or close personal contacts of immunocompromised persons with no evidence of immunity to measles, mumps, or rubella:** 1 dose MMR if previously received 1 dose MMR, or 2-dose series MMR at least 4 weeks apart if previously did not receive any MMR
- **Health care personnel born in 1957 or later with no evidence of immunity to measles, mumps, or rubella:** 2-dose series MMR at least 4 weeks apart for measles or mumps, or at least 1 dose MMR for rubella; if born before 1957, consider 2-dose series MMR at least 4 weeks apart for measles or mumps, or 1 dose MMR for rubella

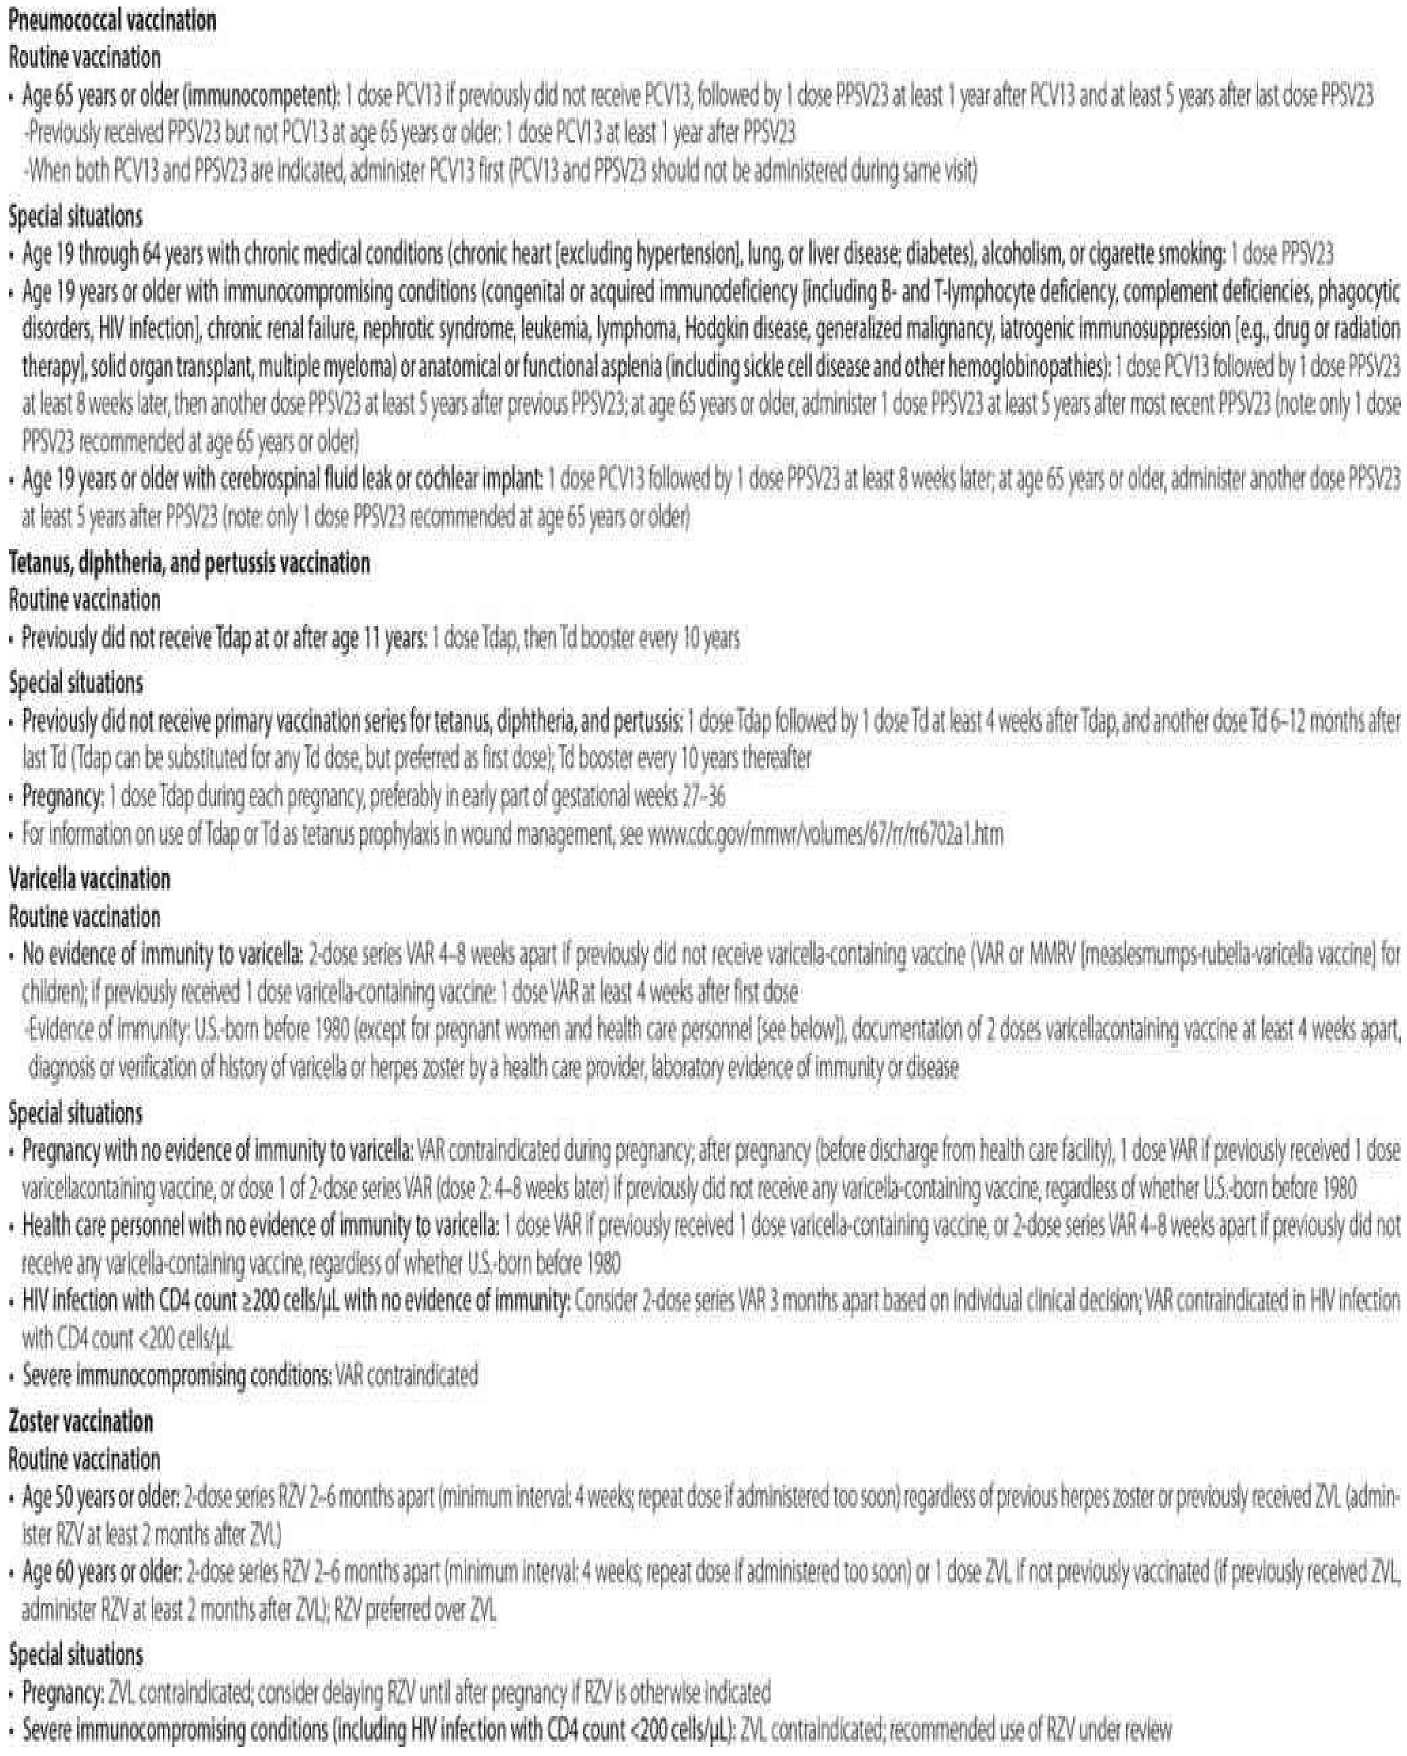
Meningococcal vaccination

Special situations for MenACWY

- **Anatomical or functional asplenia (including sickle cell disease), HIV infection, persistent complement component deficiency, eculizumab use:** 2-dose series MenACWY (Menactra, Menveo) at least 8 weeks apart and revaccinate every 5 years if risk remains
- **Travel in countries with hyperendemic or epidemic meningococcal disease, microbiologists routinely exposed to *Neisseria meningitidis*:** 1 dose MenACWY and revaccinate every 5 years if risk remains
- **First-year college students who live in residential housing (if not previously vaccinated at age 16 years or older) and military recruits:** 1 dose MenACWY

Special situations for MenB

- **Anatomical or functional asplenia (including sickle cell disease), persistent complement component deficiency, eculizumab use, microbiologists routinely exposed to *Neisseria meningitidis*:** 2-dose series MenB-4C (Bexsero) at least 1 month apart, or 3-dose series MenB-FHbp (Trumenba) at 0, 1–2, 6 months (if dose 2 was administered at least 6 months after dose 1, dose 3 not needed); MenB-4C and MenBFHbp are not interchangeable (use same product for all doses in series)
- **Pregnancy:** Delay MenB until after pregnancy unless at increased risk and vaccination benefit outweighs potential risks
- **Healthy adolescents and young adults age 16 through 23 years (age 16 through 18 years preferred) not at increased risk for meningococcal disease:** Based on individual clinical decision, may receive 2-dose series MenB-4C at least 1 month apart, or 2-dose series MenB-FHbp at 0, 6 months (if dose 2 was administered less than 6 months after dose 1, administer dose 3 at least 4 months after dose 2); MenB-4C and MenB-FHbp are not interchangeable (use same product for all doses in series)



Pneumococcal vaccination

Routine vaccination

- **Age 65 years or older (immunocompetent):** 1 dose PCV13 if previously did not receive PCV13, followed by 1 dose PPSV23 at least 1 year after PCV13 and at least 5 years after last dose PPSV23
  -Previously received PPSV23 but not PCV13 at age 65 years or older: 1 dose PCV13 at least 1 year after PPSV23
  -When both PCV13 and PPSV23 are indicated, administer PCV13 first (PCV13 and PPSV23 should not be administered during same visit)

Special situations

- **Age 19 through 64 years with chronic medical conditions (chronic heart [excluding hypertension], lung, or liver disease; diabetes), alcoholism, or cigarette smoking:** 1 dose PPSV23
- **Age 19 years or older with immunocompromising conditions (congenital or acquired immunodeficiency [including B- and T-lymphocyte deficiency, complement deficiencies, phagocytic disorders, HIV infection], chronic renal failure, nephrotic syndrome, leukemia, lymphoma, Hodgkin disease, generalized malignancy, iatrogenic immunosuppression [e.g., drug or radiation therapy], solid organ transplant, multiple myeloma) or anatomical or functional asplenia (including sickle cell disease and other hemoglobinopathies):** 1 dose PCV13 followed by 1 dose PPSV23 at least 8 weeks later, then another dose PPSV23 at least 5 years after previous PPSV23; at age 65 years or older, administer 1 dose PPSV23 at least 5 years after most recent PPSV23 (note: only 1 dose PPSV23 recommended at age 65 years or older)
- **Age 19 years or older with cerebrospinal fluid leak or cochlear implant:** 1 dose PCV13 followed by 1 dose PPSV23 at least 8 weeks later; at age 65 years or older, administer another dose PPSV23 at least 5 years after PPSV23 (note: only 1 dose PPSV23 recommended at age 65 years or older)

Tetanus, diphtheria, and pertussis vaccination

Routine vaccination

- **Previously did not receive Tdap at or after age 11 years:** 1 dose Tdap, then Td booster every 10 years

Special situations

- **Previously did not receive primary vaccination series for tetanus, diphtheria, and pertussis:** 1 dose Tdap followed by 1 dose Td at least 4 weeks after Tdap, and another dose Td 6–12 months after last Td (Tdap can be substituted for any Td dose, but preferred as first dose); Td booster every 10 years thereafter
- **Pregnancy:** 1 dose Tdap during each pregnancy, preferably in early part of gestational weeks 27–36
- For information on use of Tdap or Td as tetanus prophylaxis in wound management, see www.cdc.gov/mmwr/volumes/67/rr/rr6702a1.htm

Varicella vaccination

Routine vaccination

- **No evidence of immunity to varicella:** 2-dose series VAR 4–8 weeks apart if previously did not receive varicella-containing vaccine (VAR or MMRV [measlesmumps-rubella-varicella vaccine] for children); if previously received 1 dose varicella-containing vaccine: 1 dose VAR at least 4 weeks after first dose
  -Evidence of immunity: U.S.-born before 1980 (except for pregnant women and health care personnel [see below]), documentation of 2 doses varicellacontaining vaccine at least 4 weeks apart, diagnosis or verification of history of varicella or herpes zoster by a health care provider, laboratory evidence of immunity or disease

Special situations

- **Pregnancy with no evidence of immunity to varicella:** VAR contraindicated during pregnancy; after pregnancy (before discharge from health care facility), 1 dose VAR if previously received 1 dose varicellacontaining vaccine, or dose 1 of 2-dose series VAR (dose 2: 4–8 weeks later) if previously did not receive any varicella-containing vaccine, regardless of whether U.S.-born before 1980
- **Health care personnel with no evidence of immunity to varicella:** 1 dose VAR if previously received 1 dose varicella-containing vaccine, or 2-dose series VAR 4–8 weeks apart if previously did not receive any varicella-containing vaccine, regardless of whether U.S.-born before 1980
- **HIV infection with CD4 count ≥200 cells/μL with no evidence of immunity:** Consider 2-dose series VAR 3 months apart based on individual clinical decision; VAR contraindicated in HIV infection with CD4 count <200 cells/μL
- **Severe immunocompromising conditions:** VAR contraindicated

Zoster vaccination

Routine vaccination

- **Age 50 years or older:** 2-dose series RZV 2–6 months apart (minimum interval: 4 weeks; repeat dose if administered too soon) regardless of previous herpes zoster or previously received ZVL (administer RZV at least 2 months after ZVL)
- **Age 60 years or older:** 2-dose series RZV 2–6 months apart (minimum interval: 4 weeks; repeat dose if administered too soon) or 1 dose ZVL if not previously vaccinated (if previously received ZVL, administer RZV at least 2 months after ZVL); RZV preferred over ZVL

Special situations

- **Pregnancy:** ZVL contraindicated; consider delaying RZV until after pregnancy if RZV is otherwise indicated
- **Severe immunocompromising conditions (including HIV infection with CD4 count <200 cells/μL):** ZVL contraindicated; recommended use of RZV under review

1. Healthy Adults

Vaccination recommendations are made by the Advisory Committee on Immunization Practices (ACIP) of the US Centers for Disease Control and Prevention (Table 30–7).

2. Pregnant Women

Given the uncertainty of risks to the fetus, vaccination during pregnancy is generally avoided with the following exceptions: tetanus (transfer of maternal antibodies across the placenta is important to prevent neonatal tetanus), diphtheria, and influenza. Live vaccines are avoided during pregnancy.

Influenza can be a serious infection if acquired in pregnancy, and all pregnant women should be offered influenza (inactivated) vaccination. The live attenuated (intranasal) influenza vaccine is not recommended during pregnancy.

3. HIV-Infected Adults

HIV-infected patients have impaired cellular and B cell responses. Inactivated or killed vaccinations can generally be given without any consequence, but the recipient may not be able to mount an adequate antibody response. Live or attenuated vaccines are generally avoided with some exceptions (ie, in patients with $CD4^+$ T lymphocytes greater than 200 cells/mcL). Guidelines for vaccinating HIV-infected patients have been issued jointly by the Centers for Disease Control and Prevention, the US National Institutes of Health, and the HIV Medical Association of the Infectious Diseases Society of America. Timing of vaccination is important to optimize response. If possible, vaccination should be given early in the course of HIV disease or following immune reconstitution.

4. Hematopoietic Cell Transplant Recipients

Hematopoietic cell transplant (HCT) recipients have varying rates of immune reconstitution following transplantation, depending on (1) the type of chemotherapy or radiotherapy used pretransplant (in autologous HCT), (2) the preparative regimen used for the transplant, (3) whether graft-versus-host disease is present, and (4) the type of immunosuppression used posttransplantation (in allogeneic HCT). Vaccines may not work immediately in the posttransplant period. B cells may take 3–12 months to return to normal posttransplant, and naïve T cells that can respond to new antigens appear only 6–12 months posttransplant. B cells of posttransplant patients treated with rituximab may take up to 6 months to fully recover after the last dose of the medication. Vaccines are therefore administered 6–12 months following transplantation with a minimum of 1 month between doses to maximize the probability of response.

5. Solid Organ Transplant Recipients

Solid organ transplant recipients demonstrate a broad spectrum of immunosuppression, depending on the reason for and type of organ transplantation and the nature of the immunosuppression (including T-cell-depleting agents during treatment of organ rejection). These factors affect the propensity for infection posttransplantation and the ability to develop antibody responses to vaccination. In many cases, the time between placing a patient on a transplant list and undergoing the transplantation takes months or years. Providers should take this opportunity to ensure that indicated vaccines are given during this pretransplant period to optimize antibody responses. If this is not possible, most experts give vaccines 3–6 months following transplantation. Live vaccines are contraindicated in the posttransplant period.

RECOMMENDED IMMUNIZATIONS FOR TRAVELERS

Individuals traveling to other countries frequently require immunizations in addition to those routinely recommended and may benefit from chemoprophylaxis against various diseases. Vaccinations against yellow fever and meningococcus are the only ones required by certain countries. These and other travel-specific vaccines are listed at http://wwwnc.cdc.gov/travel/destinations/list.

Various vaccines can be given simultaneously at different sites. Some, such as cholera, plague, and typhoid vaccine, cause significant discomfort and are best given at different times. In general, live attenuated vaccines (measles, mumps, rubella, yellow fever, and oral typhoid vaccine) should not be given to immunosuppressed individuals or household members of immunosuppressed people or to pregnant women. Immunoglobulin should not be given for 3 months before or at least 2 weeks after live virus vaccines, because it may attenuate the antibody response.

Chemoprophylaxis of malaria is discussed in Chapter 35.

VACCINE SAFETY

Most vaccines are safe to administer. In general, it is recommended that the use of live vaccines be avoided in immunocompromised patients, including pregnant women. Vaccines are generally not contraindicated in the following situations: mild, acute illness with low-grade fevers (less than 40.5°C); concurrent antibiotic therapy; soreness or redness at the site; and family history of adverse reactions to vaccinations. Absolute contraindications to vaccines are rare (Table 30–8).

Table 30–8. Adverse effects and contraindications to commonly used vaccines in adults (listed in alphabetical order).

Vaccine	Adverse Effects	Contraindications[1]
Haemophilus influenzae Type b (Hib)	Minimal Consist mainly of pain at the injection site	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Hepatitis A	Minimal Consist mainly of pain at the injection site	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Hepatitis B	Minimal Consist mainly of pain at the injection site	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Human papillomavirus	Minimal Consist mainly of mild to moderate localized pain, erythema, swelling Systemic reactions, mainly fever, seen in 4% of recipients	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component.
Influenza (intramuscular inactivated and intranasal live attenuated vaccines)	**Intramuscular, inactivated vaccine:** Local reactions (erythema and tenderness) at the site of injection are common, but fevers, chills, and malaise (which last in any case only 2–3 days) are rare. **Either inactivated or live attenuated vaccine:** A potential association between Guillain-Barré syndrome (3000–6000 cases per year in the United States, usually following respiratory infections) and vaccination with intramuscular, inactivated influenza vaccine has been reported (possibly, 1–2 persons per million persons vaccinated), but this rate is lower than the risk of the syndrome developing after influenza itself (given that approximately 750 persons per million adults are hospitalized annually with influenza, and many more cases remain as outpatients). Influenza vaccination may be associated with multiple false-positive serologic tests to HIV, HTLV-1, and hepatitis C, but it is self-limited, lasting 2–5 months.	Contraindication to both inactivated and live attenuated vaccine: History of Guillain-Barré syndrome, especially within 6 weeks of receiving a previous influenza vaccine. Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component, including egg protein.[2] Intranasal, live attenuated vaccine [FluMist] should not be used in: • People 50 years of age and over • Immunosuppressed individuals and those on immunosuppressive therapy • Household members of immunosuppressed individuals • Health care workers, or others with close contact with immunosuppressed persons • Presence of reactive airway disease (eg, asthma) or chronic underlying metabolic (eg, kidney), pulmonary, or heart diseases (use intramuscular inactivated vaccine) • Pregnancy[3] It is recommended that salicylates should be avoided for 6 weeks following vaccination (to prevent Reye syndrome).
Measles, mumps, and rubella (MMR)[4]	Fever will develop in about 5–15% of unimmunized individuals, and a mild rash will develop in about 5% 5–12 days after vaccination. Fever and rash are self-limited, lasting only 2–3 days. Local swelling and induration are particularly common in individuals previously vaccinated with inactivated vaccine.	Pregnancy[5] Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy [eg, > 2 weeks of prednisone 20 mg daily or higher]), other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised. May be used in asymptomatic HIV-infected individuals whose CD4 count is > 200/mcL. Severe allergic reaction (eg, anaphylaxis) to a previous dose or to a vaccine component (eg, neomycin or to related agents such as streptomycin).
Meningococcal, oligosaccharide conjugate; (MCV4 or MenACWY [Menactra, Menveo]; meningococcal polysaccharide conjugate MPSV4 [Menomune]); meningococcal group B, recombinant (MenB [Bexsero, Trumenba])	Minor reactions (fever, redness, swelling, erythema, pain) occur slightly more commonly with MCV4. Major reactions are rare. A potential association between Guillain-Barré syndrome (3000–6000 cases per year in the United States, usually following respiratory infections) and vaccination with MCV4 has been reported, but current recommendations favor continued use of MCV4, since the benefits of preventing the serious consequences of meningococcal infection outweigh the theoretical risk of Guillain-Barré syndrome.	Any severe allergic reaction (eg, anaphylaxis) to a previous dose or to a vaccine component (eg, persons with history of adverse reaction to diphtheria toxoid should not receive meningococcal oligosaccharide conjugate and polysaccharide conjugate vaccines since the protein conjugate used in them is diphtheria toxoid).

Pneumococcal conjugate (PCV13 [Prevnar]); Pneumococcal polysaccharide (PPSV23) [Pneumovax])	Mild local reactions (erythema and tenderness) occur in up to 50% of recipients, but systemic reactions are uncommon. Similarly, revaccination at least 5 years after initial vaccination is associated with mild self-limited local but not systemic reactions.	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, for PCV13 to any vaccine containing diphtheria toxoid).
Tetanus, diphtheria, and pertussis (DTP, Tdap); tetanus, diphtheria (Td)	Minimal Consist mainly of pain at the injection site	Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component. For pertussis-containing vaccines: any history of unexplained encephalopathy (eg, coma, decreased level of consciousness, or prolonged seizures) within 7 days of administration of a previous dose of Tdap or diphtheria and tetanus toxoids and pertussis (DTP) or diphtheria and tetanus toxoids and acellular pertussis (Tdap) vaccine.
Varicella	Can occur as late as 4–6 weeks after vaccination. Tenderness and erythema at the injection site are seen in 25%, fever in 10–15%, and a localized maculopapular or vesicular rash in 5%; a diffuse rash, usually with five or fewer vesicular lesions, develops in a smaller percentage. Spread of virus from vaccinees to susceptible individuals is possible, but the risk of such transmission even to immunocompromised patients is small, and disease, when it develops, is mild and treatable with acyclovir.	Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy [eg, > 2 weeks of prednisone 20 mg daily or higher; other immunosuppressive medications], other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised). Pregnancy. Severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, neomycin). For theoretic reasons, it is recommended that salicylates should be avoided for 6 weeks following vaccination (to prevent potential for Reye syndrome).
Zoster	Mild and limited to local reactions Although it is theoretically possible to transmit the virus to susceptible contacts, no such cases have been reported.	Known severe immunodeficiency (eg, from hematologic and solid cancers, receipt of chemotherapy, congenital immunodeficiency, long-term immunosuppressive therapy [eg, > 2 weeks of prednisone 20 mg daily or higher; other immunosuppressive medications], other disease- or therapy-related immune suppression, or patients with HIV infection who are severely immunocompromised. May be used in asymptomatic HIV-infected individuals whose CD4 count is > 200/mcL). Pregnancy. Any severe allergic reaction (eg, anaphylaxis) after a previous dose or to a vaccine component (eg, gelatin or neomycin).

Appendix A. Epidemiology and prevention of vaccine preventable diseases. 13th edition. Washington, DC, Public Health Foundation, 2015. Available at www.cdc.gov/vaccines/pubs/pinkbook/index.html.

[2] The vaccine has typically been prepared using embryonated chicken eggs. However, a new vaccine using mammalian cell culture is now FDA approved.

[3] The inactivated influenza vaccine can be given during any trimester.

[4] MMR vaccine can be safely given to patients with a history of egg allergy even when severe.

[5] Although vaccination of pregnant women is *not* recommended, with the currently available RA27/3 vaccine strain, the congenital rubella syndrome does not occur in the offspring of those inadvertently vaccinated during pregnancy or within 3 months before conception.

HIV Infection & AIDS

Mitchell H. Katz, MD

ESSENTIALS OF DIAGNOSIS

- Modes of transmission: sexual contact with an infected person, parenteral exposure to infected blood (transfusion or needle sharing), perinatal exposure.
- Prominent systemic complaints: sweats, diarrhea, weight loss, and wasting.
- Opportunistic infections due to diminished cellular immunity—often life-threatening.
- Aggressive cancers, particularly non-Hodgkin lymphoma.
- Neurologic manifestations, including dementia, aseptic meningitis, and neuropathy.

General Considerations

The Centers for Disease Control and Prevention (CDC) AIDS case definition (Table 31–1) includes opportunistic infections and malignancies that rarely occur in the absence of severe immunodeficiency (eg, Pneumocystis pneumonia, central nervous system lymphoma). It also classifies persons as having AIDS if they have positive HIV serology and certain infections and malignancies that can occur in immunocompetent hosts but that are more common among persons infected with HIV (pulmonary tuberculosis, invasive cervical cancer). Several nonspecific conditions, including dementia and wasting (documented weight loss)—in the presence of a positive HIV serology—are considered AIDS. The definition includes criteria for both definitive and presumptive diagnoses of certain infections and malignancies. Finally, persons with positive HIV serology who have ever had a CD4 lymphocyte count below 200 cells/mcL or a CD4 lymphocyte percentage below 14% are considered to have AIDS. Inclusion of persons with low CD4 counts as AIDS cases reflects the recognition that immunodeficiency is the defining characteristic of AIDS. The choice of a cutoff point at 200 cells/mcL is supported by several cohort studies showing that AIDS will develop within 3 years in over 80% of persons with counts below this level in the absence of effective antiretroviral therapy. The prognosis of persons with HIV/AIDS has dramatically improved due to the development of effective antiretroviral treatment. One consequence is that fewer persons with HIV ever develop an infection or malignancy or have a low enough CD4 count to classify them as having AIDS, which means that the

CDC definition has become a less useful measure of the impact of HIV/AIDS in the United States. Conversely, persons in whom AIDS had been diagnosed based on a serious opportunistic infection, malignancy, or immunodeficiency may now be markedly healthier, with high CD4 counts, due to the use of antiretroviral treatment. Therefore, the Social Security Administration as well as most social service agencies focus on functional assessment for determining eligibility for benefits rather than the simple presence or absence of an AIDS-defining illness.

Table 31–1. CDC AIDS case definition for surveillance of adults and adolescents.

Definitive AIDS Diagnoses (with or without laboratory evidence of HIV infection)

1. Candidiasis of the esophagus, trachea, bronchi, or lungs.
2. Cryptococcosis, extrapulmonary.
3. Cryptosporidiosis with diarrhea persisting longer than 1 month.
4. Cytomegalovirus disease of an organ other than liver, spleen, or lymph nodes.
5. Herpes simplex virus infection causing a mucocutaneous ulcer that persists longer than 1 month; or bronchitis, pneumonitis, or esophagitis of any duration.
6. Kaposi sarcoma in a patient younger than 60 years of age.
7. Lymphoma of the brain (primary) in a patient younger than 60 years of age.
8. *Mycobacterium avium* complex or *Mycobacterium kansasii* disease, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes).
9. *Pneumocystis jirovecii* pneumonia.
10. Progressive multifocal leukoencephalopathy.
11. Toxoplasmosis of the brain.

Definitive AIDS Diagnoses (with laboratory evidence of HIV infection)

1. Coccidioidomycosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes).
2. HIV encephalopathy.
3. Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes).
4. Isosporiasis with diarrhea persisting longer than 1 month.
5. Kaposi sarcoma at any age.
6. Lymphoma of the brain (primary) at any age.
7. Other non-Hodgkin lymphoma of B cell or unknown immunologic phenotype.
8. Any mycobacterial disease caused by mycobacteria other than *Mycobacterium tuberculosis*, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes).
9. Disease caused by extrapulmonary *M tuberculosis*.
10. Salmonella (nontyphoid) septicemia, recurrent.
11. HIV wasting syndrome.
12. CD4 lymphocyte count below 200 cells/mcL or a CD4 lymphocyte percentage below 14%.
13. Pulmonary tuberculosis.
14. Recurrent pneumonia.
15. Invasive cervical cancer.

Presumptive AIDS Diagnoses (with laboratory evidence of HIV infection)

1. Candidiasis of esophagus: (a) recent onset of retrosternal pain on swallowing; and (b) oral candidiasis.
2. Cytomegalovirus retinitis. A characteristic appearance on serial ophthalmoscopic examinations.
3. Mycobacteriosis. Specimen from stool or normally sterile body fluids or tissue from a site other than lungs, skin, or cervical or hilar lymph nodes, showing acid-fast bacilli of a species not identified by culture.
4. Kaposi sarcoma. Erythematous or violaceous plaque-like lesion on skin or mucous membrane.
5. *Pneumocystis jirovecii* pneumonia: (a) a history of dyspnea on exertion or nonproductive cough of recent onset (within the past 3 months); and (b) chest film evidence of diffuse bilateral interstitial infiltrates or gallium scan evidence of diffuse bilateral pulmonary disease; and (c) arterial blood gas analysis showing an arterial oxygen partial pressure of less than 70 mm Hg or a low respiratory diffusing capacity of less than 80% of predicted values or an increase in the alveolar-arterial oxygen tension gradient; and (d) no evidence of a bacterial pneumonia.
6. Toxoplasmosis of the brain: (a) recent onset of a focal neurologic abnormality consistent with intracranial disease or a reduced level of consciousness; and (b) brain imaging evidence of a lesion having a mass effect or the radiographic appearance of which is enhanced by injection of contrast medium; and (c) serum antibody to toxoplasmosis or successful response to therapy for toxoplasmosis.
7. Recurrent pneumonia: (a) more than one episode in a 1-year period; and (b) acute pneumonia (new symptoms, signs, or radiologic evidence not present earlier) diagnosed on clinical or radiologic grounds by the patient's clinician.
8. Pulmonary tuberculosis: (a) apical or miliary infiltrates and (b) radiographic and clinical response to antituberculous therapy.

Epidemiology

The modes of transmission of HIV are similar to those of hepatitis B, in particular with respect to sexual, parenteral, and vertical transmission. Although certain sexual practices (eg, receptive anal intercourse) are significantly riskier than other sexual practices (eg, oral sex), it is difficult to quantify per-contact risks. The reason is that studies of sexual transmission of HIV show that most people at risk for HIV infection engage in a variety of sexual practices and have sex with multiple persons, only some of whom may actually be HIV infected. Thus, it is difficult to determine which practice with which person actually resulted in HIV transmission.

Nonetheless, the best available estimates indicate that the risk of HIV transmission with receptive anal intercourse is between 1:100 and 1:30, with insertive anal intercourse 1:1000, with receptive vaginal intercourse 1:1000, with insertive vaginal intercourse 1:10,000, and with receptive fellatio with ejaculation 1:1000. The per-contact risk of HIV transmission with other behaviors, including receptive fellatio without ejaculation, insertive fellatio, and cunnilingus, is not known.

A number of cofactors are known to increase the risk of HIV transmission during a given encounter, including the presence of ulcerative or inflammatory sexually transmitted diseases, trauma, menses, and lack of male circumcision.

The risk of acquiring HIV infection from a needlestick with infected blood is approximately 1:300. Factors known to increase the risk of transmission include depth of penetration, hollow bore needles, visible blood on the needle, and advanced stage of disease in the source. The risk of HIV transmission from a mucosal splash with infected blood is unknown but is assumed to be significantly lower.

The risk of acquiring HIV infection from illicit drug use with sharing of needles from an HIV-infected source is estimated to be 1:150. Use of clean needles markedly decreases the chance of HIV transmission, but does not eliminate it if other drug paraphernalia are shared (eg, cookers).

When blood transfusion from an HIV-infected donor occurs, the risk of transmission is 95%. Fortunately, since 1985, blood donor screening using the HIV enzyme-linked immunosorbent assay (ELISA) has been universally practiced in the United States. Also, persons who have recently engaged in unsafe behaviors (eg, sex with a person at risk for HIV, injection drug use) are not allowed to donate. This essentially eliminates donations from persons who are HIV infected but have not yet developed antibodies (ie, persons in the “window” period). HIV antigen and viral load testing have been added to the screening of blood to further lower the chance of HIV transmission. With these precautions, the chance of HIV transmission with receipt of blood transfusion in the United States is about 1:1,000,000. Between 13% and 40% of children born to HIV-infected mothers contract HIV infection when the mother has not received treatment or when the child has not received perinatal HIV prophylaxis. The risk is higher with vaginal than with cesarean delivery, higher among mothers with high viral loads, and higher among those who breast-feed their children. The combination of prenatal HIV testing and counseling, antiretroviral treatment for infected mothers during pregnancy and for the infant immediately after birth, scheduled cesarean delivery when the mother has a viral load of greater than 1000 copies/mL, and avoidance of breastfeeding has reduced the rate of perinatal transmission of HIV to less than 2% in the United States and Europe.

HIV has not been shown to be transmitted by respiratory droplet spread, by vectors such as mosquitoes, or by casual nonsexual contact. Saliva, sweat, stool, and tears are not considered infectious fluids.

Since the epidemic began in the early 1980s, a total of 1,232,346 Americans have been diagnosed with AIDS. There are an estimated 1.1 million adults and adolescents in the United States living with HIV, 15% of whom are undiagnosed. Young people (age 13 to 24) are the most likely to not know they are infected (51%). In 2016, 39,782 Americans were newly diagnosed with HIV infection. Gay and bisexual men accounted for most of the new diagnoses (67%), and among them, black/African-American men accounted for more new diagnoses (10,223) than Latinos (7425) or whites (7390). Between 2011 and 2015, new HIV diagnoses decreased by 10% among white gay and bisexual males, but increased 4% among African-American gay and bisexual males, and 14% among Latino gay and bisexual men. Heterosexual contacts accounted for 24% (9578) of new HIV diagnoses, women accounted for 19% (7529) and injection drug users for 9% (3425) of new HIV diagnoses, including gay and bisexual men who inject drugs. In 2016, African Americans and Latinos were disproportionately hard hit by the epidemic. Though representing 12% of the US population, African Americans accounted for 44% of new HIV diagnoses (17,528 cases). Latinos, who represent about 18% of the US population, accounted for 25% of new HIV diagnoses (9766 cases).

In general, the progression of HIV-related illness is similar in men and women. However, there are some important differences. Women are at risk for gynecologic complications of HIV, including recurrent candidal vaginitis, pelvic inflammatory disease, and cervical dysplasia. Violence directed against women, pregnancy, and frequent occurrence of drug use and poverty all complicate the treatment of HIV-infected women.

Worldwide there are an estimated 36.9 million persons infected with HIV, with heterosexual spread being the most common mode of transmission for men and women. The reason for the greater risk for transmission with heterosexual intercourse in Africa and Asia than in the United States may relate to cofactors such as general health status, the presence of genital ulcers, relative lack of male circumcision, the number of sexual partners, and different HIV serotypes. It is estimated that in 2016, 19.5 million persons infected with HIV were receiving treatment (53%), up from 17.1 million in 2015.

Pathophysiology

Clinically, the syndromes caused by HIV infection are usually explicable by one of three known mechanisms: immunodeficiency, autoimmunity, and allergic and hypersensitivity reactions.

A. Immunodeficiency

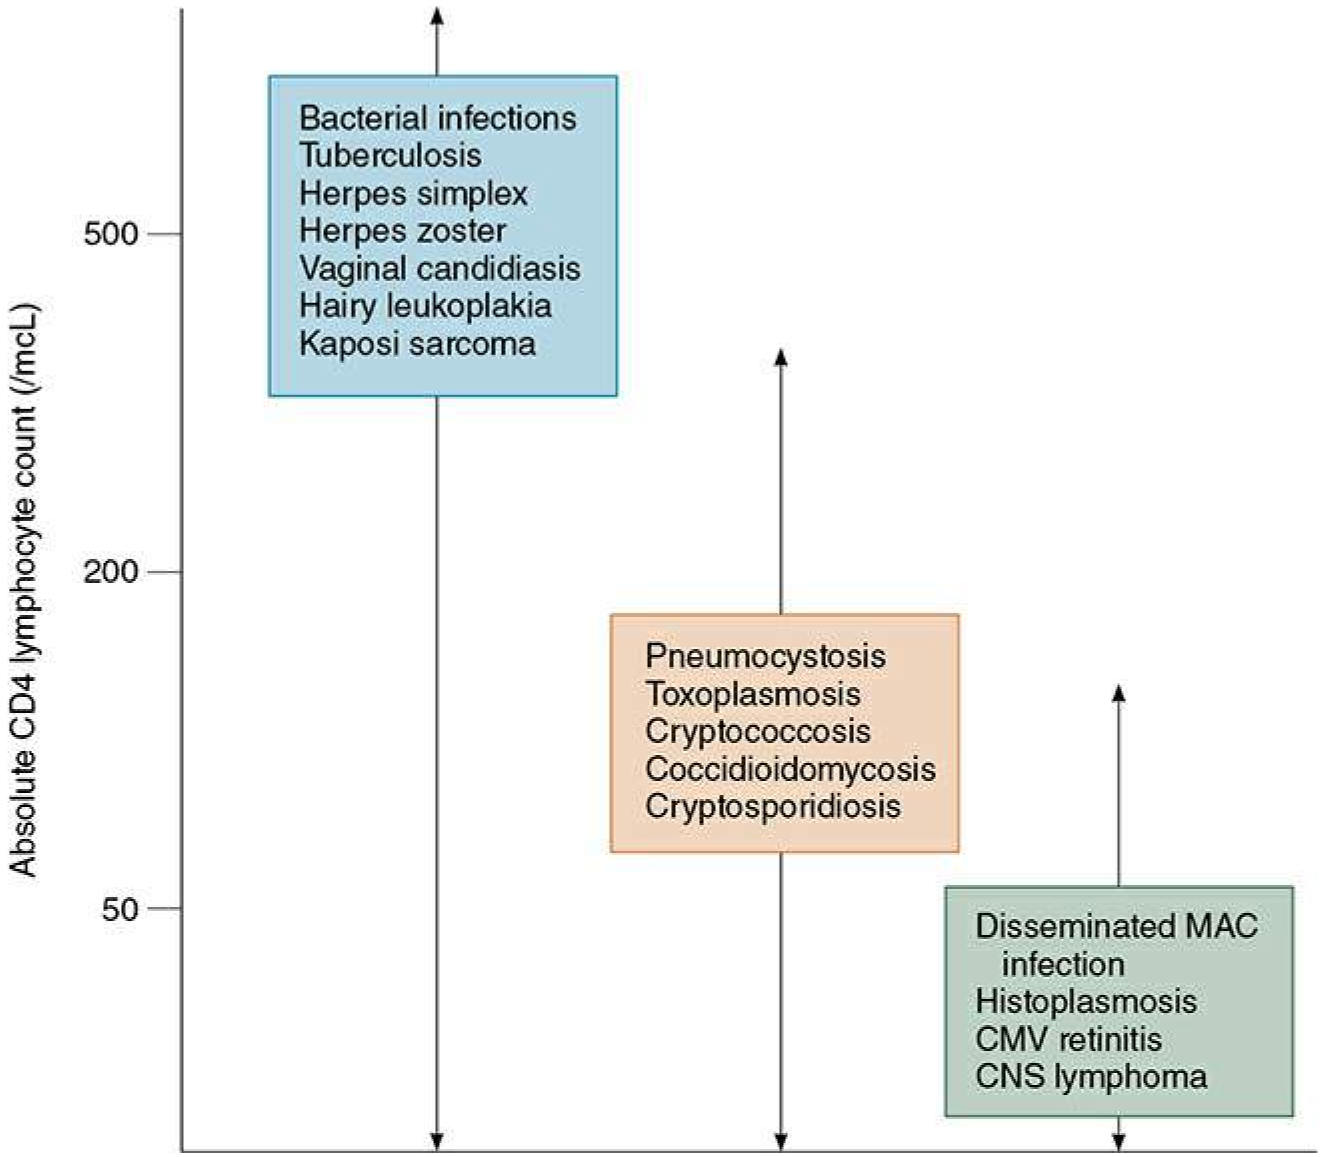
Immunodeficiency is a direct result of the effects of HIV upon immune cells as well as the indirect impact of a generalized state of inflammation and immune activation due to chronic viral infection. A spectrum of infections and neoplasms is seen, as in other congenital or acquired immunodeficiency states. Two remarkable features of HIV immunodeficiency are the low incidence of certain infections such as listeriosis and aspergillosis and the frequent occurrence of certain neoplasms such as lymphoma or Kaposi sarcoma. This latter complication has been seen primarily in men who have sex with men (MSM) or in bisexual men, and its incidence steadily declined through the first 15 years of the epidemic. A herpesvirus (KSHV or HHV-8) is the cause of Kaposi sarcoma.

B. Autoimmunity/Allergic and Hypersensitivity Reactions

Autoimmunity can occur as a result of disordered cellular immune function or B lymphocyte dysfunction. Examples of both lymphocytic infiltration of organs (eg, lymphocytic interstitial pneumonitis) and autoantibody production (eg, immunologic thrombocytopenia) occur. These phenomena may be the only clinically apparent disease or may coexist with obvious immunodeficiency. Moreover, HIV-infected individuals appear to have higher rates of allergic reactions to unknown allergens as seen with eosinophilic pustular folliculitis ("itchy red bump syndrome") as well as increased rates of hypersensitivity reactions to medications (for example, the fever and sunburn-like rash seen with trimethoprim-sulfamethoxazole reactions).

Clinical Findings

The complications of HIV-related infections and neoplasms affect virtually every organ. The general approach to the HIV-infected person with symptoms is to evaluate the organ systems involved, aiming to diagnose treatable conditions rapidly. As can be seen in Figure 31–1, the CD4 lymphocyte count result enables the clinician to focus on the diagnoses most likely to be seen at each stage of immunodeficiency. Certain infections may occur at any CD4 count, while others rarely occur unless the CD4 lymphocyte count has dropped below a certain level. For example, a patient with a CD4 count of 600 cells/mcL, cough, and fever may have a bacterial pneumonia but would be very unlikely to have Pneumocystis pneumonia.



▲ **Figure 31–1. Relationship of CD4 count to development of opportunistic infections. MAC, Mycobacterium avium complex; CMV, cytomegalovirus; CNS, central nervous system.**

A. Symptoms and Signs

Many individuals with HIV infection remain asymptomatic for years even without antiretroviral treatment, with a mean time of approximately 10 years between infection and development of AIDS. When symptoms occur, they may be remarkably protean and nonspecific. Since virtually all the findings may be seen with other diseases, a combination of complaints is more suggestive of HIV infection than any one symptom.

Physical examination may be entirely normal. Abnormal findings range from completely nonspecific to highly specific for HIV infection. Those that are specific for HIV infection include hairy leukoplakia of the tongue, disseminated Kaposi sarcoma, and cutaneous bacillary angiomatosis. Generalized lymphadenopathy is common early in infection.

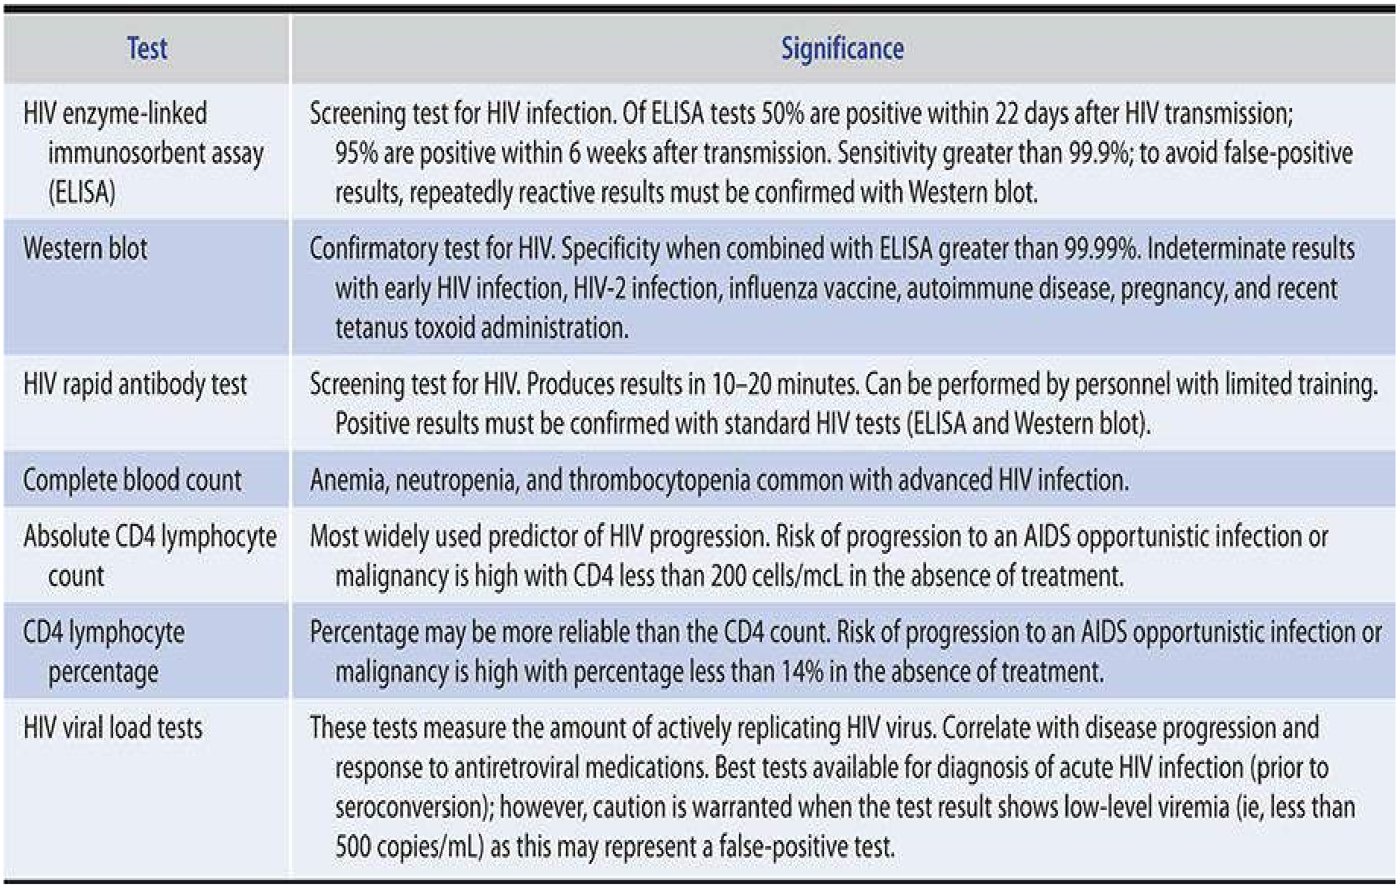
The specific presentations and management of the various complications of HIV infection are discussed under the Complications section below.

Henn A et al. Primary HIV infection: clinical presentation, testing, and treatment. Curr Infect Dis Rep. 2017 Sep 7; 19(10):37. [PMID: 28884279]

B. Laboratory Findings

Specific tests for HIV include antibody and antigen detection (Table 31–2). Conventional HIV antibody testing is done by ELISA. Positive specimens are then confirmed by a different method (eg, Western blot). The sensitivity of screening serologic tests is greater than 99.9%. The specificity of positive results by two different techniques approaches 100% even in low-risk populations. False-positive screening tests may occur as normal biologic variants or in association with recent influenza vaccination or other disease states, such as connective tissue disease. These are usually detected by negative confirmatory tests. Antibodies will be detectable with current screening serologic tests in 95% of persons within 6 weeks after infection.

Table 31–2. Laboratory findings with HIV infection.



Test	Significance
HIV enzyme-linked immunosorbent assay (ELISA)	Screening test for HIV infection. Of ELISA tests 50% are positive within 22 days after HIV transmission; 95% are positive within 6 weeks after transmission. Sensitivity greater than 99.9%; to avoid false-positive results, repeatedly reactive results must be confirmed with Western blot.
Western blot	Confirmatory test for HIV. Specificity when combined with ELISA greater than 99.99%. Indeterminate results with early HIV infection, HIV-2 infection, influenza vaccine, autoimmune disease, pregnancy, and recent tetanus toxoid administration.
HIV rapid antibody test	Screening test for HIV. Produces results in 10–20 minutes. Can be performed by personnel with limited training. Positive results must be confirmed with standard HIV tests (ELISA and Western blot).
Complete blood count	Anemia, neutropenia, and thrombocytopenia common with advanced HIV infection.
Absolute CD4 lymphocyte count	Most widely used predictor of HIV progression. Risk of progression to an AIDS opportunistic infection or malignancy is high with CD4 less than 200 cells/mcL in the absence of treatment.
CD4 lymphocyte percentage	Percentage may be more reliable than the CD4 count. Risk of progression to an AIDS opportunistic infection or malignancy is high with percentage less than 14% in the absence of treatment.
HIV viral load tests	These tests measure the amount of actively replicating HIV virus. Correlate with disease progression and response to antiretroviral medications. Best tests available for diagnosis of acute HIV infection (prior to seroconversion); however, caution is warranted when the test result shows low-level viremia (ie, less than 500 copies/mL) as this may represent a false-positive test.

Rapid HIV antibody tests of blood or oral fluid provide results within 10–20 minutes and can be performed in clinician offices, including by personnel without laboratory training and without a Clinical Laboratory Improvement Amendment (CLIA)–approved laboratory. Persons who test positive on a rapid test should be told that they may be HIV-infected or their test may be falsely reactive. Standard testing (ELISA with Western blot confirmation) should be performed to distinguish these two possibilities. Rapid testing is particularly helpful in settings where a result is needed immediately (eg, a woman in labor who has not recently been tested for HIV) or when the patient is unlikely to return for a result. Rapid HIV home tests that allow the testers to learn their status privately by simply swabbing along their gum lines are also available (www.oraquick.com).

Nonspecific laboratory findings with HIV infection may include anemia, leukopenia (particularly lymphopenia), and thrombocytopenia in any combination, elevation of the erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and hypocholesterolemia. Cutaneous anergy is common.

The absolute CD4 lymphocyte count is the most widely used marker to provide prognostic information and to guide therapy decisions (Table 31–2). As counts decrease, the risk of serious opportunistic infection over the subsequent 3–5 years increases (Figure 31–1). There are many limitations to using the CD4 count, including diurnal variation, depression with intercurrent illness, and intra-laboratory and interlaboratory variability. Therefore, the trend is more important than a single determination. The frequency of performance of counts depends on the patient's health status and whether or not they are receiving antiretroviral treatment. All patients regardless of CD4 count should be offered antiretroviral treatment; CD4 counts should be monitored every 3–6 months in patients taking antiretroviral treatment consistently. Initiation of Pneumocystis jirovecii prophylactic therapy is recommended when the CD4 count drops below 200 cells/mcL, and initiation of Mycobacterium avium prophylaxis is recommended when the CD4 count drops below 75–100 cells/mcL. Some studies suggest that the percentage of CD4 lymphocytes is a more reliable indicator of prognosis than the absolute counts because the percentage does not depend on calculating a manual differential. While the CD4 count measures immune dysfunction, it does not provide a measure of how actively HIV is replicating in the body. **HIV viral load** tests assess the level of viral replication and provide useful prognostic information that is independent of the information provided by CD4 counts.

Differential Diagnosis

HIV infection may mimic a variety of other medical illnesses. Specific differential diagnosis depends on the mode of presentation. In patients presenting with constitutional symptoms such as weight loss and fevers, differential considerations include cancer, chronic infections such as tuberculosis and endocarditis, and endocrinologic diseases such as hyperthyroidism. When pulmonary processes dominate the presentation, acute and chronic lung infections must be considered as well as other causes of diffuse interstitial pulmonary infiltrates. When neurologic disease is the mode of presentation, conditions that cause mental status changes or neuropathy—eg, alcoholism, liver disease, kidney dysfunction, thyroid disease, and vitamin deficiency—should be considered. If a patient presents with headache and a cerebrospinal fluid pleocytosis, other causes of chronic meningitis enter the differential. When diarrhea is a prominent complaint, infectious enterocolitis, antibiotic-associated colitis, inflammatory bowel disease, and malabsorptive syndromes must be considered.

Complications

A. Systemic Complaints

Fever, night sweats, and weight loss are common symptoms in HIV-infected patients and may occur without a complicating opportunistic infection. Patients with persistent fever and no localizing symptoms should nonetheless be carefully examined, and evaluated with a chest radiograph (Pneumocystis pneumonia can present without respiratory symptoms), bacterial blood cultures if the fever is greater than 38.5°C, serum cryptococcal antigen, and mycobacterial cultures of the blood. Sinus CT scans should be considered to evaluate occult sinusitis. If these studies are normal, patients should be observed closely. Antipyretics are useful to prevent dehydration.

Bolduc P et al. Care of patients with HIV infection: medical complications and comorbidities. FP Essent. 2016 Apr;443:16–22. [PMID: 27092563]
Chu C et al. HIV-associated complications: a systems-based approach. Am Fam Physician. 2017 Aug 1;96(3):161–9. [PMID: 28762691]

1. Weight loss and wasting syndrome—Weight loss is a particularly distressing complication of long-standing HIV infection. Patients typically have disproportionate loss of muscle mass, with maintenance or less substantial loss of fat stores. The mechanism of HIV-related weight loss is not completely understood but appears to be multifactorial.

A. PRESENTATION—AIDS patients frequently suffer from anorexia, nausea, and vomiting, all of which contribute to weight loss by decreasing caloric intake. In some cases, these symptoms are secondary to a specific infection, such as viral hepatitis. In other cases, however, evaluation of the symptoms yields no specific pathogen, and it is assumed to be due to a primary effect of HIV. Malabsorption also plays a role in decreased caloric intake. Patients may suffer diarrhea from infections with bacterial, viral, or parasitic agents.

Exacerbating the decrease in caloric intake, many AIDS patients have an increased metabolic rate. This increased rate has been shown to exist even among asymptomatic HIV-infected persons, but it accelerates with disease progression and secondary infection. AIDS patients with secondary infections also have decreased protein synthesis, which makes maintaining muscle mass difficult.

B. MANAGEMENT—Several strategies have been developed to slow AIDS wasting. In the long term, nothing is as effective as antiretroviral treatment, since it treats the underlying HIV infection. In the short term, effective fever control decreases the metabolic rate and may slow the pace of weight loss, as does treating the underlying opportunistic infection. Food supplementation with high-calorie drinks may enable patients with not much appetite to maintain their intake. Selected patients with otherwise good functional status and weight loss due to unrelenting nausea, vomiting, or diarrhea may benefit from total parenteral nutrition (TPN). It should be noted, however, that TPN is more likely to increase fat stores than to reverse the muscle wasting process.

Two pharmacologic approaches for increasing appetite and weight gain are the progestational agent **megestrol acetate** liquid suspension (400–800 mg orally daily in divided doses) and the antiemetic agent **dronabinol** (2.5–5 mg orally three times a day), but neither of these agents increases lean body mass. Side effects from megestrol acetate are rare, but thromboembolic phenomena, edema, nausea, vomiting, and rash have been reported. Euphoria, dizziness, paranoia, and somnolence and even nausea and vomiting have been reported in 3–10% of patients using dronabinol. Dronabinol contains only one of the active ingredients in marijuana, and many patients report better relief of nausea and improvement of appetite with **medical cannabis** (administered via smoking, vaporization, essential oils, or cooked in food). In the United States, 33 states have legalized medical marijuana, and 10 states and the District of Columbia have legalized recreational (nonmedical) use. However, the use and sale of marijuana are still illegal under federal law.

Two regimens that have resulted in increases in lean body mass are growth hormone and anabolic steroids. **Growth hormone** at a dose of 0.1 mg/kg/day (up to 6 mg) subcutaneously for 12 weeks has resulted in modest increases in lean body mass. Treatment with growth hormone can cost as much as $10,000 per month. **Anabolic steroids** also increase lean body mass among HIV-infected patients. They seem to work best for patients who are able to do weight training. The most commonly used regimens are testosterone enanthate or testosterone cypionate (100–200 mg intramuscularly every 2–4 weeks). Testosterone transdermal system (apply 5 mg system each evening) and testosterone gel (1%; apply a 5-g packet [50 mg testosterone] to clean, dry skin daily) are also available. The anabolic steroid oxandrolone (20 mg orally in two divided doses) has also been found to increase lean body mass.

Badowski ME et al. Dronabinol oral solution in the management of anorexia and weight loss in AIDS and cancer. Ther Clin Risk Manag. 2018 Apr 6;14:643–51. [PMID: 29670357]

2. Nausea—Nausea leading to weight loss is sometimes due to esophageal candidiasis. Patients with oral candidiasis and nausea should be empirically treated with an oral antifungal agent. Patients with weight loss due to nausea of unclear origin may benefit from use of antiemetics prior to meals (prochlorperazine, 10 mg three times daily; metoclopramide, 10 mg three times daily; or ondansetron, 8 mg three times daily). Dronabinol (5 mg three times daily) or medical cannabis can also be used to treat nausea. Depression and adrenal insufficiency are two potentially treatable causes of weight loss.

immunodeficiency virus/AIDS: an overview. Crit Care Nurs Clin North Am. 2018 Mar;30(1):101–7. [PMID: 29413205]

B. Pulmonary Disease

1. Pneumocystis pneumonia—(See also Chapter 36.) P jirovecii pneumonia is the most common opportunistic infection associated with AIDS. Pneumocystis pneumonia may be difficult to diagnose because the symptoms—fever, cough, and shortness of breath—are nonspecific. Furthermore, the severity of symptoms ranges from fever and no respiratory symptoms through mild cough or dyspnea to frank respiratory distress.

Hypoxemia may be severe, with a PO_2 less than 60 mm Hg. The cornerstone of diagnosis is the chest radiograph. Diffuse or perihilar infiltrates are most characteristic, but only two-thirds of patients with Pneumocystis pneumonia have this finding. Normal chest radiographs are seen in 5–10% of patients with Pneumocystis pneumonia, while the remainder have atypical infiltrates. Apical infiltrates are commonly seen among patients with Pneumocystis pneumonia who have been receiving aerosolized pentamidine prophylaxis. Large pleural effusions are uncommon with Pneumocystis pneumonia; their presence suggests bacterial pneumonia, other infections such as tuberculosis, or pleural Kaposi sarcoma.

Definitive diagnosis can be obtained in 50–80% of cases by Wright-Giemsa stain or direct fluorescence antibody (DFA) test of induced sputum. Sputum induction is performed by having patients inhale an aerosolized solution of 3% saline produced by an ultrasonic nebulizer. Patients should not eat for at least 8 hours and should not use toothpaste or mouthwash prior to the procedure since they can interfere with test interpretation. The next step for patients with negative sputum examinations in whom Pneumocystis pneumonia is still suspected should be bronchoalveolar lavage. This technique establishes the diagnosis in over 95% of cases.

In patients with symptoms suggestive of Pneumocystis pneumonia but with negative or atypical chest radiographs and negative sputum examinations, other diagnostic tests may provide additional information in deciding whether to proceed to bronchoalveolar lavage. Elevation of serum lactate dehydrogenase occurs in 95% of cases of Pneumocystis pneumonia, but the specificity of this finding is at best 75%. A serum beta-glucan test is a more sensitive and specific test for Pneumocystis pneumonia compared with serum lactate dehydrogenase and may avoid more invasive tests when used in the appropriate clinical setting. Either a normal diffusing capacity of carbon monoxide (DL_{CO}) or a high-resolution CT scan of the chest that demonstrates no interstitial lung disease makes the diagnosis of Pneumocystis pneumonia very unlikely. In addition, a CD4 count greater than 250 cells/mcL within 2 months prior to evaluation of respiratory symptoms makes a diagnosis of Pneumocystis pneumonia unlikely; only

1–5% of cases occur above this CD4 count level (Figure 31–1). This is true even if the patient previously had a CD4 count lower than 200 cells/mcL but has had an increase with antiretroviral treatment. Pneumothoraces can be seen in HIV-infected patients with a history of Pneumocystis pneumonia.

Trimethoprim-sulfamethoxazole is the preferred treatment of Pneumocystis pneumonia (Table 31–3). In addition to specific anti-Pneumocystis treatment, corticosteroid therapy has been shown to improve the course of patients with moderate to severe P jirovecii pneumonia (PaO_2 less than 70 mm Hg on room air or alveolar-arterial O_2 gradient greater or equal to 35 mm Hg) when administered within 72 hours of the start of anti-Pneumocystis treatment. It should be started as early as possible after initiation of treatment, using prednisone 40 mg orally twice daily for days 1–5, 40 mg daily for days 6–10, and 20 mg daily for days 11–21 (for patients who cannot take oral medication, intravenous methylprednisolone can be substituted at 75% of the dose). The mechanism of action is presumed to be a decrease in alveolar inflammation.

Table 31–3. Treatment of AIDS-related opportunistic infections and malignancies.[1]

Infection or Malignancy	Treatment	Complications[2]
Pneumocystis jirovecii infection[3]	Preferred regimen: Trimethoprim-sulfamethoxazole, 15 mg/kg/day (based on trimethoprim component) intravenously or one double-strength tablet orally three times a day for 21 days. Add prednisone when PaO_2 < 70 mm Hg on room air or alveolar-arterial O_2 gradient > 35 mm Hg: 40 mg orally twice a day on days 1–5, 40 mg orally daily on days 6–10, 20 mg orally daily on days 11–21	Nausea, neutropenia, anemia, hepatitis, rash, Stevens-Johnson syndrome
	Pentamidine, 3–4 mg/kg/day intravenously for 21 days plus prednisone when indicated as above	Hypotension, hypoglycemia, anemia, neutropenia, pancreatitis, hepatitis
	Primaquine, 30 mg/day orally, and clindamycin, 600 mg every 8 hours orally, for 21 days plus prednisone when indicated as above	Primaquine: hemolytic anemia in G6PD-deficient patients,[3] methemoglobinemia, neutropenia, colitis Clindamycin: rash, nausea, abdominal pain, colitis
	Not recommended for severe disease: Trimethoprim, 15 mg/kg/day orally in three divided doses, with dapsone, 100 mg/day orally, for 21 days,[3] plus prednisone when indicated as above	Nausea, rash, hemolytic anemia in G6PD[3]-deficient patients; methemoglobinemia (weekly levels should be less than 10% of total hemoglobin)
	Not recommended for severe disease: Atovaquone, 750 mg orally twice daily with food for 21 days, plus prednisone when indicated as above	Rash, elevated aminotransferases, anemia, neutropenia
Mycobacterium avium complex infection	Clarithromycin, 500 mg orally twice daily with ethambutol, 15 mg/kg/day orally (maximum, 1 g). May also add:	Clarithromycin: hepatitis, nausea, diarrhea Ethambutol: hepatitis, optic neuritis
	Rifabutin, 300 mg orally daily	Rash, hepatitis, uveitis
Toxoplasmosis	Preferred regimen: Pyrimethamine, 200 mg orally as loading dose, followed by 50 mg daily (weight ≤ 60 kg) or 75 mg daily (weight > 60 kg), combined with sulfadiazine, 1000 mg orally four times daily (weight ≤ 60 kg) or 1500 mg orally four times daily (weight > 60 kg) and leucovorin 10–25 mg orally daily for at least 6 weeks. Longer courses are necessary for extensive disease or incomplete clinical or radiographic resolution. Maintenance therapy with pyrimethamine 25–50 mg orally plus sulfadiazine 2000–4000 mg in two to four divided doses plus leucovorin 10–25 mg orally daily. Long-term treatment should be maintained until immune reconstitution with antiretroviral treatment occurs.	Pyrimethamine: leukopenia, anorexia, vomiting Sulfadiazine: nausea, vomiting, Stevens-Johnson syndrome
	For patients who are intolerant of sulfa who cannot be desensitized: Substitute clindamycin 600 mg intravenously or orally every 6 hours for the sulfadiazine in the above regimen	Pyrimethamine: leukopenia, anorexia, vomiting Clindamycin: rash, nausea, abdominal pain, colitis
	If pyrimethamine not available: Trimethoprim-sulfamethoxazole, 10 mg/kg/day (based on trimethoprim component)	Nausea, neutropenia, anemia, hepatitis, rash, Stevens-Johnson syndrome
Non-Hodgkin lymphoma	Combination chemotherapy (eg, EPOCH with rituximab and G-CSF) Central nervous system disease: Radiation treatment with dexamethasone for edema	Nausea, vomiting, anemia, neutropenia, thrombocytopenia, cardiac toxicity (with doxorubicin)
Cryptococcal meningitis	Preferred regimen: Liposomal amphotericin B, 3–4 mg/kg/day intravenously, with flucytosine, 25 mg/kg/dose orally four times daily for 2 weeks (adjust dose for kidney function), then fluconazole, 400 mg orally daily for 8 weeks, then 200 mg orally daily to complete 1 year of therapy	Liposomal amphotericin: fever, chills, hypokalemia, kidney disease Flucytosine: bone marrow suppression, kidney disease, hepatitis Fluconazole: hepatitis
	Amphotericin B, 0.7 mg/kg/day intravenously, with flucytosine, 25 mg/kg/dose orally four times daily for 2 weeks (adjust dose for kidney function), then fluconazole, 400 mg orally daily for 8 weeks, then 200 mg orally daily to complete 1 year of therapy	Amphotericin: fever, chills, hypokalemia, kidney disease Flucytosine: bone marrow suppression, kidney disease, hepatitis Fluconazole: hepatitis

	Fluconazole, used alone, is inferior to amphotericin B as induction therapy; it is recommended only for patients who cannot tolerate or do not respond to the preferred regimen above. If used for primary induction therapy, give fluconazole, 1200 mg orally daily for 2 weeks, then 400 mg orally daily for 8 weeks, then 200 mg orally daily to complete 1 year of therapy. Give with flucytosine, 25 mg/kg/dose orally four times daily for > 2 weeks (adjust dose for kidney function).	Hepatitis
Cytomegalovirus retinitis (immediate sight-threatening)	Preferred regimen: Intravitreal ganciclovir (2 mg/injection) or foscarnet (2.4 mg/injection) for 1–4 doses for 7–10 days plus valganciclovir, 900 mg orally twice a day with food for 14–21 days followed by 900 mg daily (maintenance)	Neutropenia, anemia, thrombocytopenia
	Ganciclovir, 10 mg/kg/day intravenously in two divided doses for 14 days, followed by 5 mg/kg daily or valganciclovir 900 mg orally daily (maintenance)	Neutropenia (especially when used concurrently with zidovudine), anemia, thrombocytopenia Adjust ganciclovir dose for kidney function
	Foscarnet, 60 mg/kg intravenously every 8 hours or 90 mg/kg intravenously every 12 hours for 14–21 days, followed by 90–120 mg/kg once daily	Nausea, hypokalemia, hypocalcemia, hyperphosphatemia, azotemia Adjust foscarnet dose for kidney function
	Cidofovir, 5 mg/kg/week intravenously for 2 weeks, then 5 mg/kg every other week with probenecid 2 g orally 3 hours before dose, 1 g orally 2 hours after dose, and 1 g orally 8 hours after dose	Nephrotoxicity (to reduce likelihood, pre- and post-saline hydration, along with probenecid), neutropenia Avoid in patients with sulfa allergy because of cross hypersensitivity with probenecid
Esophageal candidiasis or recurrent vaginal candidiasis	Fluconazole, 100–200 mg orally daily for 14–21 days for esophageal disease and > 7 days for recurrent vaginal disease	Hepatitis, development of azole resistance
Herpes simplex infection	Acyclovir, 400 mg orally three times daily for 5–10 days; or acyclovir, 5 mg/kg intravenously every 8 hours for severe cases	Resistant herpes simplex with long-term therapy
	Famciclovir, 500 mg orally twice daily for 5–10 days	Nausea
	Valacyclovir, 1 g orally twice daily for 5–10 days	Nausea
	Foscarnet, 40 mg/kg intravenously every 8 hours, for acyclovir-resistant cases	Nausea, hypokalemia, hypocalcemia, hyperphosphatemia, azotemia Adjust foscarnet dose for kidney function
Herpes zoster	Preferred regimen: Valacyclovir, 1000 mg orally three times daily for 7–10 days	Nausea
	Preferred regimen: Famciclovir, 500 mg orally three times daily for 7–10 days	Nausea
	Acyclovir, 800 mg orally five times daily for 7–10 days. Intravenous therapy at 10 mg/kg every 8 hours for extensive cutaneous or visceral disease until clinical improvement, then switch to oral therapy to complete a 10- to 14-day course. For ocular involvement, consult an ophthalmologist immediately.	Nausea
Kaposi sarcoma		
Mild to moderate	Initiation or optimization of antiretroviral treatment	Side effects of antiretroviral treatment
Advanced disease	Combination chemotherapy (eg, daunorubicin, bleomycin, vinblastine)	Bone marrow suppression, cardiac toxicity (with daunorubicin), fever

2. Other infectious pulmonary diseases—

A. PRESENTATION—Other infectious causes of pulmonary disease in AIDS patients include bacterial, mycobacterial, and viral pneumonias. Community-acquired pneumonia is the most common cause of pulmonary disease in HIV-infected persons. An increased incidence of pneumococcal pneumonia with septicemia and Haemophilus influenzae pneumonia has been reported. Pseudomonas aeruginosa is an important respiratory pathogen in advanced disease and, more rarely, pneumonia from Rhodococcus equi infection can occur. The incidence of infection with Mycobacterium tuberculosis has markedly increased in metropolitan areas because of HIV infection as well as homelessness. Tuberculosis occurs in an estimated 4% of persons in the United States who have AIDS. Patients with active tuberculosis and CD4 counts above 350 cells/mcL are likely to present with upper lobe and hilar and paratracheal adenopathy findings similar to persons uninfected with HIV. With advanced immunodeficiency, lower lobe, middle lobe, interstitial and miliary infiltrates are more common, along with mediastinal adenopathy and extrapulmonary involvement. Although a purified protein derivative (PPD) test or an **interferon gamma release assay** (**IGRA,** including the QuantiFERON and T-SPOT tests) should be performed on all HIV-infected persons in whom a diagnosis of tuberculosis is being considered, the lower the CD4 cell count, the greater the likelihood of falsely negative PPD or IGRA test results or of indeterminate IGRA test results. Because "anergy" skin test panels do not accurately classify those patients who are infected with tuberculosis but unreactive to the PPD, they are not recommended.

B. MANAGEMENT—Treatment of HIV-infected persons with active tuberculosis is similar to treatment of HIV-uninfected tubercular individuals. However, rifampin should not be given to patients receiving a boosted protease inhibitor (PI) regimen. In these cases, rifabutin may be substituted, but it may require dosing modifications depending on the antiretroviral regimen. Multidrug-resistant tuberculosis has been a major problem in several metropolitan areas of the developed world, and reports from South Africa of “extremely resistant” tuberculosis in AIDS patients are a growing global concern. Noncompliance with prescribed antituberculous medications is a major risk factor. Several of the reported outbreaks appear to implicate nosocomial spread. The emergence of medication resistance makes it essential that antibiotic sensitivities be performed on all positive cultures. Medication therapy should be individualized. Patients with multidrug-resistant M tuberculosis infection should receive at least three medications to which their organism is sensitive. Atypical mycobacteria can cause pulmonary disease in AIDS patients with or without preexisting lung disease and responds variably to treatment. Making a distinction between M tuberculosis and atypical mycobacteria requires culture of sputum specimens. If culture of the sputum produces acid-fast bacilli, definitive identification may take several weeks using traditional techniques. DNA probes allow for presumptive identification usually within days of a positive culture. While awaiting definitive diagnosis, clinicians should err on the side of treating patients as if they have M tuberculosis infection. In cases in which the risk of atypical mycobacteria is very high (eg, a person without risk for tuberculosis exposure with a CD4 count under 50 cells/mcL—see Figure 31–1), clinicians may wait for definitive diagnosis if the person is smear-negative for acid-fast bacilli, clinically stable, and not living in a communal setting. Isolation of cytomegalovirus (CMV) from bronchoalveolar lavage fluid occurs commonly in AIDS patients but does not establish a definitive diagnosis. Diagnosis of CMV pneumonia requires biopsy; response to treatment is poor. Histoplasmosis, coccidioidomycosis, and cryptococcal disease as well as more common respiratory viral infections should also be considered in the differential diagnosis of unexplained pulmonary infiltrates.

3. Noninfectious pulmonary diseases—

A. PRESENTATION—Noninfectious causes of lung disease include Kaposi sarcoma, non-Hodgkin lymphoma, interstitial pneumonitis, and increasingly, in the current antiretroviral treatment era, lung cancer. In patients with known Kaposi sarcoma, pulmonary involvement complicates the course in approximately one-third of cases. However, pulmonary involvement is rarely the presenting manifestation of Kaposi sarcoma. Non-Hodgkin lymphoma may involve the lung as the sole site of disease, but more commonly involves other organs as well, especially the brain, liver, and gastrointestinal tract. Both of these processes may show nodular or diffuse parenchymal involvement, pleural effusions, and mediastinal adenopathy on chest radiographs.

Nonspecific interstitial pneumonitis may mimic Pneumocystis pneumonia. Lymphocytic interstitial pneumonitis seen in lung biopsies has a variable clinical course. Typically, these patients present with several months of mild cough and dyspnea; chest radiographs show interstitial infiltrates. Many patients with this entity undergo transbronchial biopsies in an attempt to diagnose Pneumocystis pneumonia. Instead, the tissue shows interstitial inflammation ranging from an intense lymphocytic infiltration (consistent with lymphoid interstitial pneumonitis) to a mild mononuclear inflammation.

B. MANAGEMENT—Corticosteroids may be helpful in some cases refractory to antiretroviral treatment.

4. Sinusitis—

A. PRESENTATION—Chronic sinusitis can be a frustrating problem for HIV-infected patients. Symptoms include sinus congestion and discharge, headache, and fever. Some patients may have radiographic evidence of sinus disease on sinus CT scan in the absence of significant symptoms.

B. MANAGEMENT—HIV-infected patients with purulent drainage should be treated for possible H influenzae with amoxicillin-potassium clavulanate (500 mg orally three times a day) (see Chapter 8). A 7-day course of pseudoephedrine 60 mg twice daily may be helpful in decreasing congestion. Prolonged treatment (3–6 weeks) with an antibiotic and guaifenesin (600 mg orally twice daily) is sometimes necessary. For patients not responding to amoxicillin-potassium clavulanate, levofloxacin may be tried (400 mg orally daily). In patients with advanced immunodeficiency, Pseudomonas infections should be suspected, especially if there is not a response to first-line antibiotics. Some patients may require referral to an otolaryngologist for sinus drainage and culture for possible fungal infection (Aspergillus, Histoplasma capsulatum).

Elansari R et al. Histoplasma capsulatum sinusitis: possible way of revelation to the disseminated form of histoplasmosis in HIV patients: case report and literature review. Int J Surg Case Rep. 2016;24:97–100. [PMID: 27227446]

C. Central Nervous System Disease

Central nervous system disease in HIV-infected patients can be divided into intracerebral space-occupying lesions, encephalopathy, meningitis, and spinal cord processes. Many of these complications have declined markedly in prevalence in the era of effective antiretroviral treatment. Cognitive declines, however, may be more common in HIV patients, especially as they age (older than 50 years), even those who are taking fully suppressive antiretroviral treatment.

Bowen LN et al. HIV-associated opportunistic CNS infections: pathophysiology, diagnosis and treatment. Nat Rev Neurol. 2016 Oct 27;12(11):662–74. [PMID: 27786246]

1. Toxoplasmosis—Toxoplasmosis is the most common CNS space-occupying lesion in HIV-infected patients. Headache, focal neurologic deficits, seizures, or altered mental status may be presenting symptoms. The diagnosis is usually made presumptively based on the characteristic appearance of cerebral imaging studies in an individual known to be seropositive for Toxoplasma. Typically, toxoplasmosis appears as multiple contrast-enhancing lesions on CT scan. Lesions tend to be peripheral, with a predilection for the basal ganglia.

Single lesions are atypical of toxoplasmosis. When a single lesion has been detected by CT scanning, MRI scanning may reveal multiple lesions because of its greater sensitivity. If a patient has a single lesion on MRI and is neurologically stable, clinicians may pursue a 2-week empiric trial of toxoplasmosis therapy. A repeat scan should be performed at 2 weeks. If the lesion has not diminished in size, biopsy of the lesion should be performed. A positive Toxoplasma serologic test does not confirm the diagnosis because many HIV-infected patients have detectable titers without having active disease. Conversely, less than 3% of patients with toxoplasmosis have negative titers. Therefore, negative Toxoplasma titers in an HIV-infected patient with a space-occupying lesion should be a cause for aggressively pursuing an alternative diagnosis. The preferred treatment of toxoplasmosis is with pyrimethamine and sulfadiazine (Table 31–3). If pyrimethamine is not available, patients can be treated with trimethoprim-sulfamethoxazole.

Martin-Iguacel R et al. Incidence, presentation and outcome of toxoplasmosis in HIV infected in the combination antiretroviral therapy era. J Infect. 2017 Sep;75(3):263–73. [PMID: 28579301]

2. Central nervous system lymphoma—Primary non-Hodgkin lymphoma is the second most common CNS space-occupying lesion in HIV-infected patients. Symptoms are similar to those with toxoplasmosis. While imaging techniques cannot distinguish these two diseases with certainty, lymphoma more often is solitary. Other less common lesions should be suspected if there is preceding bacteremia, positive tuberculin test, fungemia, or injection drug use. These include bacterial abscesses, cryptococcomas, tuberculomas, and Nocardia lesions.

Stereotactic brain biopsy should be strongly considered if lesions are solitary or do not respond to toxoplasmosis treatment, especially if they are easily accessible. Diagnosis of lymphoma is important because many patients benefit from treatment (radiation therapy). Although a positive polymerase chain reaction (PCR) assay of cerebrospinal fluid for Epstein–Barr virus DNA is consistent with a diagnosis of lymphoma, the sensitivity and specificity of the test are not high enough to obviate the need for a brain biopsy.

Brandsma D et al. Primary CNS lymphoma in HIV infection. Handb Clin Neurol. 2018;152:177–86. [PMID: 29604975]

Yang M et al. Diagnostic accuracy of SPECT, PET, and MRS for primary central nervous system lymphoma in HIV patients: a systematic review and meta-analysis. Medicine (Baltimore). 2017 May;96(19):e6676. [PMID: 28489744]

3. HIV-associated dementia and neurocognitive disorders—Patients with HIV-associated dementia typically have difficulty with cognitive tasks (eg, memory, attention), exhibit diminished motor function, and have emotional or behavioral problems. Patients may first notice a deterioration in their handwriting. The manifestations of dementia may wax and wane, with persons exhibiting periods of lucidity and confusion over the course of a day. The diagnosis of HIV-associated dementia is one of exclusion based on a brain imaging study and on spinal fluid analysis that excludes other pathogens. Neuropsychiatric testing is helpful in distinguishing patients with dementia from those with depression. Many patients improve with effective antiretroviral treatment. However, slowly progressive neurocognitive deficits may still develop in patients taking antiretroviral treatment as they age.

Metabolic abnormalities may also cause changes in mental status: hypoglycemia, hyponatremia, hypoxia, and drug overdose are important considerations in this population. Other less common infectious causes of encephalopathy include progressive multifocal leukoencephalopathy (discussed below), CMV, syphilis, and herpes simplex encephalitis.

4. Cryptococcal meningitis—Cryptococcal meningitis typically presents with fever and headache. Less than 20% of patients have meningismus. Diagnosis is based on a positive latex agglutination test of serum that detects cryptococcal antigen (or “CRAG”) or positive culture of spinal fluid for Cryptococcus. Seventy to 90% of patients with cryptococcal meningitis have a positive serum CRAG. Thus, a negative serum CRAG test makes a diagnosis of cryptococcal meningitis unlikely and can be useful in the initial evaluation of a patient with headache, fever, and normal mental status. The preferred treatment is liposomal amphotericin with flucytosine (Table 31–3).

Williamson PR et al. Cryptococcal meningitis: epidemiology, immunology, diagnosis and therapy. Nat Rev Neurol. 2017 Jan;13(1):13–24. [PMID: 27886201]

5. Meningococcal meningitis—HIV-infected persons are at increased risk for meningococcal disease. Treatment is the same as in uninfected persons. Therefore, the Advisory Committee on Immunization Practices recommends the meningococcal conjugate vaccine (serogroups A, C, W, and Y) for all HIV-infected persons aged 2 months or older.

Harris CM et al. Meningococcal disease in patients with human immunodeficiency virus infection: a review of cases reported through active surveillance in the United States, 2000–2008. Open Forum Infect Dis. 2016 Dec 20;3(4):ofw226. [PMID: 28018927]

6. HIV meningitis and HIV myelopathy—HIV meningitis, characterized by lymphocytic pleocytosis of the spinal fluid with negative culture, is common early in HIV infection. Spinal cord function may also be impaired in HIV-infected individuals. HIV myelopathy presents with leg weakness and incontinence. Spastic paraparesis and sensory ataxia are seen on neurologic examination. Myelopathy is usually a late manifestation of HIV disease, and most patients will have concomitant HIV encephalopathy. Pathologic evaluation of the spinal cord reveals vacuolation of white matter. Because HIV myelopathy is a diagnosis of exclusion, symptoms suggestive of myelopathy should be evaluated by lumbar puncture to rule out CMV polyradiculopathy (described below) and an MRI or CT scan to exclude epidural lymphoma.

Levin SN et al. HIV and spinal cord disease. Handb Clin Neurol. 2018;152:213–27. [PMID: 29604979]

7. Progressive multifocal leukoencephalopathy (PML)—PML is a viral infection of the white matter of the brain seen in patients with very advanced HIV infection. It typically results in focal neurologic deficits such as aphasia, hemiparesis, and cortical blindness. Imaging studies are strongly suggestive of the diagnosis if they show nonenhancing white matter lesions without mass effect. Extensive lesions may be difficult to differentiate from the changes caused by HIV. Several patients have stabilized or improved after the institution of effective antiretroviral treatment, and due to wide use of antiretroviral treatment, PML is now rarely seen.

Harel A et al. Successful treatment of progressive multifocal leukoencephalopathy with recombinant interleukin-7 and maraviroc in a patient with idiopathic CD4 lymphocytopenia. J Neurovirol. 2018 Oct;24(5):652–5. [PMID: 29987583]

D. Peripheral Nervous System

A. PRESENTATION—Peripheral nervous system syndromes include inflammatory polyneuropathies, sensory neuropathies, and mononeuropathies.

An **inflammatory demyelinating polyneuropathy** similar to Guillain-Barré syndrome occurs in HIV-infected patients, usually prior to frank immunodeficiency. The syndrome in many cases improves with plasmapheresis, supporting an autoimmune basis of the disease. CMV can cause an ascending polyradiculopathy characterized by lower extremity weakness and a neutrophilic pleocytosis on spinal fluid analysis with a negative bacterial culture. Transverse myelitis can be seen with herpes zoster or CMV.

Peripheral neuropathy is common among HIV-infected persons. Patients typically complain of numbness, tingling, and pain in the lower extremities. Symptoms are disproportionate to findings on gross sensory and motor evaluation. Beyond HIV infection itself, the most common cause is prior antiretroviral treatment with stavudine or didanosine. Although not used commonly in Western countries, stavudine is still being used in resource-limited settings through national antiretroviral treatment programs. Caution should be used when administering these agents to patients with a history of peripheral neuropathy. Unfortunately, medication-induced neuropathy is not always reversed when the offending agent is discontinued. Patients with advanced disease may also develop peripheral neuropathy even if they have never taken antiretroviral treatment. Evaluation should rule out other causes of sensory neuropathy such as alcoholism, thyroid disease, vitamin B_{12} deficiency, and syphilis.

B. MANAGEMENT—Treatment of peripheral neuropathy is aimed at symptomatic relief. Patients should be initially treated with gabapentin (start at 300 mg at bedtime and increase to 300–900 mg orally three times a day) or other co-analgesics for neuropathic pain (see Chapter 5). Opioid analgesics should be avoided because the condition tends to be chronic and patients are likely to become dependent on these agents without significant improvement in their well-being.

Mochan A et al. CIDP [chronic inflammatory demyelinating polyradiculoneuropathy] in a HIV endemic population: a prospective case series from Johannesburg, South Africa. J Neurol Sci. 2016 Apr 15;363:39–42. [PMID: 27000218]

E. Rheumatologic and Bone Manifestations

Arthritis, involving single or multiple joints, with or without effusion, has been commonly noted in HIV-infected patients. Involvement of large joints is most common. Although the cause of HIV-related arthritis is unknown, most patients will respond to nonsteroidal anti-inflammatory medications. Patients with a sizable effusion, especially if the joint is warm or erythematous, should have the joint aspirated, followed by culture of the fluid to rule out suppurative arthritis as well as fungal and mycobacterial disease.

Several rheumatologic syndromes, including reactive arthritis, psoriatic arthritis, sicca syndrome, and systemic lupus erythematosus, have been reported in HIV-infected patients (see Chapter 20). However, it is unclear if the prevalence is greater than in the general population. Cases of avascular necrosis of the femoral heads have been reported sporadically, generally in the setting of advanced disease with long-standing infection and in patients receiving long-term antiretroviral treatment. The etiology is not clear but is probably multifactorial in nature.

Osteoporosis and osteopenia appear to be more common in HIV-infected patients with chronic infection and perhaps associated with long-term use of antiretroviral treatment. Vitamin D deficiency appears to be quite common among HIV-infected populations and monitoring vitamin D levels and replacement therapy for detected deficiency are recommended. Bone mineral density scans for postmenopausal women and for men over the age of 50 is also recommended.

Parperis K et al. Rheumatic diseases in HIV-infected patients in the post-antiretroviral therapy era: a tertiary care center experience. Clin Rheumatol. 2019 Jan;38(1):71–6. [PMID: 29619587]

Walker-Bone K et al. Assessment and management of musculoskeletal disorders among patients living with HIV. Rheumatology (Oxford). 2017 Oct 1;56(10):1648–61. [PMID: 28013196]

F. Myopathy

Myopathies are infrequent in the era of effective antiretroviral treatment but can be related to either HIV infection or antiretroviral treatment, particularly with use of zidovudine (azidothymidine [AZT]). Proximal muscle weakness is typical, and patients may have varying degrees of muscle tenderness. Given its long-term toxicities, zidovudine is no longer recommended when alternative treatments are available.

G. Retinitis

In HIV-infected patients, complaints of visual changes must be evaluated immediately by an ophthalmologist familiar with the manifestations of HIV disease. **CMV retinitis,** characterized by perivascular hemorrhages and white fluffy exudates, is the most common retinal infection in AIDS patients and can be rapidly progressive. In contrast, cotton wool spots, which are also common in HIV-infected patients, are benign, remit spontaneously, and appear as small indistinct white spots without exudation or hemorrhage. Other rare retinal processes include other herpesvirus infections or toxoplasmosis. Choice of treatment for CMV retinitis (Table 31–3) depends on severity and location of lesions, and the patient's overall condition and circumstances.

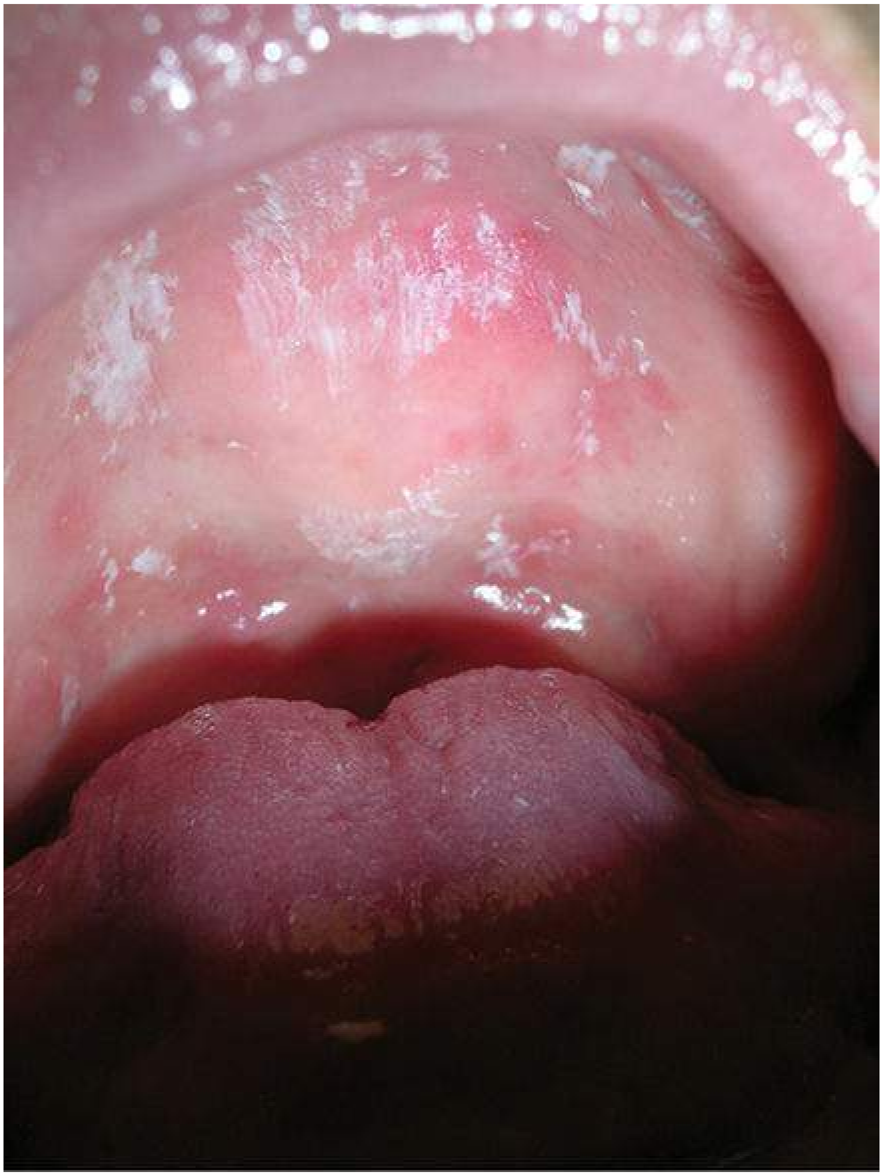
Port AD et al. Cytomegalovirus retinitis: a review. J Ocul Pharmacol Ther. 2017 May;33(4):224–34. [PMID: 28355091]

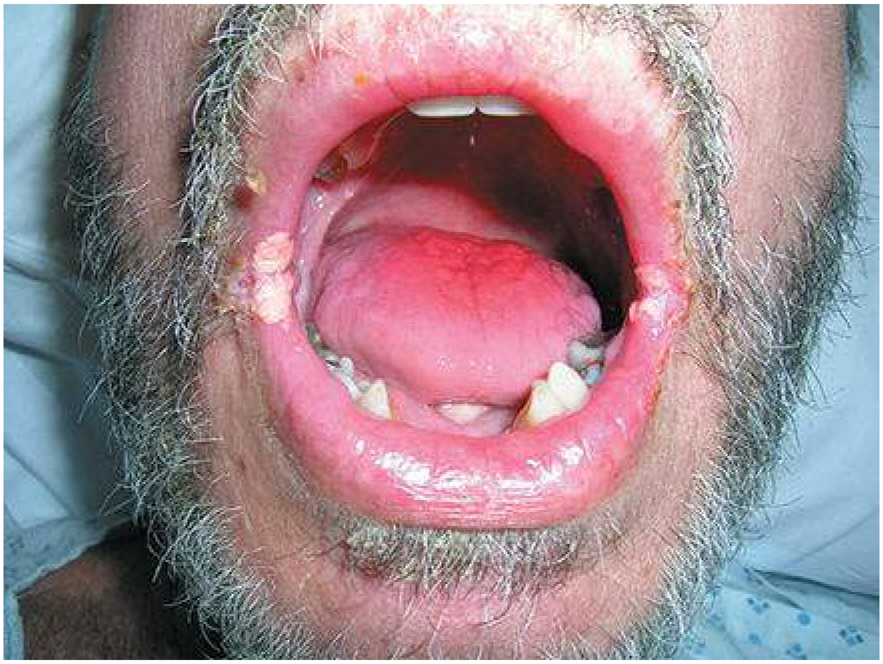
H. Oral Lesions

A. PRESENTATION—The presence of oral candidiasis or hairy leukoplakia is significant for several reasons. First, these lesions are highly suggestive of HIV infection in patients who have no other obvious cause of immunodeficiency. Second, several studies have indicated that patients with candidiasis have a high rate of progression to AIDS even with statistical adjustment for CD4 count.

Hairy leukoplakia is caused by the Epstein-Barr virus. The lesion is not usually troubling to patients and sometimes regresses spontaneously. Hairy leukoplakia is commonly seen as a white lesion on the lateral aspect of the tongue. It may be flat or slightly raised, is usually corrugated, and has vertical parallel lines with fine or thick ("hairy") projections (Figure 8–6). **Oral candidiasis** can be bothersome to patients, many of whom report an unpleasant taste or mouth dryness. The two most common forms of oral candidiasis seen are pseudomembranous (removable white plaques) (Figure 31–2A) and erythematous (red friable plaques) (Figure 31–2B).

B. MANAGEMENT—Treatment of oral candidiasis is with topical agents such as clotrimazole 10-mg troches (one troche four or five times a day). Patients with candidiasis who do not respond to topical antifungals can be treated with fluconazole (50–100 mg orally once a day for 3–7 days). **Angular cheilitis**—fissures at the sides of the mouth—is usually due to Candida as well (Figure 31–2B) and can be treated topically with ketoconazole cream (2%) twice a day.





▲ **Figure 31–2. Oral candidiasis. A: The pseudomembranous form of oral candidiasis is the most common; the white plaques over the hard palate raise the suspicion of underlying HIV/AIDS. They can be scraped off with a tongue blade, placed on a slide, and mixed with potassium hydroxide solution to make the diagnosis of Candida albicans. B: This man with HIV-AIDS has the (less common) erythematous form of oral candidiasis. The patient also has perlèche or angular cheilitis (Candida infection at the corners of the mouth).** (Used, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. The Color Atlas of Family Medicine, 2nd ed. McGraw-Hill, 2013.)

Gingival disease is common in HIV-infected patients and is thought to be due to an overgrowth of microorganisms. It usually responds to professional dental cleaning and chlorhexidine rinses. A particularly aggressive gingivitis or periodontitis will develop in some HIV-infected patients; these patients should be given antibiotics that cover anaerobic oral flora (eg, metronidazole, 250 mg four times a day for 4 or 5 days) and referred to oral surgeons with experience with these entities.

Aphthous ulcers (Figure 31–3) are painful and may interfere with eating. They can be treated with fluocinonide (0.05% ointment mixed 1:1 with plain Orabase and applied six times a day to the ulcer). For lesions that are difficult to reach, patients should use dexamethasone swishes (0.5 mg in 5 mL elixir three times a day). The pain of the ulcers can be relieved with use of an anesthetic spray (10% lidocaine). Other lesions seen in the mouths of HIV-infected patients include **Kaposi sarcoma** (usually on the hard palate) and **warts.**

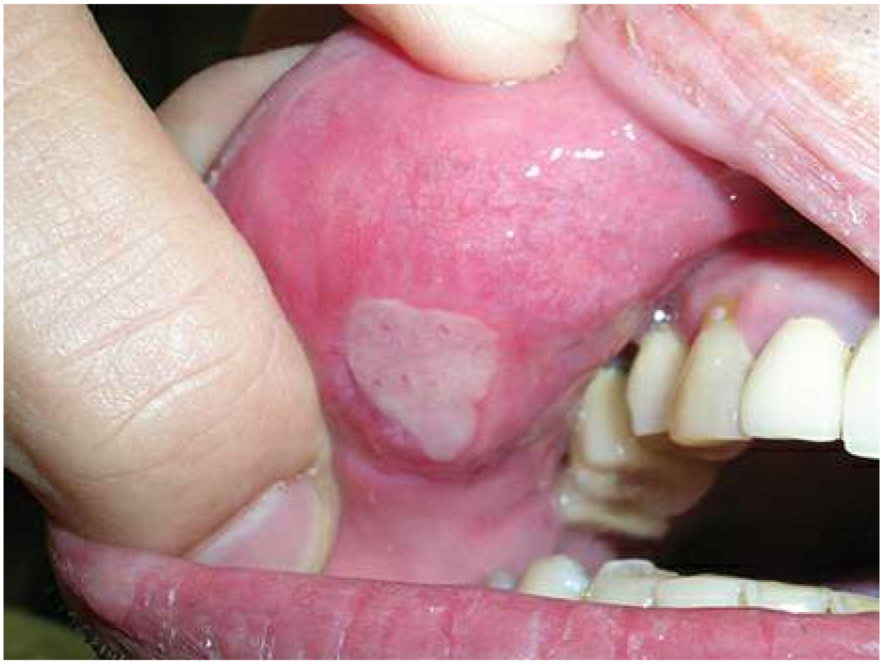


Figure 31–3. Recurrent oral aphthous stomatitis. A 58-year-old man presented with a 1-year history of recurrent painful sores in his mouth. He had lost 20 pounds over the year because it hurt so much to eat. The ulcers, which had a red base and were covered with a central white membrane, occurred in different locations—on his tongue, gums, inner lips, and buccal mucosa (shown here). HIV-AIDS is an underlying systemic disease that can be documented on work-up of such patients. (Used, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. The Color Atlas of Family Medicine, 2nd ed. McGraw-Hill, 2013.)

Nittayananta W. Oral fungi in HIV: challenges in antifungal therapies. Oral Dis. 2016 Apr;22(Suppl 1):107–13. [PMID: 27109279]

I. Gastrointestinal Manifestations

1. Candidal esophagitis—(See also Chapter 15.) Esophageal candidiasis is a common AIDS complication. In a patient with characteristic symptoms, empiric antifungal treatment is begun with fluconazole (100–200 mg orally daily for 14–21 days). Improvement in symptoms should be apparent within 1–2 days of antifungal treatment. If there is no improvement, further evaluation to identify other causes of esophagitis (herpes simplex, CMV) is recommended.

O’Rourke A. Infective oesophagitis: epidemiology, cause, diagnosis and treatment options. Curr Opin Otolaryngol Head Neck Surg. 2015 Dec;23(6):459–63. [PMID: 26371605]

2. Hepatic disease—

A. PRESENTATION—Autopsy studies have demonstrated that the liver is a frequent site of infections and neoplasms in HIV-infected patients. However, many of these infections are not clinically symptomatic. Mild elevations of alkaline phosphatase and aminotransferases are often noted on routine chemistry panels. **Mycobacterial disease, CMV, hepatitis B virus, hepatitis C virus,** and **lymphoma** cause liver disease and can present with varying degrees of nausea, vomiting, right upper quadrant abdominal pain, and jaundice. Sulfonamides, imidazole medications, antituberculous medications, pentamidine, clarithromycin, and didanosine have also been associated with hepatitis. All nucleoside reverse transcriptase inhibitors cause lactic acidosis, which can be fatal. Lactic acidosis, however, occurs most commonly when didanosine is used with stavudine; this combination is no longer recommended in antiretroviral treatment regimens. HIV-infected patients with chronic hepatitis may have more rapid progression of liver disease because of the concomitant immunodeficiency or hepatotoxicity of antiretroviral treatment. Percutaneous liver biopsy may be helpful in diagnosing liver disease, but some common causes of liver disease (eg, M avium complex, lymphoma) can be determined by less invasive measures (eg, blood culture, biopsy of a more accessible site).

B. MANAGEMENT—With patients living longer as a result of advances in antiretroviral treatment, advanced liver disease and hepatic failure due to chronic active hepatitis B and/or C are increasing causes of morbidity and mortality. HIV-infected individuals who are coinfected with hepatitis B should be treated with antiretroviral regimens that include medications with activity against both viruses (tenofovir disoproxil fumarate [TDF] or tenofovir alafenamide [TAF], lamivudine, or emtricitabine). Entecavir may be used if HIV viral load is suppressed; otherwise, its use can lead to lamivudine/emtricitabine-resistant HIV. It is important to be extremely cautious about discontinuing these medications in coinfected patients as sudden discontinuation could lead to a fatal flare of hepatitis B infection.

Hepatitis C is more virulent in persons with HIV and should be treated using the new HCV direct-acting antivirals (Table 16–6). Prior to treatment, the patient's HCV viral load and HCV genotype should be determined. Depending on the genotype and the proposed treatment regimen, HCV resistance testing is recommended. For example, HCV resistance testing is recommended for patients with genotype 1a (the most common hepatitis C genotype in the United States) who are being considered for treatment with elbasvir/grazoprevir because substitutions in certain amino acid positions confer resistance. Because the appropriate treatment regimen depends on genotype, resistance profile, whether the patient is treatment naïve or not, as well as whether or not the patient has cirrhosis (and, if so, whether it is compensated or decompensated), clinicians should check the guidelines of the AASLD/IDSA (see website in references below) to see the recommended regimens (see also Tables 16–6 and 16–7). Costs of the different regimens vary by purchaser, and many clinicians choose the least expensive of the recommended regimens.

Although the recommended regimens are the same for HIV-infected patients, potential drug interactions with antiretroviral treatment may complicate treatment. Clinicians should check the guidelines of the AASLD/IDSA and US Department of Health and Human Services or the guidelines of the University of Liverpool (see references below) to determine interactions between proposed hepatitis C regimen and HIV regimen.

Liver transplants have been performed successfully in HIV-infected patients. This strategy is most likely to be successful in persons who have CD4 counts greater than 100 cells/mcL and nondetectable viral loads.

3. Biliary disease—Cholecystitis presents with manifestations similar to those seen in immunocompetent hosts, but is more likely to be acalculous. **Sclerosing cholangitis** and **papillary stenosis** have also been reported in HIV-infected patients. Typically, the syndrome presents with severe nausea, vomiting, and right upper quadrant pain. Liver enzymes generally show alkaline phosphatase elevations disproportionate to elevation of the aminotransferases. Although dilated ducts can be seen on ultrasound, the diagnosis is made by endoscopic retrograde cholangiopancreatography, which reveals intraluminal irregularities of the proximal intrahepatic ducts with "pruning" of the terminal ductal branches. Stenosis of the distal common bile duct at the papilla is commonly seen. CMV, Cryptosporidium, and microsporidia are thought to play inciting roles in this syndrome, but these conditions are rarely seen unless the patient is suffering with very advanced HIV-related immunodeficiency.

4. Enterocolitis—

A. PRESENTATION—Enterocolitis is a common problem in HIV-infected individuals. Organisms known to cause enterocolitis include bacteria (Campylobacter, Salmonella, Shigella), viruses (CMV, adenovirus), and protozoans (Cryptosporidium, Entamoeba histolytica, Giardia, Isospora, microsporidia). HIV itself may cause enterocolitis. Several of the organisms causing enterocolitis in HIV-infected individuals also cause diarrhea in immunocompetent persons. However, HIV-infected patients tend to have more severe and more chronic symptoms, including high fevers and severe abdominal pain that can mimic acute abdominal catastrophes. Bacteremia and concomitant biliary involvement are also more common with enterocolitis in HIV-infected patients. Relapses of enterocolitis following adequate therapy have been reported with both Salmonella and Shigella infections.

Because of the wide range of agents known to cause enterocolitis, a stool culture and multiple stool examinations for ova and parasites (including modified acid-fast staining for Cryptosporidium) should be performed. Those patients who have Cryptosporidium in one stool with improvement in symptoms in less than 1 month should not be considered to have AIDS, as Cryptosporidium is a cause of self-limited diarrhea in HIV-negative persons. More commonly, HIV-infected patients with Cryptosporidium infection have persistent enterocolitis with profuse watery diarrhea.

B. MANAGEMENT—To date, no consistently effective treatments have been developed for Cryptosporidium infection. The most effective treatment of cryptosporidiosis is to improve immune function through the use of effective antiretroviral treatment. The diarrhea can be treated symptomatically with diphenoxylate with atropine (one or two tablets orally three or four times a day). Those who do not respond may be given paregoric with bismuth (5–10 mL orally three or four times a day). Octreotide in escalating doses (starting at 0.05 mg subcutaneously every 8 hours for 48 hours) has been found to ameliorate symptoms in approximately 40% of patients with cryptosporidia or idiopathic HIV-associated diarrhea, although the benefit is often short-lived.

Patients with a negative stool examination and persistent symptoms should be evaluated with colonoscopy and biopsy. Patients whose symptoms last longer than 1 month with no identified cause of diarrhea are considered to have a presumptive diagnosis of **AIDS enteropathy.** Patients may respond to institution of effective antiretroviral treatment. Upper endoscopy with small bowel biopsy is not recommended as a routine part of the evaluation.

Wang RJ et al. Widespread occurrence of Cryptosporidium infections in patients with HIV/AIDS: epidemiology, clinical feature, diagnosis, and therapy. Acta Trop. 2018 Nov;187:257–63. [PMID: 30118699]

5. Other disorders—Two other important gastrointestinal abnormalities in HIV-infected patients are **gastropathy** and malabsorption. It has been documented that some HIV-infected patients do not produce normal levels of stomach acid and therefore are unable to absorb medications that require an acid medium. This decreased acid production may explain, in part, the susceptibility of HIV-infected patients to Campylobacter, Salmonella, and Shigella, all of which are sensitive to acid concentration. There is no evidence that Helicobacter pylori is more common in HIV-infected persons.

A **malabsorption** syndrome occurs commonly in AIDS patients. It can be due to infection of the small bowel with M avium complex, Cryptosporidium, or microsporidia.

Logan C et al. HIV and diarrhoea: what is new? Curr Opin Infect Dis. 2016 Oct;29(5):486–94. [PMID: 27472290]

J. Endocrinologic Manifestations

Hypogonadism is probably the most common endocrinologic abnormality in HIV-infected men. The adrenal gland is also a commonly afflicted endocrine gland in patients with AIDS. Abnormalities demonstrated on autopsy include infection (especially with CMV and M avium complex), infiltration with Kaposi sarcoma, and injury from hemorrhage and presumed autoimmunity. The prevalence of clinically significant adrenal insufficiency is low. Patients with suggestive symptoms should undergo a cosyntropin stimulation test.

Although frank deficiency of cortisol is rare, an isolated defect in mineralocorticoid metabolism may lead to salt-wasting and hyperkalemia. Such patients should be treated with fludrocortisone (0.1–0.2 mg orally daily).

AIDS patients appear to have abnormalities of thyroid function tests different from those of patients with other chronic diseases. AIDS patients have been shown to have high levels of triiodothyronine (T_3), thyroxine (T_4), and thyroid-binding globulin and low levels of reverse triiodothyronine (rT_3). The causes and clinical significance of these abnormalities are unknown.

K. Skin Manifestations

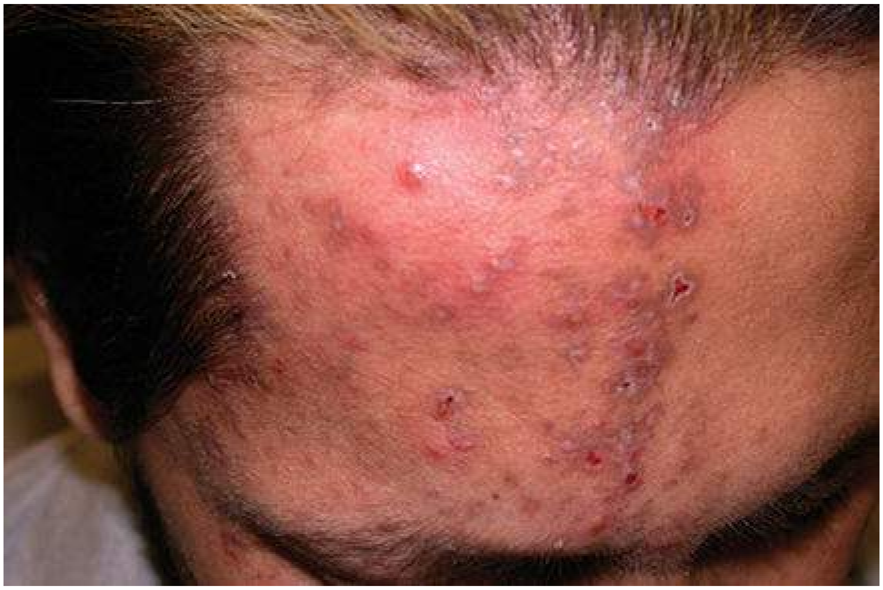
The skin manifestations that commonly develop in HIV-infected patients can be grouped into viral, bacterial, fungal, neoplastic, and nonspecific dermatitides.

1. Viral dermatitides—

A. HERPES SIMPLEX INFECTIONS—These infections occur more frequently, tend to be more severe, and are more likely to disseminate in AIDS patients than in immunocompetent persons. Because of the risk of progressive local disease, all herpes simplex attacks should be treated for 5–10 days with acyclovir (400 mg orally three times a day), famciclovir (500 mg orally twice daily), or valacyclovir (500 mg orally twice daily) (Table 31–3). To avoid the complications of attacks, many clinicians recommend suppressive therapy for HIV-infected patients with a history of recurrent herpes. Options for suppressive therapy include acyclovir (400 mg orally twice daily), famciclovir (250 mg orally twice daily), and valacyclovir (500 mg orally daily). Long-term suppressive herpes prophylaxis with acyclovir does not reduce HIV transmission between heterosexual men and women from developing countries.

Andrei G et al. The anti-HIV drug tenofovir, a reverse transcriptase inhibitor, also targets the herpes simplex virus (HSV) DNA polymerase. J Infect Dis. 2018 Feb 14;217(5):790–801. [PMID: 29186456]

B. HERPES ZOSTER—This is a common manifestation of HIV infection (Figure 31–4). Patients with herpes zoster infections should be treated for 7–10 days with famciclovir (500 mg orally three times a day) or valacyclovir (500 mg three times a day). Acyclovir can also be used, but it requires very frequent dosing (800 mg orally four or five times per day for 7 days). Vesicular lesions should be cultured if there is any question about their origin, since herpes simplex responds to much lower doses of acyclovir. Disseminated zoster and cases with ocular involvement should be treated with intravenous (10 mg/kg every 8 hours for 7–10 days) rather than oral acyclovir. The recombinant zoster vaccine (Shingrix, two doses administered 2–6 months apart) can be given to HIV-infected patients. Because it is not a live virus like the previous zoster vaccine (Zostavax), it is not contraindicated in patients with immune deficiency but, based on other vaccines, HIV-infected patients are likely to develop more robust immune response to the vaccine when their CD4 count is greater than 200/mcL. The long-term benefit of Shingrix in preventing shingles in HIV-infected persons has yet to be established.



▲ **Figure 31–4. Herpes zoster. A painful vesicular eruption developed over the right**

forehead in this 44-year-old HIV-positive man. Herpes zoster was diagnosed clinically and confirmed by a positive direct fluorescent antibody test on fluid from one of the vesicles. (Used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. The Color Atlas of Family Medicine, 2nd ed. McGraw-Hill, 2013.)

c. MOLLUSCUM CONTAGIOSUM—This infection is caused by a pox virus and is seen in HIV-infected patients, as in other immunocompromised patients. The characteristic umbilicated fleshy papular lesions have a propensity for spreading widely over the patient’s face and neck and should be treated with topical liquid nitrogen.

Martin P. Interventions for molluscum contagiosum in people infected with human immunodeficiency virus: a systematic review. Int J Dermatol. 2016 Sep;55(9):956–66. [PMID: 26991246]

van der Wouden JC et al. Interventions for cutaneous molluscum contagiosum. Cochrane Database Syst Rev. 2017 May 17;5:CD004767. [PMID: 28513067]

2. Bacterial dermatitides—

a. STAPHYLOCOCCAL INFECTION—Staphylococcus is the most common bacterial cause of skin disease in HIV-infected patients; it usually presents as **folliculitis, superficial abscesses (furuncles),** or **bullous impetigo.** These lesions should be treated aggressively since sepsis can occur. Folliculitis is initially treated with topical clindamycin or mupirocin, and patients may benefit from regular washing with an antibacterial soap such as chlorhexidine. Intranasal mupirocin has been used successfully for staphylococcal decolonization in other settings. In HIV-infected patients with recurrent staphylococcal infections, weekly intranasal mupirocin should be considered in addition to topical care and systemic antibiotics. Abscesses often require incision and drainage. Patients may need antistaphylococcal antibiotics as well. Due to high frequency of methicillin-resistant Staphylococcus aureus (MRSA) skin infections in HIV-infected populations, lesions should be cultured prior to initiating empiric antistaphylococcal therapy. Recommendations for empiric treatment are either (1) trimethoprim-sulfamethoxazole (one double-strength tablet orally twice daily) with or without clindamycin (500 mg orally three times daily); or (2) doxycycline (100 mg orally twice daily) with close follow-up.

Hemmige V et al. Predictors of skin and soft tissue infections in HIV-infected outpatients in the community-associated methicillin resistant Staphylococcus aureus era. Eur J Clin Microbiol Infect Dis. 2015 Feb;34(2):339–47. [PMID: 25213720]

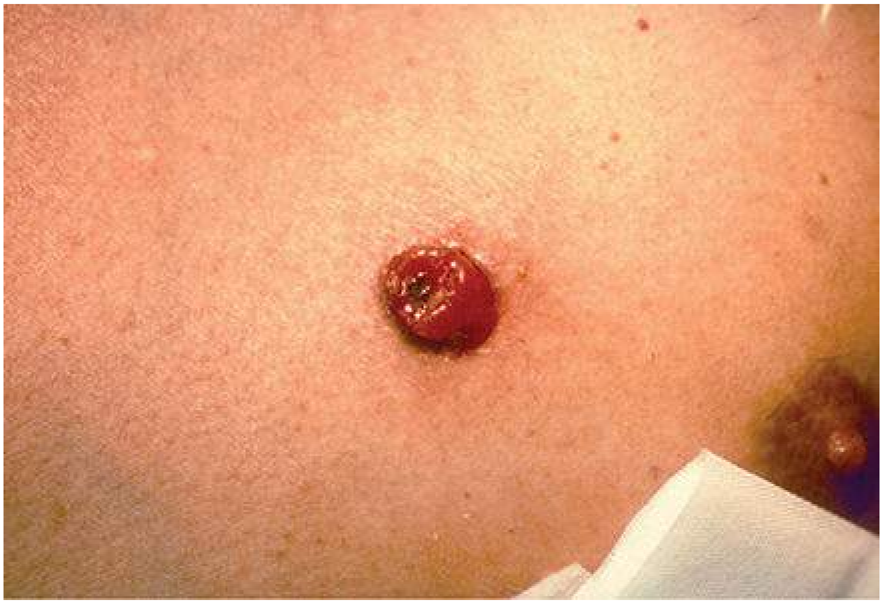
B. BACILLARY ANGIOMATOSIS—It is caused by two closely related organisms: Bartonella henselae and Bartonella quintana. The epidemiology of these infections suggests zoonotic transmission from fleas of infected domestic cats. The most common manifestation is raised, reddish, highly vascular skin lesions (Figure 31–5) that can mimic the lesions of Kaposi sarcoma. Fever is a common manifestation of this infection; involvement of bone, lymph nodes, and liver has also been reported. The infection responds to doxycycline, 100 mg orally twice daily, or erythromycin, 250 mg orally four times daily. Therapy is continued for at least 14 days, and patients who are seriously ill with visceral involvement may require months of therapy.



▲ **Figure 31–5. Bacillary angiomatosis. Bacillary angiomatosis is a systemic infection caused by Bartonella species. Its cutaneous lesions appear as scattered papules and nodules (like the one shown here) or as abscesses. In HIV-infected patients, bacillary angiomatosis most often occurs when the CD4 count is below**

200/mcL. It can be treated with antibiotics. (Reproduced, with permission, from Usatine RP, Moy RL, Tobinick EL, Siegel DM. Skin Surgery: A Practical Guide. Mosby, 1998. Copyright © Elsevier.)

Markowicz M et al. Bacillary angiomatosis presenting with facial tumor and multiple abscesses: a case report. Medicine (Baltimore). 2016 Jul;95(28):e4155. [PMID: 27428207]

3. Fungal rashes—

A. RASHES DUE TO DERMATOPHYTES AND CANDIDA—Most **fungal rashes** afflicting AIDS patients are due to dermatophytes and Candida. While particularly common in the inguinal region, they may occur anywhere on the body. Fungal rashes generally respond well to topical clotrimazole (1% cream twice a day) or ketoconazole (2% cream twice a day).

B. SEBORRHEIC DERMATITIS—This is more common in HIV-infected patients. Scrapings of seborrhea have revealed Malassezia furfur (Pityrosporum ovale), implying that the seborrhea is caused by this fungus. Consistent with the isolation of this fungus is the clinical finding that seborrhea responds well to topical clotrimazole (1% cream) as well as hydrocortisone (1% cream).

Forrestel AK et al. Diffuse HIV-associated seborrheic dermatitis—a case series. Int J STD AIDS. 2016 Dec; 27(14):1342–5. [PMID: 27013615]

4. Neoplastic dermatitides—See Chapter 6 and the Kaposi sarcoma section below.

5. Nonspecific dermatitides—

A. XEROSIS—This condition presents in HIV-infected patients with severe pruritus. The patient may have no rash, or nonspecific excoriations from scratching. Treatment is with emollients (eg, absorption base cream) and antipruritic lotions (eg, camphor 9.5% and menthol 0.5%).

B. PSORIASIS—Psoriasis can be very severe in HIV-infected patients. Phototherapy and etretinate (0.25–9.75 mg/kg/day orally in divided doses) may be used for recalcitrant cases in consultation with a dermatologist.

L. HIV-Related Malignancies

Four cancers are currently included in the CDC classification of AIDS: Kaposi sarcoma, non-Hodgkin lymphoma, primary lymphoma of the brain, and invasive cervical carcinoma. Epidemiologic studies have shown that between 1973 and 1987, among single men in San Francisco, the risk of Kaposi sarcoma increased more than 5000-fold and the risk of non-Hodgkin lymphoma more than 10-fold. The increase in incidence of malignancies is probably a function of impaired cell-mediated immunity. In the current treatment era, cancers not classified as AIDS-related, such as lung cancer, are being increasingly diagnosed in aging HIV-infected individuals despite optimal antiretroviral treatment treatment. Cohort studies suggest that HIV-infected adults are at increased risk for a variety of cancers compared to age-matched uninfected populations. Mortality secondary to malignancies represents an increasing cause of death in HIV-infected populations.

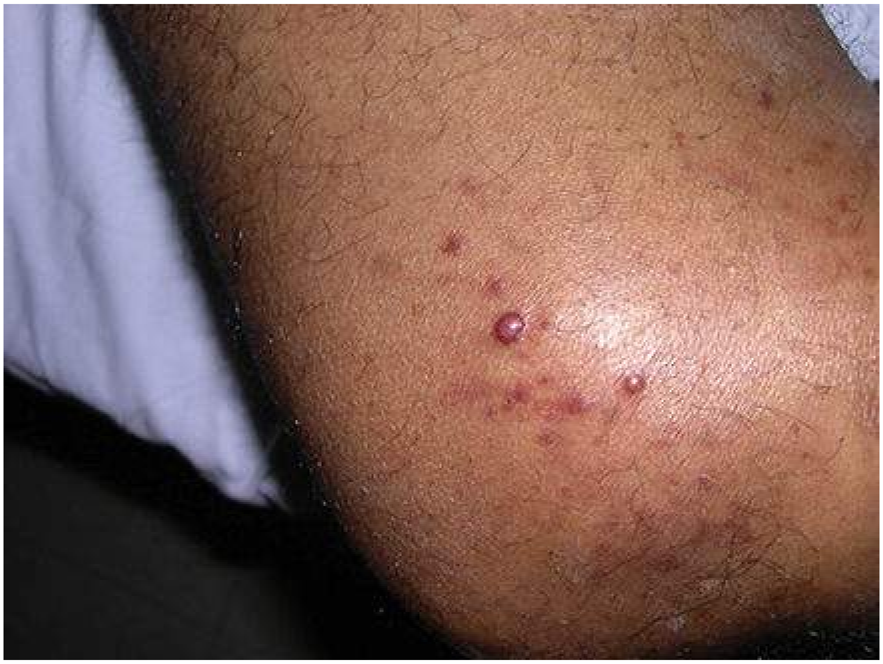
Shiels MS et al. Projected cancer incidence rates and burden of incident cancer cases in HIV-infected adults in the United States through 2030. Ann Intern Med. 2018 Jun 19;168(12):866–73. [PMID: 29801099]

Valanikas E et al. Cancer prevention in patients with human immunodeficiency virus infection. World J Clin Oncol. 2018 Sep 14;9(5):71–3. [PMID: 30254961]

1. Kaposi sarcoma—

A. PRESENTATION—Lesions may appear anywhere; careful examination of the eyelids, conjunctiva, pinnae, palate, and toe webs is mandatory to locate potentially occult lesions. In light-skinned individuals, Kaposi lesions usually appear as purplish, nonblanching lesions that can be papular or nodular (Figure 31–6). In dark-skinned individuals, the lesions may appear browner. In the mouth, lesions are most often palatal papules, though exophytic lesions of the tongue and gingivae may also be seen. Kaposi lesions may be confused with other vascular lesions such as angiomas and pyogenic granulomas. Kaposi sarcoma lesions can occur shortly after initiating antiretroviral treatment, especially in patients starting antiretroviral treatment who have advanced immunodeficiency. In this situation, Kaposi sarcoma is likely to be an immune reconstitution reaction (see Inflammatory Reactions below). Kaposi sarcoma can also cause visceral disease (eg, gastrointestinal, pulmonary).



▲ **Figure 31–6. Kaposi sarcoma. A 35-year-old man presented with several reddish-purple papular lesions on his elbow. When these were diagnosed on shave biopsy as Kaposi sarcoma (KS), he was tested and found to be positive for HIV. He was begun on systemic treatment with combination antiretroviral therapy and topical treatment with alitretinoin gel and the KS lesions eventually resolved.** (Used, with permission, from Heather Wickless, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. The Color Atlas of Family Medicine, 2nd ed. McGraw-Hill, 2013.)

B. MANAGEMENT—Patients with mild to moderate forms of Kaposi sarcoma do not require specific treatment as the lesions usually resolve with effective antiretroviral treatment. However, it should be noted that the lesions may flare when antiretroviral treatment is first initiated—probably as a result of an immune reconstitution process. Advanced disease is treated with combination chemotherapy (Table 31–3).

Franco JB et al. Regression of human immunodeficiency virus-associated oral Kaposi sarcoma with combined antiretroviral therapy: a case report and literature review. Head Neck. 2019 Feb;41(2):E21–5. [PMID: 30552825]

Liu Z et al. The world-wide incidence of Kaposi's sarcoma in the HIV/AIDS era. HIV Med. 2018 May;19(5):355–64. [PMID: 29368388]

2. Non-Hodgkin lymphoma—

a. Presentation—Non-Hodgkin lymphomas in HIV-infected persons tends to be very aggressive. These malignancies are usually of B cell origin and characterized as diffuse large-cell tumors. Over 70% of the malignancies are extranodal.

b. Management—The prognosis of patients with systemic non-Hodgkin lymphoma depends primarily on the degree of immunodeficiency at the time of diagnosis. Patients with high CD4 counts do markedly better than those diagnosed at a late stage of illness. Patients with primary central nervous system lymphoma are treated with radiation. Response to treatment is good, but prior to the availability of antiretroviral treatment, most patients died within a few months after diagnosis due to their underlying disease. Systemic disease is treated with combination chemotherapy (eg, EPOCH [etoposide, prednisolone, vincristine, cyclophosphamide, doxorubicin]) with rituximab. Granulocyte colony-stimulating factor (G-CSF; filgrastim) is used to maintain white blood counts.

3. Hodgkin disease—Although Hodgkin disease is not included as part of the CDC definition of AIDS, studies have found that HIV infection is associated with a fivefold increase in the incidence of Hodgkin disease. HIV-infected persons with Hodgkin disease are more likely to have mixed cellularity and lymphocyte depletion subtypes of Hodgkin disease and to seek medical attention at an advanced stage of disease.

Lawal IO et al. The role of F-18 FDG PET/CT in evaluating the impact of HIV infection on tumor burden and therapy outcome in patients with Hodgkin lymphoma. Eur J Nucl Med Mol Imaging. 2017 Nov;44(12):2025–33. [PMID: 28660348]

Sorigué M et al. HIV-infection has no prognostic impact on advanced-stage classical Hodgkin lymphoma. AIDS. 2017 Jun 19;31(10):1445–9. [PMID: 28358739]

4. Anal dysplasia and squamous cell carcinoma—These lesions have been strongly correlated with previous infection by human papillomavirus (HPV) and have been noted in HIV-infected men and women. Although many of the infected MSM report a history of anal warts or have visible warts, a significant percentage have silent papillomavirus infection. Cytologic (using Papanicolaou smears) and papillomavirus DNA studies can easily be performed on specimens obtained by anal swab. Because of the risk of progression from dysplasia to cancer in immunocompromised patients, some experts suggest that annual anal swabs for cytologic examination should be done in all HIV-infected persons. An anal Papanicolaou smear is performed by rotating a moistened Dacron swab about 2 cm into the anal canal. The swab is immediately inserted into a cytology bottle. However, there is no evidence that screening for anal cancer with Papanicolaou smears decreases the incidence of invasive cancer.

HPV also appears to play a causative role in **cervical dysplasia** and **neoplasia**. The incidence and clinical course of cervical disease in HIV-infected women are discussed below.

Cajas-Monson LC et al. Expectant management of high-grade anal dysplasia in people with HIV: long-term data. Dis Colon Rectum. 2018 Dec;61(12):1357–63. [PMID: 30346366]

M. Gynecologic Manifestations

Vaginal candidiasis, cervical dysplasia and neoplasia, and pelvic inflammatory disease are more common in HIV-infected women than in uninfected women. These manifestations also tend to be more severe when they occur in association with HIV infection. Therefore, HIV-infected women need frequent gynecologic care. **Vaginal candidiasis** may be treated with topical agents or a single dose of oral fluconazole (150 mg) (see Chapter 36). Recurrent vaginal candidiasis should be treated with fluconazole (100–200 mg) for at least 7 days.

The incidence of **cervical dysplasia** in HIV-infected women is 40%. Because of this finding, recommended screening for HIV-infected women is more extensive than for uninfected women (see Chapter 18). For women younger than age 30 years, a Papanicolaou smear should be performed within a year of the onset of sexual activity, but no later than age 21 years. If normal, Papanicolaou smears should be performed yearly. After three negative examinations, screening should be done every 3 years. HPV DNA testing of the cervical specimen is not recommended for women younger than age 30 years.

For women age 30 and older, screening should continue beyond age 65 unlike the general population. There are two accepted screening protocols, one using cytology alone, the other using cytology with HPV DNA cotesting. A Papanicolaou smear is done when HIV is diagnosed and every 12 months thereafter and after three negative examinations, ongoing screening should be performed every 3 years. Alternatively, a Papanicolaou smear with cotesting for HPV DNA can be performed when HIV is diagnosed or starting when patients are age 30 years old. If Papanicolaou is normal and HPV test is negative, then the next screening should be in 3 years.

The management of abnormal Papanicolaou tests and positive HPV tests is the same in infected women as in uninfected women. Treatment should follow the consensus guidelines in the references below.

While **pelvic inflammatory disease** appears to be more common in HIV-infected women, the bacteriology of this condition appears to be the same as among HIV-uninfected women. HIV-infected women with pelvic inflammatory disease should be treated with the same regimens as uninfected women (see Chapter 18).

Ghebre RG et al. Cervical cancer control in HIV-infected women: past, present and future. Gynecol Oncol Rep. 2017 Jul 21;21:101–8. [PMID: 28819634]

N. Coronary Artery Disease

HIV-infected persons are at higher risk for coronary artery disease than age- and sex-matched controls. Part of this increase in coronary artery disease is due to changes in lipids caused by antiretroviral agents (see Treatment section on Antiretroviral Therapy below), especially stavudine and several of the PIs. However, some of the risk appears to be due to HIV infection, independent of its therapy. It is important that clinicians pay close attention to this issue because myocardial infarctions tend to present at a younger age in HIV-infected individuals than in HIV-uninfected individuals. HIV-infected patients with symptoms of coronary artery disease such as chest pain or dyspnea should be rapidly evaluated. Clinicians should aggressively treat conditions that result in increased risk of heart disease, especially smoking, hypertension, hyperlipidemia, obesity, diabetes mellitus, and sedentary lifestyle.

O. Inflammatory Reactions (Immune Reconstitution Inflammatory Syndromes)

With initiation of antiretroviral treatment, some patients experience **inflammatory reactions** that appear to be associated with immune reconstitution as indicated by a rapid increase in CD4 count. These inflammatory reactions may present with generalized signs of fevers, sweats, and malaise with or without more localized manifestations that usually represent unusual presentations of opportunistic infections. For example, vitreitis has developed in patients with CMV retinitis after they have been treated with antiretroviral treatment.

M avium can present as focal even suppurative lymphadenitis or granulomatous masses in patients receiving antiretroviral treatment. Tuberculosis may paradoxically worsen with new or evolving pulmonary infiltrates and lymphadenopathy. PML and cryptococcal meningitis may also behave atypically. Clinicians should be alert to these syndromes, which are most often seen in patients who have initiated antiretroviral treatment in the setting of advanced disease and who show rapid increases in CD4 counts with treatment. The diagnosis of **immune reconstitution inflammatory syndrome (IRIS)** is one of exclusion and can be made only after recurrence or new opportunistic infection has been ruled out as the cause of the clinical deterioration. Management of IRIS is conservative and supportive with use of corticosteroids only for severe reactions. Most authorities recommend that antiretroviral treatment be continued unless the IRIS reaction is life-threatening.

Prevention

A. Primary Prevention

Until vaccination is a reality, prevention of HIV infection will depend on HIV testing and counseling, including precautions regarding sexual practices and injection drug use, initiation of antiretroviral treatment as a prevention tool for transmission to others, preexposure and postexposure use of antiretroviral treatment, perinatal management including antiretroviral treatment of the mother, screening of blood products, and infection control practices in the health care setting.

1. HIV testing and counseling—Primary care clinicians should routinely obtain a sexual history and provide risk factor assessment of their patients. Because approximately 15% of the HIV-infected persons in the United States do not know they are infected, the US Preventive Services Task Force recommends that clinicians screen for HIV infection in adolescents and adults ages 15 to 65 years. Younger adolescents and older adults who are at increased risk should also be screened. Clinicians should review the risk factors for HIV infection with the patient and discuss safer sex and safer needle use as well as the meaning of a positive test. Although the CDC recommends “opt-out” testing in medical settings, some states require specific written consent. For persons whose test results are positive, it is critically important that they be connected to ongoing medical care. Many public health systems advocate for initiating care and treatment the same day that someone tests positive if appropriate resources are available (see C. Antiviral Treatment, below). Referrals for partner-notification services, social services, mental health services, and HIV-prevention services should also be provided. Prevention interventions focused on the importance of HIV-infected persons not putting others at risk have been successful.

For patients whose test results are negative, clinicians should review safer sex and needle use practices, including counseling not to exchange bodily fluids unless they are in a long-term mutually monogamous relationship with someone who has tested HIV antibody-negative and has not engaged in unsafe sex, injection drug use, or other HIV risk behaviors for at least 6 months prior to or at any time since the negative test.

To prevent sexual transmission of HIV, only latex or polyurethane condoms should be used, along with a water-soluble lubricant. Although nonoxynol-9, a spermicide, kills HIV, it is contraindicated because in some patients it may cause genital ulcers that could facilitate HIV transmission. Patients should be counseled that condoms are not 100% effective. They should be made familiar with the use of condoms, including, specifically, the advice that condoms must be used every time, that space should be left at the tip of the condom as a receptacle for semen, that intercourse with a condom should not be attempted if the penis is only partially erect, that men should hold on to the base of the condom when withdrawing the penis to prevent slippage, and that condoms should not be reused. Although anal intercourse remains the sexual practice at highest risk for transmitting HIV, seroconversions have been documented with vaginal and oral intercourse as well. Therefore, condoms should be used when engaging in these activities. Women as well as men having sex with men should understand how to use condoms to be sure that their partners are using them correctly. Partners of HIV-infected women should use latex or polyurethane barriers such as dental dams (available at dental supply stores) to prevent direct oral contact with vaginal secretions. Several randomized trials in Africa demonstrated that male circumcision significantly reduced HIV incidence in men, but there are a number of barriers to performing widespread circumcisions among men in Africa.

Persons using injection drugs should be cautioned never to share needles or other drug paraphernalia. When sterile needles are not available, bleach does appear to inactivate HIV and should be used to clean needles.

2. Antiretroviral treatment for decreasing transmission of HIV to others—Besides preventing progression of HIV disease, effective antiretroviral treatment likely decreases the risk of HIV transmission between sexual partners. Among serodiscordant couples, stably suppressing HIV with antiretroviral treatment almost completely eliminates the risk of HIV transmission to the uninfected partner. Although HIV-negative persons in stable long-term partnerships with HIV-infected persons represent only one group of at-risk persons, theoretically increasing the use of antiretroviral treatment among the population of HIV-infected persons could decrease community-wide transmission of HIV. Despite major improvements in effectiveness and tolerability of antiretroviral treatment, only about 60% of HIV-infected persons in the United States are virally suppressed. Persons in whom the HIV virus has been “undetectable” for a prolonged period have virtually no chance of sexually transmitting HIV. Still, because of the possibility of variations in measured viral load, and not knowing whether their partners are virally suppressed, and the possibility of transmission through blood, all HIV-infected persons should practice safer sex and not share needles so as to avoid the possibility of transmitting HIV.

3. Preexposure antiretroviral treatment prophylaxis—Several large randomized double-blind placebo-controlled trials demonstrated that administering emtricitabine/TDF (Truvada) can reduce the risk of sexual transmission of HIV among uninfected individuals at high risk for infection; one study was of HIV-negative men and transgender women who have sex with men, and two studies were of heterosexual HIV-discordant couples. Preexposure tenofovir has also been shown to reduce HIV infection among injection drug users from Thailand. In addition, real-world studies of men who have sex with men, where adherence with emtricitabine/TDF has been high, have found **preexposure prophylaxis (PrEP)** to be highly effective in preventing HIV infection. Emtricitabine/TAF (Descovy) is under study for PrEP, but is not currently recommended because of questions of whether it has as good penetration into genital fluids.

Who should be prescribed PrEP is not a simple question. PrEP is best thought of as one “option” for HIV prevention, rather than as the only option. Whether it is the “best” option depends on three things: (1) the likelihood that a person will have HIV-infected partners or use the needles of infected persons, (2) whether there is a better option available to prevent HIV, and (3) the patient’s ability to take a daily medication. CDC guidelines recommend offering PrEP to persons at “substantial risk” for HIV. Risk for

HIV is a combination of the likelihood of having a partner who is HIV-infected and the likelihood that the behavior (eg, type of intercourse, shared needles) transmits HIV. Men who have sex with men, and transgender male-to-females are the groups with the highest HIV seroprevalence in the United States, and they are likely to have partners who are known to be or at risk for being HIV-infected. Those who have receptive anal intercourse have the highest risk of HIV because the behavior is much more efficient at transmitting HIV than other sexual practices. Heterosexual drug users are also at high risk for HIV-infection if they do not consistently use clean needles or if they trade drugs for sex. It can be hardest to assess the risk of heterosexual non-drug users because it requires assessing the likelihood that their partners have HIV risks such as being bisexual men or using injection drugs. Factors known to increase the risk of HIV transmission and therefore make PrEP a good choice for particular groups of patients are shown in Table 31–4.

Table 31–4. Recommendations for preexposure prophylaxis (PrEP) of HIV infection.

- **Patients for whom PrEP should be considered as an option for HIV prevention**
  - Sexually active homosexual and bisexual men, male-to-female transgender persons, and heterosexuals and bisexual women who are likely to have partners with HIV risks
  - Injection drug users
- **Factors that increase the likelihood that PrEP is a good option**
  - Patient has receptive anal intercourse
  - Patient has a known HIV-infected partner
  - Patient has a history of sexually transmitted diseases
  - Patient has a high number of sex partners
  - Patient is a commercial sex worker
  - Patient with inconsistent or no condom use
  - Patient who is sharing needles or related paraphernalia ("works")
- **Initial assessment before prescribing PrEP**
  - HIV antibody test to confirm HIV negative
  - Symptom review to exclude primary HIV infection (eg, no history of acute illness with fever and rash in prior month)
  - STD tests: syphilis; gonorrhea (at risk site-specific); and chlamydia (at risk site-specific)
  - Serum creatinine and eGFR[1]
  - Confirm immunity to HBV or vaccinate if nonimmune[2]
  - Pregnancy test
  - Discuss risks, including that PrEP is not 100% effective, does not protect against other STDs, and may have side effects
  - Counsel patients to use latex or polyurethane condoms and clean needles, in addition to PrEP
  - Assess substance use and offer treatment, if needed
  - Discuss importance of daily medication adherence
- **PrEP prescription**
  - Emtricitabine/TDF daily (Truvada) 1 tablet orally daily, initially for 90 days
- **Follow-up assessment**
  - HIV antibody test every 3 months
  - Serum creatinine every 6 months
  - Pregnancy test every 3 months
  - STD tests: syphilis, gonorrhea (at risk site-specific); and chlamydia (at risk site-specific)
  - Assess and support daily medication adherence
  - Reinforce benefits of using latex or polyurethane condoms and clean needles with PrEP
  - Assess substance use and offer treatment, if needed

---

[1] Emtricitabine/TDF is contraindicated if creatinine clearance < 60 mL/min.

[2] HBV-infected persons may experience HBV reactivation and liver damage if emtricitabine/TDF is stopped.

eGFR, estimated glomerular filtration rate; HBV, hepatitis B virus; STD, sexually transmitted disease; TDF, tenofovir diproxil fumarate.

PrEP checklists for providers and patients are available at https://www.cdc.gov/hiv/risk/prep/index.html (Last updated November 1, 2018).

How does PrEP compare to other options for preventing HIV? Latex or polyurethane condoms are an excellent choice for preventing sexual transmission of HIV because they are inexpensive, have no side effects, and prevent other sexually transmitted diseases and pregnancy. However, for a variety of reasons, people do not always use condoms even when taught to do so. In addition, condoms break or slip on occasion, so even persons who always use condoms may want the extra protection of PrEP if they have a known HIV-infected partner. History of sexually transmitted diseases is proof of unprotected sex and increases the likelihood that PrEP is a good option for a patient.

Finally, for PrEP to be effective, patients have to be willing to take it. Taking one pill right before sex would not be expected to offer protection because the medicine would not have adequate drug levels in the body. Maximum concentrations are achieved in various locations in the body at different treatment intervals: in blood, maximum levels are achieved after 20 days of daily dosing; in rectal tissue, after 7 days; in cervicovaginal tissue, after 20 days. Study participants who took at least 4 daily doses in a week were protected almost as well as those who took the drug every day, indicating that missed doses do not render the treatment ineffective; however, adherence to daily dosing is the safest method.

Recommendations on initial and follow-up assessments are shown in Table 31–4. Emtricitabine/TDF is contraindicated for persons with kidney disease (creatinine clearance less than 60 mL) because of the small risk of kidney toxicity with TDF. Decreases in bone mineral density have been documented in persons taking emtricitabine/TDF for PrEP at 24 weeks; whether this decrease will have clinical significance is unknown. In someone with osteoporosis or at high risk for osteoporosis, clinical judgement would be needed to assess whether the benefits of emtricitabine/TDF justified the risks of worsening bone density. If emtricitabine/TAF is found to be effective as PrEP, it would be a good alternative to emtricitabine/TDF for patients with kidney disease or osteoporosis since TAF appears to have less effect on the kidney and bone than TDF.

Substantial increases in sexually transmitted diseases have also been seen in persons taking PrEP, indicating the importance of regular follow-up in patients using PrEP. Some patients are reluctant to use insurance to cover the cost of the medication for fear of revealing that they are at risk for HIV; without insurance, the cost is high. Compassionate use programs are available from the medication manufacturer for low-income uninsured persons.

4. Postexposure prophylaxis for sexual and drug use exposures to HIV—The goal of **postexposure prophylaxis** is to reduce or prevent local viral replication prior to dissemination such that the infection can be aborted. Although there is no proof that administration of antiretroviral medications following a sexual or parenteral drug use exposure reduces the likelihood of infection, there is suggestive data from animal models, perinatal experience, and a case-control study of health care workers who experienced a needle stick.

Treatment of persons who have been exposed to HIV should be within 72 hours, but sooner is better. All exposed persons should first receive HIV testing to exclude the possibility that they are already infected. If rapid tests are not available, treatment should begin pending the results of a standard HIV test.

The choice of antiretroviral agents and the duration of treatment are the same as those for exposures that occur through the occupational route; the preferred regimen is tenofovir 300 mg with emtricitabine 200 mg daily with raltegravir 400 mg twice a day. In contrast to those with occupational exposures, some individuals may present very late after exposure. Because the likelihood of success declines with length of time from HIV exposure, treatment is not recommended after more than 72 hours after exposure. In addition, because the psychosocial issues involved with postexposure prophylaxis for sexual and drug use exposures are complex, it should be offered with prevention counseling. Counseling should focus on how to prevent future exposures. Individuals with ongoing risk for HIV infection should be considered candidates for PrEP. Clinicians needing more information on postexposure prophylaxis for occupational or nonoccupational exposures should contact the National Clinicians' Post-Exposure Prophylaxis Hotline (1-888-448-4911; http://nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/).

5. Prevention of perinatal transmission of HIV—Prevention of perinatal transmission of HIV begins by offering HIV counseling and testing to all women who are pregnant or considering pregnancy. HIV-infected women who are pregnant should start antiretroviral treatment with at least three medications. Recommended regimens are zidovudine and lamivudine with either ritonavir-boosted lopinavir or ritonavir-boosted atazanavir. Cesarean delivery should be planned if HIV viral load is greater than 1000 copies/mL near the time of delivery. Zidovudine should be given to the infant after birth for 6 weeks. When possible, breastfeeding should be avoided.

6. Prevention of HIV transmission in health care settings—In health care settings, universal body fluid precautions should be used, including use of gloves when handling body fluids and the addition of gown, mask, and goggles for procedures that may result in splash or droplet spread, and use of specially designed needles with sheath devices to decrease the risk of needle sticks. Because transmission of tuberculosis may occur in health care settings, all patients with cough should be encouraged to wear masks. Hospitalized HIV-infected patients with cough should be placed in respiratory isolation until tuberculosis can be excluded by chest radiograph and sputum smear examination.

Epidemiologic studies show that needle sticks occur commonly among health care professionals, especially among surgeons performing invasive procedures, inexperienced hospital housestaff, and medical students. Efforts to reduce needle sticks should focus on avoiding recapping needles and use of safety needles whenever doing invasive procedures under controlled circumstances. The risk of HIV transmission from a needle stick with blood from an HIV-infected patient is about 1:300. The risk is higher with deep punctures, large inoculum, and source patients with high viral loads. The risk from mucous membrane contact is too low to quantitate.

Health care professionals who sustain needle sticks should be counseled and offered HIV testing as soon as possible. HIV testing is done to establish a negative baseline for worker's compensation claims in case there is a subsequent conversion. Follow-up testing is usually performed at 6 weeks, 3 months, and 6 months. With the patient's permission, their blood can be tested for HIV antibody and HIV viral load.

A case-control study by the CDC indicates that administration of zidovudine following a needle stick decreases the rate of HIV seroconversion by 79%. Therefore, providers should be offered antiretroviral treatment as soon as possible after exposure and continued for 4 weeks. The preferred regimen is TDF 300 mg with emtricitabine 200 mg (Truvada) daily with raltegravir 400 mg twice a day. Providers who have exposures to persons who are likely to have antiretroviral medication resistance (eg, persons receiving therapy who have detectable viral loads) should have their therapy individualized, using at least two medications to which the source is unlikely to be resistant. Because reports have noted hepatotoxicity due to nevirapine in this setting, this agent should be avoided. Unfortunately, there have been documented cases of seroconversion following potential parenteral exposure to HIV despite prompt use of zidovudine prophylaxis. Counseling of the provider should include "safer sex" guidelines.

Centers for Disease Control and Prevention. Human Immunodeficiency Virus (HIV) in Healthcare Settings. https://www.cdc.gov/hai/organisms/hiv/hiv.html

7. Prevention of transmission of HIV through blood or blood products—Current efforts in the United States to screen blood and blood products have lowered the risk of HIV transmission with transfusion of a unit of blood to 1:1,000,000. Use of blood and blood products should be judicious, with patients receiving the least amount necessary, and patients should be encouraged to donate their own blood prior to elective procedures.

8. HIV vaccine—Primate model data have suggested that development of a protective vaccine may be possible, but clinical trials in humans have been disappointing. Only one vaccine trial has shown any degree of efficacy. In this randomized, double-blind, placebo-controlled trial, a recombinant canarypox vector vaccine plus two booster injections of a recombinant gp120 vaccine reduced the risk of HIV among a primarily heterosexual population in Thailand, but efficacy was too low (31%) for widespread use. A mosaic HIV vaccine resulted in a strong immune response among adult humans and protection against infection with an HIV-like virus in rhesus monkeys. The vaccine is currently being studied in a phase IIB trial in sub-Saharan Africa.

Barouch DH et al. Evaluation of a mosaic HIV-1 vaccine in a multicentre, randomized, double-blind, placebo-controlled, phase 1/2a clinical trial (APPROACH) and in rhesus monkeys (NHP 13-19). Lancet. 2018 Jul 21;392(10143):232–43. [PMID: 30047376]

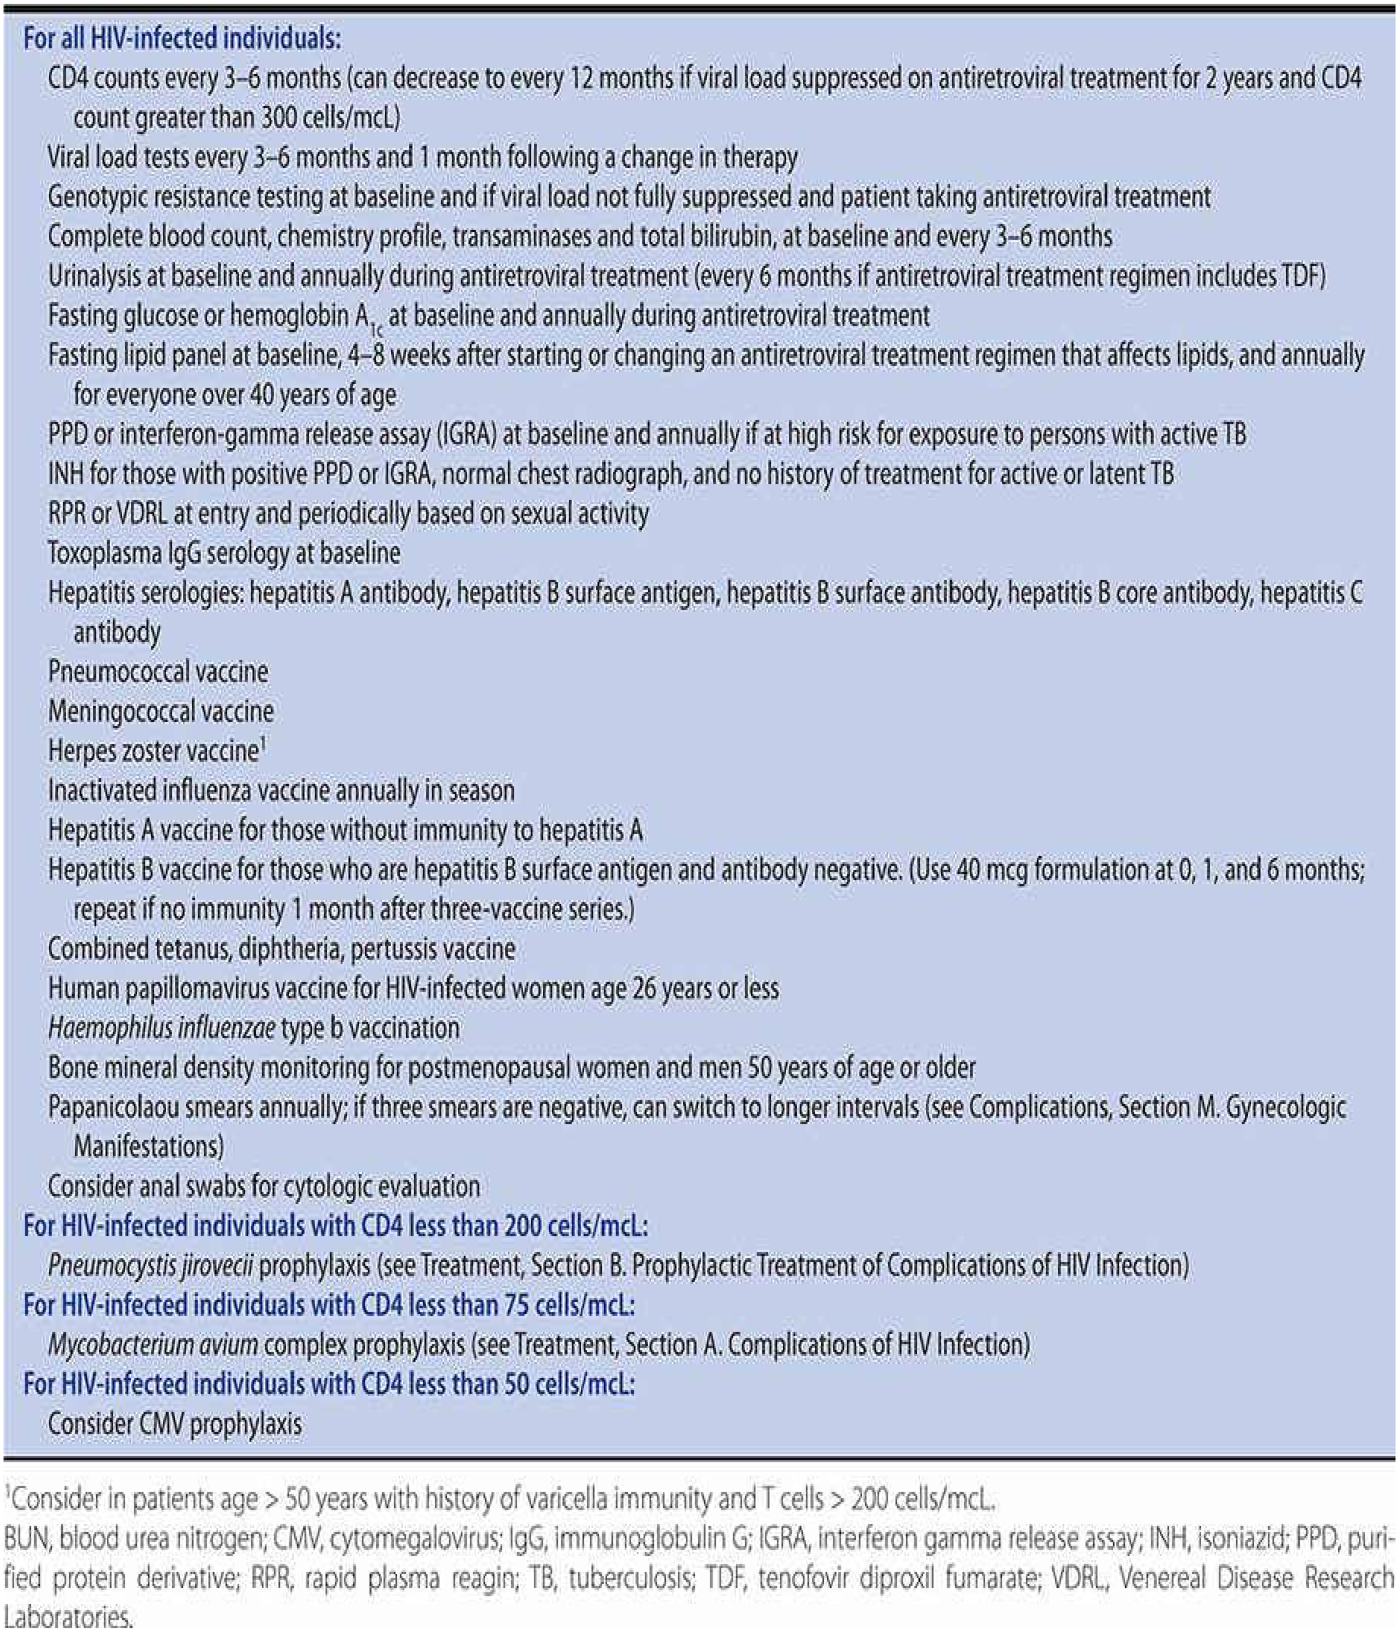
B. Secondary Prevention

In the era prior to the development of effective antiretroviral treatment, cohort studies of individuals with documented dates of seroconversion demonstrate that AIDS developed within 10 years in approximately 50% of untreated seropositive persons. With currently available treatment, progression of disease has been markedly decreased. In addition to antiretroviral treatment, prophylactic regimens can prevent opportunistic infections and improve survival. Prophylaxis and early intervention prevent several infectious diseases, including tuberculosis and syphilis, which are transmissible to others. Recommendations for screening tests, vaccinations, and prophylaxis are listed in Table 31–5.

Table 31–5. Health care maintenance and monitoring of HIV-infected individuals.



For all HIV-infected individuals:

- CD4 counts every 3–6 months (can decrease to every 12 months if viral load suppressed on antiretroviral treatment for 2 years and CD4 count greater than 300 cells/mcL)
- Viral load tests every 3–6 months and 1 month following a change in therapy
- Genotypic resistance testing at baseline and if viral load not fully suppressed and patient taking antiretroviral treatment
- Complete blood count, chemistry profile, transaminases and total bilirubin, at baseline and every 3–6 months
- Urinalysis at baseline and annually during antiretroviral treatment (every 6 months if antiretroviral treatment regimen includes TDF)
- Fasting glucose or hemoglobin A_{1c} at baseline and annually during antiretroviral treatment
- Fasting lipid panel at baseline, 4–8 weeks after starting or changing an antiretroviral treatment regimen that affects lipids, and annually for everyone over 40 years of age
- PPD or interferon-gamma release assay (IGRA) at baseline and annually if at high risk for exposure to persons with active TB
- INH for those with positive PPD or IGRA, normal chest radiograph, and no history of treatment for active or latent TB
- RPR or VDRL at entry and periodically based on sexual activity
- Toxoplasma IgG serology at baseline
- Hepatitis serologies: hepatitis A antibody, hepatitis B surface antigen, hepatitis B surface antibody, hepatitis B core antibody, hepatitis C antibody
- Pneumococcal vaccine
- Meningococcal vaccine
- Herpes zoster vaccine[1]
- Inactivated influenza vaccine annually in season
- Hepatitis A vaccine for those without immunity to hepatitis A
- Hepatitis B vaccine for those who are hepatitis B surface antigen and antibody negative. (Use 40 mcg formulation at 0, 1, and 6 months; repeat if no immunity 1 month after three-vaccine series.)
- Combined tetanus, diphtheria, pertussis vaccine
- Human papillomavirus vaccine for HIV-infected women age 26 years or less
- *Haemophilus influenzae* type b vaccination
- Bone mineral density monitoring for postmenopausal women and men 50 years of age or older
- Papanicolaou smears annually; if three smears are negative, can switch to longer intervals (see Complications, Section M. Gynecologic Manifestations)
- Consider anal swabs for cytologic evaluation

For HIV-infected individuals with CD4 less than 200 cells/mcL:

- *Pneumocystis jirovecii* prophylaxis (see Treatment, Section B. Prophylactic Treatment of Complications of HIV Infection)

For HIV-infected individuals with CD4 less than 75 cells/mcL:

- *Mycobacterium avium* complex prophylaxis (see Treatment, Section A. Complications of HIV Infection)

For HIV-infected individuals with CD4 less than 50 cells/mcL:

- Consider CMV prophylaxis

---

[1] Consider in patients age > 50 years with history of varicella immunity and T cells > 200 cells/mcL.

BUN, blood urea nitrogen; CMV, cytomegalovirus; IgG, immunoglobulin G; IGRA, interferon gamma release assay; INH, isoniazid; PPD, purified protein derivative; RPR, rapid plasma reagin; TB, tuberculosis; TDF, tenofovir diproxil fumarate; VDRL, Venereal Disease Research Laboratories.

1. Tuberculosis—Because of the increased occurrence of tuberculosis among HIV-infected patients, all such individuals should undergo an intradermal **PPD test** or an **interferon-gamma release assay (IGRA)** blood test at baseline and yearly thereafter if they remain at risk of exposure (eg, incarcerated, living in congregate settings). Those with a positive PPD (defined for HIV-infected patients as greater than 5 mm of induration) or a positive IGRA assay (results that are reported as positive and not negative or indeterminate) should be clinically evaluated for active tuberculosis, including by a chest radiograph. Patients with an infiltrate in any location, especially if accompanied by mediastinal adenopathy, should have sputum sent for acid-fast staining. Patients with active tuberculosis should be treated as outlined in Chapter 9 (see Tables 9–14 and 9–15). Patients with a positive PPD or IGRA assay, a normal chest radiograph, or negative sputum sample for active tuberculosis infection are classified as having latent tuberculosis infection. Patients with latent tuberculosis infection who have not been previously treated for (active or latent) tuberculosis should receive isoniazid (300 mg orally daily or twice weekly) with pyridoxine (50 mg orally daily) for 9 months. In patients with advanced immunodeficiency, both the PPD and IGRA assay are more likely to be falsely negative or (for IGRA assay) indeterminant. Therefore, it may be worth retesting patients with initially low CD4 counts once they have received antiretroviral treatment and have immune reconstitution (CD4 count greater than or equal to 200 cells/mcL).

Peters JS et al. Advances in the understanding of Mycobacterium tuberculosis transmission in HIV-endemic settings. Lancet Infect Dis. 2019 Mar;19(3):e65–e76. [PMID: 30554995]

2. Syphilis—Because of the increased number of cases of syphilis among MSM, including those who are HIV-infected, all such men should be screened for syphilis by a rapid plasma reagin (RPR) or Venereal Disease Research Laboratories (VDRL) test every 6 months. Increases of syphilis cases among HIV-infected persons are of particular concern because these individuals are at increased risk for reactivation of syphilis and progression to tertiary syphilis despite standard treatment. Because the only widely available tests for syphilis are serologic and because HIV-infected individuals are known to have disordered antibody production, there is concern about the interpretation of these titers. This concern has been fueled by a report of an HIV-infected patient with secondary syphilis and negative syphilis serologic testing. Furthermore, HIV-infected individuals may lose fluorescent treponemal antibody absorption (FTA-ABS) reactivity after treatment for syphilis, particularly if they have low CD4 counts. Thus, in this population, a nonreactive treponemal test does not rule out a past history of syphilis. In addition, persistence of treponemes in the spinal fluid after one dose of benzathine penicillin has been demonstrated in HIV-infected patients with primary and secondary syphilis. Therefore, the CDC has recommended an aggressive diagnostic approach to HIV-infected patients with reactive RPR or VDRL tests of longer than 1 year (or unknown) duration. All such patients should have a lumbar puncture with cerebrospinal fluid cell count and cerebrospinal fluid VDRL. Those with a normal cerebrospinal fluid evaluation are treated as having late latent syphilis (benzathine penicillin G, 2.4 million units intramuscularly weekly for 3 weeks) with follow-up titers. Those with a pleocytosis or a positive cerebrospinal fluid-VDRL test are treated as having neurosyphilis (aqueous penicillin G, 2–4 million units intravenously every 4 hours, or procaine penicillin G, 2.4 million units intramuscularly daily, with probenecid, 500 mg four times daily, for 10 days) followed by weekly benzathine penicillin G 2.4 million units intramuscularly for 3 weeks. Some clinicians take a less aggressive approach to patients who have low titers (less than 1:8), a history of having been treated for syphilis, and a normal neurologic examination. Close follow-up of titers is mandatory if such a course is taken. For a more detailed discussion of this topic, see Chapter 34.

Cantor AG et al. Screening for syphilis: updated evidence report and systematic review for the U.S. Preventive Services Task Force. JAMA. 2016 Jun 7;315(21):2328–37. [PMID: 27272584]

3. Immunizations—HIV-infected individuals should receive immunizations as outlined in Table 31–5. Patients without evidence of hepatitis B surface antigen or surface antibody should receive hepatitis B vaccination, using the 40-mcg formulation; the higher dose is to increase the chance of developing protective immunity. If the patient does not have immunity 1 month after the three-shot series, then the series should be repeated. HIV-infected persons should also receive the standard inactivated vaccines such as tetanus and diphtheria boosters that would be given to uninfected persons. Most live vaccines, such as yellow fever vaccine, should be avoided. Measles vaccination, while a live virus vaccine, appears relatively safe when administered to HIV-infected individuals and should be given if the patient has never had measles or been adequately vaccinated. The new recombinant adjuvanted herpes zoster vaccine (Shingrix), two doses 2–6 months apart, is recommended for HIV-infected persons with CD4 counts greater than 200 cells/mcL. However, it is not known if it is efficacious in preventing herpes zoster in this population.

Catherine FX et al. Hepatitis B virus vaccination in HIV-infected people: a review. Hum Vaccin Immunother. 2017 Jun 3;13(6):1–10. [PMID: 28267387]

4. Other measures—A randomized study found that multivitamin supplementation decreased HIV disease progression and mortality in HIV-infected women in Africa. However, supplementation is unlikely to be as effective in well-nourished populations.

HIV-infected individuals should be counseled with regard to the importance of practicing safer sex even with other HIV-infected persons because of the possibility of contracting a sexually transmitted disease, such as gonorrhea or syphilis. There is also the possibility of transmission of a particularly virulent or a drug-resistant strain between HIV-infected persons. Substance abuse treatment should be recommended for persons who are using recreational drugs. They should be warned to avoid consuming raw meat, eggs, or shellfish to avoid infections with Toxoplasma, Campylobacter, and Salmonella. HIV-infected patients should wash their hands thoroughly after cleaning cat litter or should forgo this household chore to avoid possible exposure to toxoplasmosis. To reduce the likelihood of infection with Bartonella species, patients should avoid activities that might result in cat scratches or bites. Although the data are not conclusive, many clinicians recommend that HIV-infected persons—especially those with low CD4 counts—drink bottled water instead of tap water to prevent cryptosporidia infection.

Because of the emotional impact of HIV infection and subsequent illness, many patients will benefit from supportive counseling.

Treatment

Treatment for HIV infection can be broadly divided into the following categories: (1) prophylaxis for opportunistic infections, malignancies, and other complications of HIV infection; (2) treatment of opportunistic infections, malignancies, and other complications of HIV infection; and (3) treatment of the HIV infection itself with combination antiretroviral treatment.

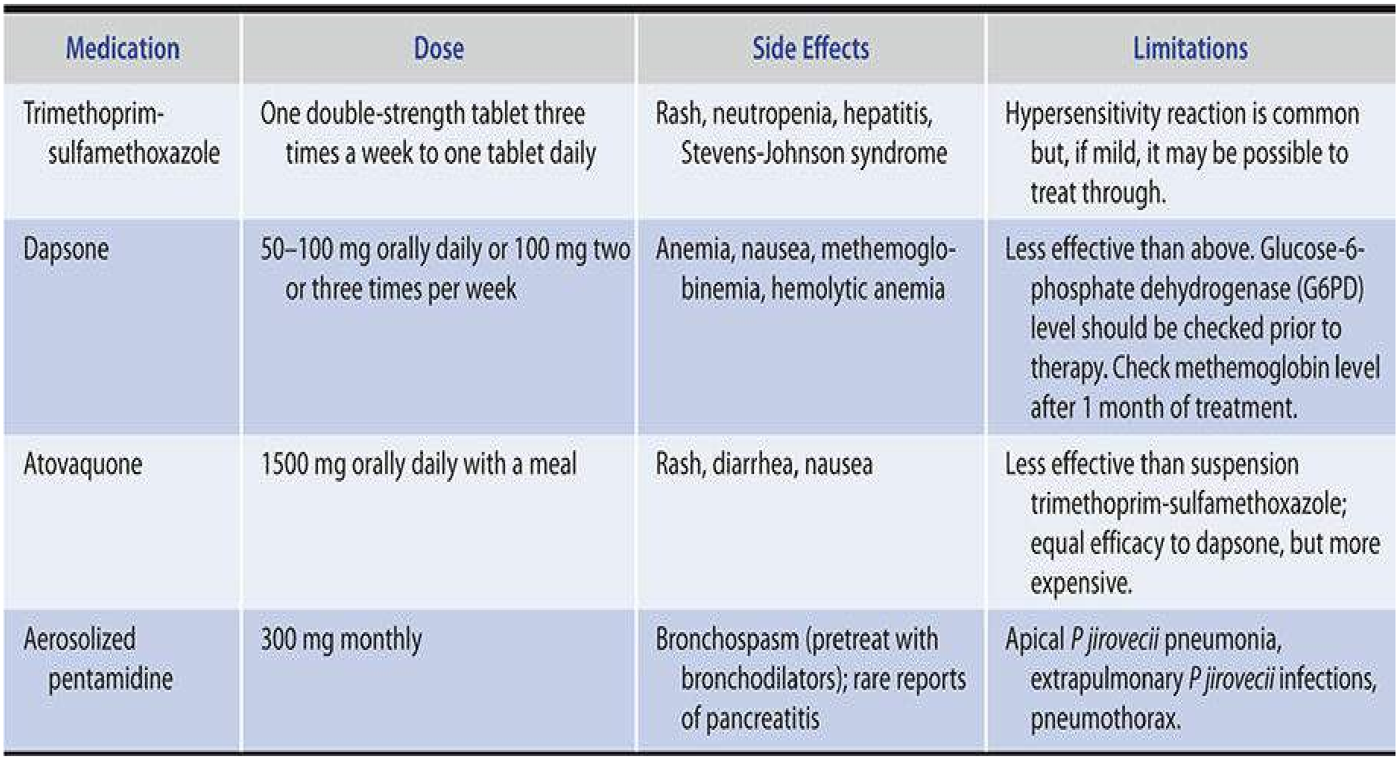
A. Prophylaxis for Complications of HIV Infection

In general, decisions about prophylaxis of opportunistic infections are based on the CD4 count, recent HIV viral load, and a history of having had the infection in the past. In the era prior to antiretroviral treatment, patients who started taking prophylactic regimens were maintained on them indefinitely. However, studies have shown that in patients with robust improvements in immune function—as measured by increases in CD4 counts above the levels that are used to initiate treatment—prophylactic regimens can safely be discontinued.

Because individuals with advanced HIV infection are susceptible to a number of opportunistic pathogens, the use of agents with activity against more than one pathogen is preferable.

1. Prophylaxis against Pneumocystis pneumonia—Patients with CD4 counts below 200 cells/mcL, a CD4 lymphocyte percentage below 14%, or weight loss or oral candidiasis should be offered primary prophylaxis for Pneumocystis pneumonia. Patients with a history of Pneumocystis pneumonia should receive secondary prophylaxis until their viral load is undetectable and they have maintained a CD4 count of 200 cells/mcL or more while receiving antiretroviral treatment for longer than 3 months. Regimens for Pneumocystis prophylaxis are given in Table 31–6.

Table 31–6. Pneumocystis jirovecii prophylaxis, in order of preference.



Medication	Dose	Side Effects	Limitations
Trimethoprim-sulfamethoxazole	One double-strength tablet three times a week to one tablet daily	Rash, neutropenia, hepatitis, Stevens-Johnson syndrome	Hypersensitivity reaction is common but, if mild, it may be possible to treat through.
Dapsone	50–100 mg orally daily or 100 mg two or three times per week	Anemia, nausea, methemoglobinemia, hemolytic anemia	Less effective than above. Glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to therapy. Check methemoglobin level after 1 month of treatment.
Atovaquone	1500 mg orally daily with a meal	Rash, diarrhea, nausea	Less effective than suspension trimethoprim-sulfamethoxazole; equal efficacy to dapsone, but more expensive.
Aerosolized pentamidine	300 mg monthly	Bronchospasm (pretreat with bronchodilators); rare reports of pancreatitis	Apical *P jirovecii* pneumonia, extrapulmonary *P jirovecii* infections, pneumothorax.

2. Prophylaxis against M avium complex infection—Patients whose CD4 counts fall to below 75–100 cells/mcL should be given prophylaxis against M avium complex infection. Clarithromycin (500 mg orally twice daily) and azithromycin (1200 mg orally weekly) have both been shown to decrease the incidence of disseminated M avium complex infection by approximately 75%, with a low rate of breakthrough of resistant disease. The azithromycin regimen is generally preferred based on high compliance and low cost. Prophylaxis against M avium complex infection may be discontinued in patients whose CD4 counts rise above 100 cells/mcL in response to antiretroviral treatment for longer than 3 months.

3. Prophylaxis against toxoplasmosis—Toxoplasmosis prophylaxis is desirable in patients with a positive IgG toxoplasma serology and CD4 counts below 100 cells/mcL. Trimethoprim-sulfamethoxazole (one double-strength tablet daily) offers good protection against toxoplasmosis, as does a combination of pyrimethamine, 25 mg orally once a week, plus dapsone, 50 mg orally daily, plus leucovorin, 25 mg orally once a week. A glucose-6-phosphate dehydrogenase (G6PD) level should be checked prior to dapsone therapy, and a methemoglobin level should be checked at 1 month. Prophylaxis can be discontinued when the CD4 cells have increased to greater than 200 cells/mcL for more than 3 months.

B. Treatment of Complications of HIV Infection

Treatment of common AIDS-related complications is detailed above and in Table 31–3. In the era prior to the use of antiretroviral treatment, patients required lifelong treatment for many infections, including CMV retinitis, toxoplasmosis, and cryptococcal meningitis. However, among patients who have a good response to antiretroviral treatment, maintenance therapy for some opportunistic infections can be terminated. For example, in consultation with an ophthalmologist, maintenance treatment for CMV infection can be discontinued when persons receiving antiretroviral treatment have had a sustained increase in CD4 count to greater than 100 cells/mcL for at least 3–6 months. Similar results have been observed in patients with M avium complex bacteremia, who have completed a year or more of therapy for M avium complex and have an increase in their CD4 count to 100 cells/mcL for greater than 6 months while receiving antiretroviral treatment. Cessation of secondary prophylaxis for Pneumocystis pneumonia is described above.

Treating patients with repeated episodes of the same opportunistic infection can pose difficult therapeutic challenges. For example, patients with second or third episodes of Pneumocystis pneumonia may have developed allergic reactions to standard treatments with a prior episode. Fortunately, there are several alternatives available for the treatment of Pneumocystis infection. Trimethoprim with dapsone and primaquine with clindamycin are two combinations that often are tolerated in patients with a prior allergic reaction to trimethoprim-sulfamethoxazole and intravenous pentamidine. Patients in whom second episodes of Pneumocystis pneumonia develop while taking prophylaxis tend to have milder courses.

Adjunctive Treatments—Epoetin alfa (erythropoietin) is approved for use in HIV-infected patients with anemia, including those with anemia secondary to zidovudine use. As zidovudine is rarely used now, especially at high doses, the use of epoetin alfa has also decreased. An erythropoietin level less than 500 milli-units/mL should be demonstrated before starting therapy. The starting dose of epoetin alfa is 8000 units subcutaneously three times a week. Hypertension is the most common side effect.

Human G-CSF (filgrastim) and granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]) have been shown to increase the neutrophil counts of HIV-infected patients. Because of the high cost of this therapy, the dosage should be closely monitored and minimized, aiming for a neutrophil count of 1000/mcL. When the medication is used for indications other than cytotoxic chemotherapy, one or two doses at 5 mcg/kg per week subcutaneously are usually sufficient.

C. Antiretroviral Therapy

The availability of agents that in combination suppress HIV replication (Table 31–7) has had a profound impact on the natural history of HIV infection. Indeed, with the advent of effective antiretroviral treatment, the life expectancy of HIV-infected persons approaches that of uninfected persons when treatment is initiated early in the course of the disease and maintained.

Table 31–7. Antiretroviral therapy agents by class (alphabetical order within class). (continued)

Medication	Dose	Common Side Effects	Special Monitoring[1]	Cost[2]	Cost/Month
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)					
Abacavir (Ziagen)	300 mg orally twice daily	Rash, fever—if occur, rechallenge may be fatal	No special monitoring	$9.64/300 mg	$578.56
Didanosine (Videx)	400 mg orally daily (enteric-coated capsule) for persons greater or equal to 60 kg 250 mg orally daily (enteric-coated capsule) for persons 30–59 kg	Peripheral neuropathy, pancreatitis, dry mouth, hepatitis	Bimonthly neurologic questionnaire for neuropathy, potassium, amylase, bilirubin, triglycerides	$12.29/400 mg	$368.72
Emtricitabine (Emtriva)	200 mg orally once daily	Skin discoloration palms/soles (mild)	No special monitoring	$21.46/200 mg	$643.82
Lamivudine (Epivir)	150 mg orally twice daily or 300 mg daily	Rash, peripheral neuropathy	No special monitoring	$7.16/150 mg	$429.60
Stavudine (Zerit)	40 mg orally twice daily for persons ≥ 60 kg 30 mg orally twice daily for persons < 60 kg	Peripheral neuropathy, hepatitis, pancreatitis	Monthly neurologic questionnaire for neuropathy, amylase	$6.85/40 mg	$410.70
Zidovudine (AZT) (Retrovir)	600 mg orally daily in two divided doses	Anemia, neutropenia, nausea, malaise, headache, insomnia, myopathy	CBC with differential 4–8 weeks after starting AZT	$0.90/300 mg	$54.00
Nucleotide Reverse Transcriptase Inhibitors (NRTI)					
Tenofovir alafenamide (TAF)/ emtricitabine (Descovy)	25 mg of TAF with 200 mg of emtricitabine once daily	Nephrotoxicity; hepatoxicity (if HBsAg positive, HBV exacerbation after discontinuation); bone resorption	Creatinine at baseline, at 2–8 weeks, then every 3–6 months; urinalysis and urine glucose and protein at baseline and repeated as clinically indicated; HBsAg, liver enzymes at baseline at 2–8 weeks, every 3–6 months, continue for months after discontinuation; consider bone densitometry	$70.32/tablet	$2109.48
Tenofovir (TDF) (Viread)	300 mg orally once daily	Kidney dysfunction, bone resorption, gastrointestinal distress	Creatinine at baseline, at 2–8 weeks, every 3–6 months; urinalysis and urine glucose and protein at baseline and repeated as clinically indicated; consider bone densitometry	$38.51/300 mg	$1155.30
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)					
Delavirdine (Rescriptor)	400 mg orally three times daily	Rash	No special monitoring	$2.97/200 mg	$533.89
Doravirine	100 mg daily	Headache, fatigue, abdominal pain	No special monitoring	$55.20/100 mg	$1656.00

Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs) (cont.)					
Efavirenz (Sustiva)	600 mg orally daily	Neurologic disturbances, rash, hepatitis	No special monitoring	$37.26/600 mg	$1117.80
Etravirine (Intelence)	200 mg orally twice daily	Rash, peripheral neuropathy	No special monitoring	$13.57/100 mg	$1628.02
Nevirapine (Viramune)	200 mg orally daily for 2 weeks, then 200 mg orally twice daily	Rash	No special monitoring	$10.83/200 mg	$649.80
Rilpivirine (Edurant)	25 mg daily	Depression, rash	No special monitoring	$44.60/25 mg	$1338.13
Protease Inhibitors (PIs)					
Atazanavir (Reyataz)	400 mg orally once daily or 300 mg atazanavir with 100 mg ritonavir daily	Hyperbilirubinemia	Bilirubin level every 3–4 months	$27.80/200 mg or $52.20/300 mg	$1668.00 (plus cost of ritonavir) $1566.00 (plus cost of ritonavir)
Atazanavir/cobicistat (Evotaz)	300 mg of atazanavir with 150 mg of cobicistat orally once daily	Hyperbilirubinemia	Bilirubin level every 3–4 months	$64.22/tablet	$1926.56
Darunavir/cobicistat (Prezcobix)	800 mg of darunavir and 150 mg of cobicistat orally once daily	Rash	No special monitoring	$72.27/tablet	$2167.96
Darunavir/ritonavir (Prezista/Norvir)	**PI-experienced patients:** 600 mg of darunavir and 100 mg of ritonavir orally twice daily **For PI-naïve patients:** 800 mg of darunavir and 100 mg of ritonavir orally daily	Rash	No special monitoring	$33.79/600 mg (darunavir) $9.26/100 mg (ritonavir) $67.59/800 mg (darunavir)	$2027.40 (plus cost of ritonavir) $2027.70 (plus cost of ritonavir)
Fosamprenavir (Lexiva)	**For PI-experienced patients:** 700 mg orally twice daily and 100 mg of ritonavir orally twice daily **For PI-naïve patients:** 1400 mg orally twice daily or 1400 mg orally once daily and 200 mg of ritonavir orally once daily	Gastrointestinal, rash	No special monitoring	$20.83/700 mg	$1249.86/700 mg (plus cost of ritonavir) $2499.72/1400 mg (plus cost of ritonavir)
Indinavir (Crixivan)	800 mg orally three times daily	Renal calculi	Bilirubin level every 3–4 months	$3.05/400 mg	$548.12
Lopinavir/ritonavir (Kaletra)	400 mg/100 mg orally twice daily	Diarrhea	No special monitoring	$10.24/200 mg (Kaletra)	$1228.97
Nelfinavir (Viracept)	750 mg orally three times daily or 1250 mg twice daily	Diarrhea	No special monitoring	$4.86/250 mg or $12.14/625 mg	$1456.80 (for either dose)
Ritonavir (Norvir)	600 mg orally twice daily or in lower doses (eg, 100 mg orally once or twice daily) for boosting other PIs	Gastrointestinal distress, peripheral paresthesias	No special monitoring	$9.26/100 mg	$3333.60 ($555.60 in lower doses)

Protease Inhibitors (PIs) (cont.)					
Saquinavir hard gel (Invirase)	1000 mg orally twice daily with 100 mg of ritonavir orally twice daily	Gastrointestinal distress	No special monitoring	\$12.02/500 mg	\$1442.09 (plus cost of ritonavir)
Tipranavir/ritonavir (Aptivus/Norvir)	500 mg of tipranavir and 200 mg of ritonavir orally twice daily	Gastrointestinal, rash	No special monitoring	\$16.73/250 mg (tipranavir) \$9.26/100 mg (ritonavir)	\$2007.58 (plus cost of ritonavir)
Entry Inhibitors					
Enfuvirtide (Fuzeon)	90 mg subcutaneously twice daily	Injection site pain and allergic reaction	No special monitoring	\$71.71/90 mg	\$4302.67
Maraviroc (Selzentry)	150 mg orally twice daily or 300 mg orally twice daily	Cough, fever, rash	No special monitoring	\$31.12 (for either dose)	\$1867.44 (for either dose)
Integrase Inhibitors					
Bictegravir	50 mg orally daily. No longer marketed as a single agent; used in antiretroviral combination (Table 31–8)	Diarrhea, nausea, headache	No special monitoring	No longer marketed as a single agent	No longer marketed as a single agent
Dolutegravir (Tivicay)	Treatment-naïve or integrase-naïve patients: 50 mg daily. When administered with efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin: 50 mg twice daily. When administered to integrase-experienced patients with suspected integrase resistance: 50 mg twice daily.	Hypersensitivity, insomnia, fatigue, headache, rash	No special monitoring	\$69.62/50 mg	\$2088.59/50 mg daily or \$4177.18/50 mg twice daily
Elvitegravir	No longer marketed as a single agent; used in antiretroviral combinations (Table 31–8)	Diarrhea, headache	No special monitoring	No longer marketed as a single agent	No longer marketed as a single agent
Raltegravir (Isentress)	400 mg orally twice daily	Diarrhea, nausea, headache	No special monitoring	\$30.00/400 mg	\$1800.00

[1] Standard monitoring is complete blood count (CBC) and differential, basic chemistries, serum aminotransferases and total bilirubin every 3–6 months, urinalysis at baseline and annually during antiretroviral treatment, fasting glucose or hemoglobin A_{1c} at baseline and annually during antiretroviral treatment, and fasting lipid profile at baseline, 4–8 weeks after starting an antiretroviral treatment regimen that affects lipids, and annually for everyone over 40 years of age.

The recognition that HIV damages the immune system from the beginning of infection, even when the damage is not easily measured by conventional tests, combined with the greater potency, the improved side-effect profile, and the decreased pill burden of modern HIV regimens, have led to the recommendation to start treatment for all HIV-infected persons regardless of CD4 count. The START trial demonstrated that immediate treatment is associated with a greater than 50% reduction in risk for serious illness or death, compared to delaying treatment until the CD4 count falls below 350 cells/mcL.

Rapid initiation programs have been created, where treatment can be started on the same day that patients test positive for HIV, so patients can start receiving treatment promptly and avoid being lost to follow-up. To do this, the clinic must have sufficient resources, medical and nonmedical, to help patients cope with these major events in a short time. Also, 5–20% of patients in developed countries who are treatment-naïve have a virus that is resistant to some medications; therefore, if treatment is started before the results of resistance testing are available, a nonnucleoside reverse transcriptase inhibitor (NNRTI) should not be used. Recommended regimens for initiating treatment before resistance testing results are available include (1) dolutegravir/TAF or TDF/emtricitabine (or lamivudine), (2) bictegravir/TAF/emtricitabine, or (3) boosted darunavir/TAF or TDF/emtricitabine (or lamivudine). Also, patients requiring abacavir as part of their regimen, should not start treatment prior to the results of HLA-B*5701 allele testing.

Once a decision to initiate therapy has been made, several important principles should guide therapy. First, because medication resistance to antiretroviral agents develops in HIV-infected patients, a primary goal of therapy should be complete suppression of viral replication as measured by the serum viral load. Therapy that achieves undetectable viral load has been shown to provide a durable response to the therapy. To achieve this and maintain virologic control over time, combination therapy with at least three medications from at least two different classes is necessary. Partially suppressive combinations should be avoided. Similarly, if toxicity develops, it is preferable to change the offending medication rather than reduce individual doses. Exceptions to the three-drug rule from at least two different classes are emerging. A combination of dolutegravir plus lamivudine has been shown to be noninferior to dolutegravir plus TDF and emtricitabine as initial therapy in patients with HIV viral load of less than 500,000 copies/mL. In April 2019, the FDA approved Dovato, a complete, once-daily, single-tablet combination of dolutegravir 50 mg and lamivudine 300 mg. A second exception is the coformulation of dolutegravir and rilpivirine (Juluca); this combination is FDA approved as an alternative treatment for patients who have been successfully virally suppressed for at least 6 months, have no history of treatment failure, and are not resistant to either of the two component agents.

The presence of an acute opportunistic infection in most cases does not preclude the initiation of antiretroviral treatment. Randomized trials compared early initiation of antiretroviral treatment (within 2 weeks of starting treatment for an opportunistic infection or tuberculosis) with antiretroviral treatment that was deferred until after treatment of the opportunistic infection was completed (6 weeks after its start); results demonstrated that early initiation reduced death or AIDS progression by 50%. The reduced progression rates were related to more rapid improvements in CD4 counts in patients with advanced immunodeficiency. Furthermore, IRIS and other adverse events were no more frequent in the early antiretroviral treatment arm.

Several randomized studies have also demonstrated improved clinical outcomes in HIV/tuberculosis coinfected patients who initiate antiretroviral treatment early in the setting of active treatment for tuberculosis and whose CD4 counts are less than 50 cells/mcL. The exception to early antiretroviral treatment in the setting of active infections may be in patients with a CNS-associated infection, such as cryptococcal or tuberculosis meningitis. Several studies from low-income countries have shown high mortality rates with early antiretroviral treatment initiation in this setting.

For hospitalized patients, initiating treatment in patients with opportunistic infections requires close coordination between inpatient and outpatient clinicians to ensure that treatment is continued once patients are discharged.

D. Choosing an Antiretroviral Treatment Regimen

Although the ideal combination of medications has not yet been defined for all possible clinical situations, optimal regimens can be better understood after a review of the available agents. These medications can be grouped into five major categories: nucleoside and nucleotide reverse transcriptase inhibitors (NRTIs); nonnucleoside reverse transcriptase inhibitors (NNRTIs); protease inhibitors (PI); entry inhibitors, which include a fusion inhibitor and CCR5 antagonists; and integrase inhibitors.

1. Nucleoside and nucleotide reverse transcriptase inhibitors (NRTI)—There are currently eight NRTI agents available (counting TDF and TAF as separate agents) for use. The choice of which agent to use depends primarily on the patient’s prior treatment experience, results of resistance testing, medication side effects, other underlying conditions, and convenience of formulation. However, most clinicians use fixed-dose combinations (see Table 31–8) of either emtricitabine/TDF, emtricitabine/TAF, or abacavir/lamivudine (ABC/lamivudine), all of which can be given once a day. Abacavir should be given only to HLA-B*5701-negative persons. In patients with viral loads greater than 100,000 copies/mL, ABC/lamivudine was less effective than emtricitabine/TDF when combined with efavirenz or ritonavir-boosted atazanavir. However, ABC/lamivudine appears to be equally efficacious as emtricitabine/TDF in patients with viral loads greater than 100,000 copies/mL when combined with dolutegravir or raltegravir. In some studies, abacavir increased risks of myocardial infarction, and therefore should be avoided in patients at high risk for cardiovascular disease. Zidovudine/lamivudine (AZT/lamivudine) is usually reserved for second- or third-line regimens because of toxicity and dosing schedule. Of the available agents, zidovudine is the most likely to cause anemia. Zidovudine and didanosine are the most likely to cause neutropenia. Stavudine is the most likely to cause lipoatrophy (loss of fat in the face, extremities, and buttocks) and should no longer be used; zidovudine is the next most likely agent to cause lipoatrophy. Didanosine is the most likely to cause peripheral neuropathy. Emtricitabine, TDF, TAF, and lamivudine have activity against hepatitis B. Didanosine, emtricitabine, TDF, TAF, and lamivudine can be administered once daily. Information specific to each medication is given below and in Table 31–7.

Table 31–8. Fixed-dose antiretroviral combinations (alphabetical order by brand name).

Name	Components	Dosing and Special Considerations	Cost per Month
Atripla	TDF 300 mg Emtricitabine 200 mg Efavirenz 600 mg	One pill daily constitutes a complete antiretroviral treatment regimen.	$3429.06
Biktarvy	Emtricitabine 200 mg TAF 25 mg Bictegravir 50 mg	One pill daily constitutes a complete antiretroviral treatment regimen. One of the recommended initial treatment regimens.	$3707.99
Complera	TDF 300 mg Emtricitabine 200 mg Rilpivirine 25 mg	One pill daily constitutes complete antiretroviral treatment regimen. Only for patients with HIV viral load less than 100,000/mL.	$3374.56
Delstrigo	TDF 300 mg Lamivudine 300 mg Doravirine 100 mg	One pill daily constitutes a complete antiretroviral treatment regimen.	$2520.00
Descovy	TAF 25 mg Emtricitabine 200 mg	One pill daily along with an NNRTI, protease inhibitor, integrase inhibitor, or maraviroc (entry inhibitor). The difference between Descovy and Truvada is that Descovy has a different form of tenofovir (TAF) that appears to be safer than the form of tenofovir (TDF) in Truvada because TAF has less effect on kidney function and bone mineral density. Descovy is not approved for use as PrEP.	$2109.48
Dovato	Dolutegravir 50 mg Lamivudine 300 mg	One pill daily constitutes a complete antiretroviral treatment regimen in adults with no antiviral treatment and no known substitutions associated with resistance to either component.	$2754.00
Epzicom	Abacavir 600 mg Lamivudine 300 mg	One pill daily along with an NNRTI, protease inhibitor, integrase inhibitor, or maraviroc (entry inhibitor).	$1550.05
Genvoya	TAF 10 mg Emtricitabine 200 mg Elvitegravir 150 mg Cobicistat 150 mg	One pill daily constitutes a complete antiretroviral treatment regimen. Although it contains four medications, one component (cobicistat) is a medication booster only. The only difference between Stribild and Genvoya is that Genvoya has a different form of tenofovir (TAF) that appears to be safer than tenofovir TDF with less effect on kidney function and bone mineral density.	$3707.99
Juluca	Dolutegravir 50 mg Rilpivirine 25 mg	One pill daily with a meal for patients who have been virologically suppressed (viral load < 50 copies/mL) on a stable antiretroviral treatment regimen for 6 months or more and no history of treatment failure or resistance to dolutegravir or rilpivirine.	$3249.54
Odefsey	TAF 25 mg Emtricitabine 200 mg Rilpivirine 25 mg	One pill daily constitutes a complete antiretroviral treatment regimen. Only for patients with no history of HIV viral load greater or equal to 100,000 copies/mL or replacement of stable antiretroviral regimen in patients fully suppressed for more than 6 months, with no history of treatment failure, and with no known resistance to components of the drug combination.	$3374.56
Stribild	TDF 300 mg Emtricitabine 200 mg Elvitegravir 150 mg Cobicistat 150 mg	One pill daily constitutes a complete antiretroviral treatment regimen. Although it contains four medications, one component (cobicistat) is a medication booster only.	$3889.68
Symtuza	TAF 10 mg Emtricitabine 200 mg Darunavir 800 mg Cobicistat 150 mg	One pill daily constitutes a complete antiretroviral treatment regimen. Although it contains four medications, one component (cobicistat) is a medication booster only. One of the recommended initial treatment regimens.	$4466.71
Triumeq	Abacavir 600 mg Lamivudine 300 mg Dolutegravir 50 mg	One pill constitutes a complete antiretroviral treatment regimen. One of the recommended initial treatment regimens.	$3467.23
Trizivir	Abacavir 300 mg Lamivudine 150 mg Zidovudine 300 mg	One tablet twice daily with an NNRTI, protease inhibitor, integrase inhibitor, or maraviroc (entry inhibitor). Although it contains three medications it *does not* constitute a complete antiretroviral treatment regimen.	$1931.64
Truvada	TDF 300 mg Emtricitabine 200 mg	One pill daily with an NNRTI, protease inhibitor, integrase inhibitor, or maraviroc (entry inhibitor). TDF is the most commonly used NRTI backbone.	$2109.48

NNRTI, non-nucleoside reverse transcriptase inhibitor (eg, delavirdine, efavirenz, etravirine, nevirapine, rilpivirine); NRTI, nucleoside/nucleotide reverse transcriptase inhibitor (eg, abacavir, didanosine, emtricitabine, lamivudine, stavudine, tenofovir, zidovudine); PrEP, preexposure prophylaxis; TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate.

Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: IBM Micromedex Red Book (electronic version) IBM Watson Health, Greenwood Village, CO, USA. Available at https://www.micromedexsolutions.com (cited April 25, 2019). AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

A. ZIDOVUDINE—Zidovudine was the first approved antiviral medication for HIV infection. It is administered at a dose of 300 mg orally twice daily. A combination of zidovudine 300 mg and lamivudine 150 mg (Combivir) is available. Approximately 40% of patients experience subjective side effects that usually remit within 6 weeks. The common dose-limiting side effects are anemia and neutropenia, which require ongoing laboratory monitoring. Long-term use has been associated with lipoatrophy.

B. LAMIVUDINE—Lamivudine is a safe and well-tolerated agent. The dosage is 150 mg orally twice daily or 300 mg orally once a day. The dose should be reduced in patients with chronic kidney disease. There are no significant side effects with lamivudine; it has activity against hepatitis B, though HBV resistance to it is an increasing problem.

C. EMTRICITABINE—Emtricitabine is dosed at 200 mg orally once daily. Emtricitabine also has activity against hepatitis B. Its dosage should be reduced in patients with chronic kidney disease.

D. ABACAVIR—Abacavir is dosed at 300 mg orally twice daily. Prior to initiation of abacavir, patients should undergo testing for HLA typing. Those with the B*5701 allele should not be treated with abacavir because the likelihood of a hypersensitivity reaction developing is high; the reaction is characterized by a flu-like syndrome with rash and fever that worsens with successive doses. Unfortunately, the absence of this allele does not guarantee that the patient will avoid the hypersensitivity reaction. Individuals in whom the hypersensitivity reaction develops should not be rechallenged with this agent because subsequent hypersensitivity reactions can be fatal. Abacavir has also been associated with an increased risk of myocardial infarction in some cohort studies, generally in patients who have underlying risks for cardiovascular disease. Consequently, abacavir should not be used in such patients if effective alternative nucleoside or nucleotide analog agents exist. Abacavir is usually prescribed as a fixed-dose combination pill with lamivudine for use as a once-daily pill (Epzicom; Table 31–8).

Abacavir is also formulated with zidovudine and lamivudine in a single pill (Trizivir, one tablet orally twice daily; Table 31–8). Trizivir is not recommended as solo treatment for HIV because it is not as efficacious as combining two nucleoside/nucleotide analogs with a ritonavir-boosted PI, an NNRTI, or an integrase inhibitor.

E. TENOFOVIR—Tenofovir is the only licensed nucleotide analog. It comes in two forms: tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF). TDF is available for use both in the form of a single pill at an oral dose of 300 mg once daily and as an oral fixed-dose combination pill with emtricitabine 200 mg (Truvada; Table 31–8) once daily. Several other single-tablet once-a-day complete regimens include TDF (Atripla, Complera, Stribild) (Table 31–8). Tenofovir is active against hepatitis B, including isolates that have resistance to lamivudine. TDF is associated with a clinically modest loss of kidney function, a small increased risk of acute renal injury, and increased rate of bone resorption. It should not be used in patients at risk for kidney disease or without dose adjustment in those with creatinine clearance below 60 mL/min or in those with or at risk for osteopenia/osteoporosis. For these patients, TAF is the better choice.

TAF attains higher levels in cells with a much lower plasma level. For this reason, it appears to cause less harm to kidneys and less bone resorption. It is not available as a single agent but is available in a combination tablet with emtricitabine (Descovy, Table 31–8). Single-tablet once-a-day regimens that include TAF (Genvoya and Odefsey) are also available (Table 31–8). TAF should not be used with rifamycins.

Because of concern regarding nephrotoxicity for both TDF and TAF, it is recommended that the serum creatinine be checked at baseline, at 2–8 weeks, and then every 3–6 months and that a urinalysis and urine glucose and protein be checked at baseline and monitored periodically as clinically indicated.

F. DIDANOSINE—The most convenient formulation of didanosine is the enteric-coated capsule. For adults weighing at least 60 kg, the dose is one 400-mg enteric-coated capsule orally daily; for those 30–59 kg, the dose is one 250-mg enteric-coated capsule orally daily. Didanosine should be taken on an empty stomach.

Didanosine has been associated with pancreatitis. The incidence of pancreatitis with didanosine is 5–10%—of fatal pancreatitis, less than 0.4%. Patients with a history of pancreatitis, as well as those taking other medications associated with pancreatitis (including trimethoprim-sulfamethoxazole and intravenous pentamidine) are at higher risk for this complication. Other common side effects with didanosine include a dose-related, reversible, painful peripheral neuropathy, which occurs in about 15% of patients, and dry mouth. Fulminant hepatic failure and electrolyte abnormalities, including hypokalemia, hypocalcemia, and hypomagnesemia, have been reported in patients taking didanosine. Because of the side-effect profile, didanosine is rarely used today.

2. Nonnucleoside reverse transcriptase inhibitors—NNRTIs inhibit reverse transcriptase at a site different from that of the nucleoside and nucleotide agents described above. The major advantage of NNRTIs is that four of them (efavirenz, rilpivirine, doravirine, and nevirapine) have potencies comparable to that of PI (next section), at least for patients with viral loads under 100,000 copies/mL—with lower pill burden and fewer side effects. Unlike PI, they do not appear to cause lipodystrophy;

patients with cholesterol and triglyceride elevations who are switched from a PI to an NNRTI may have improvement in their lipids. The resistance patterns of NNRTIs are distinct from those of the PI. Because these agents may cause alterations in the clearance of PIs, dose modifications may be necessary when these two classes of medications are administered concomitantly. There is a high degree of cross-resistance among the “first-generation” NNRTIs, such that resistance to one medication in this class uniformly predicts resistance to other medications. However, the “second-generation” NNRTI etravirine appears to have consistent antiviral activity in patients with prior exposure and resistance to nevirapine, efavirenz, or delavirdine. In particular, the K103N mutation does not appear to have an impact on etravirine (or rilpivirine). There is no therapeutic reason for using more than one NNRTI at the same time.

A. EFAVIRENZ—The major advantages of efavirenz are that it can be given once daily in a single dose (600 mg orally) and is available in a once-daily fixed-dose combination with TDF and emtricitabine in a single pill (Atripla; Table 31–8). The major side effects are rash and psychiatric/neurologic complaints, with patients reporting symptoms ranging from lack of concentration and strange dreams to delusions and mania. These side effects tend to wane over time, usually within a month or so; however, there are some patients who cannot tolerate these effects, especially if they persist longer than a month. Participant level data from four randomized trials of efavirenz regimens versus non-efavirenz containing regimens found increased suicidality (hazard ratio of 2.6) among those taking efavirenz. Administration of efavirenz with food, especially fatty food, may increase its serum levels and consequent neurotoxicity. Therefore, it should be taken on an empty stomach; taking before bedtime may also reduce patients’ experience of neuropsychiatric symptoms.

B. DORAVIRINE—Dosed at 100 mg orally daily, this drug can be taken with or without food. Two 48-week Phase III studies showed that, in previously untreated individuals, doravirine, when used with two NRTIs resulted in similar levels of viral suppression as efavirenz plus two NRTIs or darunavir/ritonavir plus two NRTIs. It is also available as a single-pill combination with TDF and lamivudine (Delstrigo; Table 31–8). It is well tolerated. In cases of virologic failure, NNRTI cross-resistance may develop.

C. RILPIVIRINE—This medication, dosed at 25 mg once daily, is equal in efficacy to efavirenz in patients with HIV viral loads below 100,000 copies/mL. Rilpivirine should not be used in patients with baseline viral loads of 100,000 copies/mL or greater or those with CD4 counts below 200 cells/mcL because of greater risk of viral failure. As is true of efavirenz, rilpivirine is available in a once-daily fixed-dose combination with TDF and emtricitabine (Complera; Table 31–8) and with TAF and emtricitabine (Odefsey; Table 31–8) to be taken with a meal. It is also available in a two-drug regimen with dolutegravir (Juluca, Table 31–8). Proton pump inhibitors should not be given with rilpivirine. Rilpivirine has fewer neurologic side effects than efavirenz.

D. NEVIRAPINE—The dose of nevirapine is 400 mg orally daily (extended release), but it is initiated at a dose of 200 mg once a day to decrease the incidence of rash, which is as high as 40% when full doses are begun immediately. If rash develops while the patient is taking 200 mg daily, liver enzymes should be checked and the dose should not be increased until the rash resolves. Patients with mild rash and no evidence of hepatotoxicity can continue to be treated with nevirapine. Nevirapine should not be used in treatment-naïve women with CD4 counts greater than 250 cells/mcL or in males with CD4 counts greater than 400 cells/mcL because they have greater risk of hepatotoxicity. In general, because of the risk of fatal hepatotoxicity, nevirapine should be used only when there is not a better alternative.

E. DELAVIRDINE—Of the available NNRTIs, delavirdine is used the least largely because of its inconvenient dosing and pill burden compared with the other available NNRTIs. Unlike nevirapine and efavirenz, delavirdine inhibits P450 cytochromes rather than inducing these enzymes. This means that delavirdine can act like ritonavir and boost other antiretrovirals, although delavirdine is not as potent as ritonavir in this capacity. The dosage is 400 mg orally three times a day. The major side effect is rash.

F. ETRAVIRINE—Etravirine is an NNRTI approved for the treatment of patients with prior NNRTI intolerance or resistance. Etravirine has been shown to be effective even when some degree of NNRTI resistance is present, making it a true “second-generation” medication in this class. Etravirine dosage is one 200-mg tablet twice daily. It should be used with a PI and an NRTI and not just with two NRTIs. The most common side effects are nausea and rash; rarely, the rash can be severe (toxic epidermal necrolysis). Patients with signs of severe rash or hypersensitivity reactions should immediately discontinue the medication. Prior rash due to treatment with one of the other NNRTIs does not make rash more likely with etravirine. Etravirine should not be taken by people with severe liver disease or administered with tipranavir/ritonavir, fosamprenavir/ritonavir, atazanavir/ritonavir, full-dose ritonavir, or PI without low-dose ritonavir.

3. Protease inhibitors—Ten PIs—indinavir, nelfinavir, ritonavir, saquinavir, amprenavir, fosamprenavir, lopinavir (in combination with ritonavir), atazanavir, darunavir, and tipranavir—are available. PIs are potent suppressors of HIV replication and are administered as part of a combination regimen.

All of the PIs—to differing degrees—are metabolized by the cytochrome P450 system, and each can inhibit and induce various P450 isoenzymes. Therefore, medication interactions are common and difficult to predict. Clinicians should consult the product inserts before prescribing PIs with other medications. Medications such as rifampin that are known to induce the P450 system should be avoided.

The fact that the PIs are dependent on metabolism through the cytochrome P450 system has led to the use of ritonavir to boost the medication levels of saquinavir, lopinavir, indinavir, atazanavir, tipranavir, darunavir, and amprenavir, allowing use of lower doses and simpler dosing schedules of these PIs. A second boosting agent, cobicistat, is coformulated with the PI atazanavir (Evotaz) and darunavir (Prescobix). Similar to ritonavir, cobicistat also inhibits liver enzymes that metabolize other HIV medications.

In fact, guidelines recommend that all PI-containing regimens except nelfinavir use boosting if possible.

When choosing which PI to use, prior patient experience, resistance patterns, side effects, and ease of administration are the major considerations. The first three PIs to be developed—indinavir, saquinavir, and ritonavir (as single agents)—are now rarely used because of the superiority of the second generation of PIs. Amprenavir has been almost entirely replaced by its prodrug, fosamprenavir. Unfortunately, all PIs, with the exception of unboosted atazanavir have been linked to a constellation of metabolic abnormalities, including elevated cholesterol levels, elevated triglyceride levels, insulin resistance, diabetes mellitus, and changes in body fat composition (eg, buffalo hump, abdominal obesity). The lipid abnormalities and body habitus changes are referred to as **lipodystrophy.** Although lipodystrophy is commonly associated with PIs, it has been seen also in HIV-infected persons who have never been treated with these agents. In particular, the lipoatrophy effects seen in patients receiving antiretroviral treatment appears to be more related to the nucleoside toxicity and in particular to the thymidine analogs (stavudine and zidovudine).

Of the different manifestations of lipodystrophy, the dyslipidemias that occur are of particular concern because of the likelihood that increased levels of cholesterol and triglycerides will result in increased prevalence of heart disease. All patients taking PIs or NRTIs should have fasting serum cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels performed every 12 months. Clinicians should assess for coronary heart disease risk (see Chapter 28) and consider initiating dietary changes or medication therapy (or both). PIs inhibit statin metabolism. Lovastatin and simvastatin should be avoided. In general, the least interaction is with pravastatin (20 mg daily orally). Atorvastatin (10 mg daily orally) or rosuvastatin (5 mg/day orally initially; maximum 10 mg/day) may also be used cautiously. Fish oil (3000 mg daily) combined with exercise and dietary counseling has been found to decrease triglyceride levels by 25%. Patients with persistently elevated fasting serum triglyceride levels of 500 mg/dL or more who do not respond to dietary intervention should be treated with gemfibrozil (600 mg twice daily prior to the morning and evening meals). PIs are associated with abnormalities in cardiac conduction, especially prolongation of the PR interval.

A. INDINAVIR—Indinavir is usually dosed at 800 mg twice daily in combination with 100 mg of ritonavir twice daily. Nausea and headache are common complaints with this medication. Indinavir crystals are present in the urine in approximately 40% of patients; this results in clinically apparent nephrolithiasis in about 15% of patients receiving indinavir. Lower urinary tract symptoms and acute kidney injury also have been reported. Patients taking this medication should be instructed to drink at least 48 ounces of fluid a day to ensure adequate hydration in an attempt to limit these complications. Mild indirect hyperbilirubinemia is also commonly observed in patients taking indinavir but is not an indication for discontinuation of the medication.

B. SAQUINAVIR—Saquinavir is formulated only as a hard-gel capsule (Invirase). It should be used only with ritonavir (1000 mg of hard-gel saquinavir with 100 mg of ritonavir orally twice daily). The most common side effects with saquinavir are diarrhea, nausea, dyspepsia, and abdominal pain.

C. RITONAVIR—Use of this potent PI at full dose (600 mg orally twice daily) has been limited by its inhibition of the cytochrome P450 pathway causing a large number of drug-drug interactions and by its frequent side effects of fatigue, nausea, and paresthesias. However, it is widely used in lower dose (eg, 100 mg daily to 100 mg twice daily) as a booster of other PIs.

D. NELFINAVIR—Nelfinavir is the only PI for which ritonavir boosting is not recommended. Unboosted nelfinavir is generally not as potent as a boosted PI regimen (eg, lopinavir plus ritonavir). The dose of nelfinavir is 1250 mg orally twice daily. Diarrhea is a side effect in 25% of patients taking nelfinavir, but this symptom may be controlled with over-the-counter antidiarrheal agents in most patients.

E. AMPRENAVIR—Amprenavir has efficacy and side effects similar to those of other PIs. Common side effects are nausea, vomiting, diarrhea, rash, and perioral paresthesia. The dose is 1200 mg orally twice daily. The concentration of amprenavir decreases when coadministered with ethinyl estradiol; therefore, amprenavir should be used with circumspection in the treatment of transgender persons requiring high-dose estrogen.

F. FOSAMPRENAVIR—Fosamprenavir is a prodrug of amprenavir. Its major advantage over using amprenavir is a much lower pill burden. For PI-naïve patients, it can be dosed at 1400 mg orally twice daily (four capsules a day) or at 1400 mg orally daily (two capsules) with ritonavir 200 mg orally daily (two capsules) or at 700 mg orally with ritonavir 100 mg orally twice daily. Patients previously treated with a PI should receive 700 mg orally with ritonavir 100 mg orally twice daily. Side effects are similar to those with amprenavir—most commonly gastrointestinal distress and hyperlipidemia. As with amprenavir, the concentration of fosamprenavir decreases when coadministered with ethinyl estradiol; therefore, fosamprenavir should be used with circumspection in the treatment of transgender persons requiring high-dose estrogen.

G. LOPINAVIR/R—Lopinavir/r is lopinavir (200 mg) coformulated with a low dose of ritonavir (50 mg) to maximize the bioavailability of lopinavir. It has been shown to be more effective than nelfinavir when used in combination with stavudine and lamivudine. The usual dose is lopinavir 400 mg with ritonavir 100 mg (two tablets) orally twice daily with food. When given along with efavirenz or nevirapine, a higher dose (600 mg/150 mg—three tablets) is usually prescribed. The most common side effect is diarrhea, and lipid abnormalities are frequent. Because of these side effects, lopinavir/r has fallen off the list of medications recommended as part of first-line treatment regimens.

H. ATAZANAVIR—Atazanavir is available alone and coformulated with cobicistat (Evotaz). Atazanavir can be dosed as 400 mg (two 200-mg capsules) daily with food or it can be dosed as 300 mg in combination with 100 mg of ritonavir once daily with food. When coformulated with cobicistat, it is dosed at 300-mg atazanavir and 150-mg cobicistat. The most common side effect is mild hyperbilirubinemia that resolves with discontinuation of the medication. Nephrolithiasis and cholelithiasis have also been reported with this PI. Both tenofovir and efavirenz lower the serum concentration of atazanavir. Therefore, when either of these two medications is used with atazanavir, it should be boosted by administering ritonavir or given coformulated with cobicistat. Proton pump inhibitors are contraindicated in patients taking atazanavir because atazanavir requires an acidic pH to remain in solution.

I. TIPRANAVIR—Tipranavir is the only nonpeptidic PI approved by the US Food and Drug Administration (FDA). Because of its unique structure, it is active against some strains of HIV that are resistant to other PIs. It is dosed with ritonavir (two 250-mg capsules of tipranavir with two 100-mg capsules of ritonavir orally twice daily with food). The most common side effects are nausea, vomiting, diarrhea, fatigue, and headache. Tipranavir/ritonavir has been also associated with liver damage and should be used very cautiously in patients with underlying liver disease. Reports of intracranial hemorrhage in patients taking tipranavir-containing regimens have raised additional safety concerns about this potent PI. Because it is a sulfa-containing medication, its use should be closely monitored in patients with sulfa allergy.

J. DARUNAVIR—Darunavir has impressive antiviral activity in the setting of significant

PI resistance and in treatment-naïve patients. It is formulated by itself and coformulated with cobicistat (Prezcobix). When formulated without cobicistat it requires boosting with ritonavir. For initial treatment of HIV or for treatment-experienced patients without darunavir-related resistance mutations, daily dosing is 800 mg of darunavir with 100 mg of ritonavir or with 150 mg of cobicistat. Darunavir 800 mg is also available in a coformulated tablet with emtricitabine, TAF, and cobicistat (Symtuza, Table 31–8). It has been approved for use by the FDA and the European Commission. For patients with prior PI treatment experience or PI resistance (with mutations known to impact darunavir), darunavir should be dosed at 600 mg orally twice daily, with ritonavir, 100 mg orally twice daily. Darunavir has a safety profile similar to other PIs, such as ritonavir-boosted lopinavir, but is generally better tolerated. Like tipranavir, darunavir is a sulfa-containing medication, and its use should be closely monitored in patients with sulfa allergy.

4. Entry inhibitors—

A. ENFUVIRTIDE—Enfuvirtide (Fuzeon) is known as a fusion inhibitor; it blocks the entry of HIV into cells by blocking the fusion of the HIV envelope to the cell membrane. The addition of enfuvirtide to an optimized antiretroviral regimen improved CD4 counts and lowered viral loads in heavily pretreated patients with multidrug-resistant HIV. Unfortunately, resistance develops rapidly in patients receiving nonsuppressive treatment. The dose is 90 mg by subcutaneous injection twice daily; unfortunately, painful injection site reactions develop in most patients, which makes long-term use problematic.

B. MARAVIROC—Maraviroc is a CCR5 co-receptor antagonist. Medications in this class prevent the virus from entering uninfected cells by blocking the CCR5 co-receptor. Before starting therapy, a viral tropism assay should be performed because this class of entry inhibitors is only active against “CCR5-tropic virus.” This form of the HIV-1 virus tends to predominate early in infection, while so-called dual/mixed tropic virus (which utilizes either R5 or CXCR4 co-receptors) emerges later as infection progresses. Approximately 50–60% of previously treated HIV-infected patients have circulating CCR5-tropic HIV. The medication has been shown to be effective in HIV-infected persons with ongoing viral replication despite being heavily treated and who have CCR5-tropic virus. The dose of maraviroc is 150–300 mg orally twice daily, based on the other medications the patient is taking at the time—in combination with a ritonavir boosted PI, 150 mg daily of maraviroc has been used successfully. Common side effects are cough, fever, rash, musculoskeletal problems, abdominal pain, and dizziness; however, maraviroc is generally well tolerated with limited impact on serum lipids.

5. Integrase inhibitors—Integrase inhibitors slow HIV replication by blocking the HIV integrase enzyme needed for the virus to multiply. They are now the preferred regimens for initiating therapy because of the combination of efficacy, ease of administration, and low incidence of side effects. Four integrase inhibitors are currently available: raltegravir, elvitegravir, dolutegravir and bictegravir. A fifth agent, cabotegravir, currently in phase III testing, can be coformulated with rilpivirine in a long-acting injectable form; it may prove to be an effective two-drug antiretroviral treatment regimen for patients successfully suppressed on a three-drug regimen. Clinical trials of available integrase inhibitors reveal a consistent pattern of more rapid decline in viral load compared with more standard PI/r or NNRTI-based regimens. Integrase inhibitors are effective (when combined with other active medications) in the treatment of HIV-infected patients with documented resistance to each of the three main classes of antiretroviral medications (nucleoside analogs, PIs, NNRTIs). Avoid administering integrase inhibitors with antacids or other medications with divalent cations (Ca^{2+}, Mg^{2+}, Al^{2+}, Fe^{2+}) because chelation of the integrase inhibitor by the cation reduces absorption. When these medications must be taken with integrase inhibitors, consult a pharmacist to determine the best separation of times of administration.

A. RALTEGRAVIR—The dose of raltegravir is 400 mg orally twice daily. It has been found to be superior to efavirenz and ritonavir-boosted darunavir and ritonavir-boosted atazanavir. It is the recommended integrase inhibitor for pregnant women. Common side effects are diarrhea, nausea, and headache, but overall, it is well tolerated and has the additional advantage over PI-based regimens and efavirenz-based regimens in that it appears to have little impact on lipid profiles or glucose metabolism.

B. ELVITEGRAVIR—Elvitegravir is not manufactured as a single agent. It can be prescribed in a once-a-day combination pill (Stribild) that contains 125 mg of elvitegravir and 150 mg of cobicistat, a boosting agent, along with standard doses of TDF and emtricitabine (Table 31–8). Stribild has been shown to be noninferior to two preferred first-line regimens: Atripla and boosted atazanavir with emtricitabine/TDF. The main side effect of Stribild is an increase in serum creatinine levels that has been shown to be related to the cobicistat inhibition of tubular secretion of creatinine by the kidney and is thought to be nonpathologic and reversible. However, because of this effect, Stribild is recommended in patients with estimated creatinine clearance greater than 70 mL/min. A urine analysis should be done at baseline and at initial follow-up to look for proteinuria and glycosuria, which are signs of tubulopathy. Diarrhea and rash may also occur, although overall the medication is well tolerated. Elvitegravir is also coformulated with emtricitabine and TAF along with cobicistat boosting in a single once-a-day pill (Genvoya, Table 31–8). Since TAF appears to have fewer side effects than TDF, this is likely to become the preferred elvitegravir regimen.

c. Dolutegravir—Dolutegravir shows excellent potency and tolerability and is dosed once a day in most circumstances. It has been shown to be superior to efavirenz and darunavir. Unlike elvitegravir, dolutegravir does not require a boosting agent and has fewer drug-drug interactions. Similar to cobicistat, it inhibits tubular secretion of creatinine by the kidney, resulting in small increases in serum creatinine levels. The standard dosage used in treatment-naïve, integrase-naïve patients is 50 mg/day. It is available combined with abacavir and lamivudine in a single once a day tablet (Triumeq, Table 31–8). In patients receiving efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin, the dose should be increased to 50 mg twice daily. It should also be dosed at 50 mg twice daily in integrase-experienced patients in whom integrase resistance is suspected. Indeed, when combined with other active medications, it has been shown to provide some activity in patients with integrase resistance who have not responded to prior raltegravir- or elvitegravir-containing regimens. Dolutegravir has demonstrated impressive results in clinical trials of treatment-naïve patients, in terms of effectiveness, tolerability, and high barrier to resistance, when compared with the more standard NNRTI, boosted PI, and raltegravir-containing regimens. Dolutegravir is coformulated in combination with rilpivirine (Juluca, Table 31–8) for use as a once-a-day (to be taken with a meal) treatment for patients who are virologically suppressed (viral load less than 50 copies/mL) on a stable regimen for at least 6 months, with no history of treatment failures or resistance to either of the two agents.

d. Bictegravir—Bictegravir is dosed once daily, does not require boosting, and has a high barrier to resistance. It is dosed at 50 mg daily. It has been shown to be noninferior to dolutegravir. It is not available as a single agent but is marketed as a fixed-dose combination of bictegravir with emtricitabine and TAF.

6. Ibalizumab—A novel treatment for HIV, ibalizumab is a monoclonal antibody that blocks the entry of HIV into the CD4 cell by blocking the CD4 receptor. Given as an intravenous infusion therapy along with other oral HIV medications, it is used as rescue therapy for patients with multidrug-resistant HIV that is not controlled by other treatments.

7. Constructing an initial regimen—Consensus guidelines of the International Antiviral Society—USA Panel recommend starting antiretroviral treatment with one of three integrase inhibitor–containing regimens (Table 31–9). For the two regimens that use tenofovir, the TAF form is recommended due to less kidney and bone toxicity. All three regimens are available as a single once a day pill.

Table 31–9. Recommended and alternative initial antiretroviral regimens and other commonly used three-drug regimens[1] (alphabetical order).

Regimen	Advantages	Disadvantages
Recommended Initial Regimens		
Bictegravir + TAF + emtricitabine (Bictarvy)	Single pill once-a-day regimen Low risk of resistance Noninferior to dolutegravir	Less experience than with dolutegravir
Dolutegravir + abacavir + lamivudine[2] (Triumeq)	Single pill once-a-day regimen Low risk of resistance Superior to Atripla Dolutegravir plus either abacavir/lamivudine or emtricitabine/TDF is superior to darunavir/ritonavir plus either of the NRTI backbones	Abacavir should be used only in HLA-B*5701-negative persons When used in patients with integrase resistance or combined with certain other medications, requires twice-a-day dosing
Dolutegravir (50 mg daily) + emtricitabine/TAF	Has activity in some patients with integrase resistance Once-a-day regimen	No single tablet available When used in patients with integrase resistance or combined with certain other medications, requires twice-a-day dosing
Other Integrase Inhibitor Regimens		
Emtricitabine/TAF/elvitegravir with cobicistat boosting (Genvoya)	Single tablet once-a-day regimen Excellent response across broad range of CD4 and viral loads	Lower barrier to resistance than bictegravir and dolutegravir Cobicistat boosting causes similar drug-drug interactions as ritonavir; increases in serum creatinine (nonpathologic) No dosage adjustment with estimated creatinine clearance > 30 mL/min
Emtricitabine/TDF/elvitegravir with cobicistat boosting (Stribild)	Single tablet once-a-day regimen Excellent response across broad range of CD4 and viral loads	Cobicistat boosting causes similar drug-drug interactions as ritonavir; increases in serum creatinine (nonpathologic) Requires estimated creatinine clearance ≥ 70 mL/min.
Raltegravir (400 mg twice daily) + emtricitabine + TAF or TDF	Superior to Atripla over 5 years of follow-up (when studied with TDF form of tenofovir)	Lower barrier to resistance than bictegravir and dolutegravir Requires twice-a-day dosing No single tablet available
Alternative Initial Regimens for Patients Who Cannot Take an Integrase Inhibitor		
Darunavir (800 mg daily) with cobicistat + emtricitabine + TAF or TDF	Single table once-a-day regimen (with TAF)	Cobicistat boosting causes similar drug-drug interactions as ritonavir; increases in serum creatinine (nonpathologic)
Darunavir (800 mg daily) with ritonavir (100 mg daily) boosting + emtricitabine + TAF or TDF	Potent boosted PI Can be given once daily Limited risk of resistance with poor adherence	Not available as a single tablet May cause rash in patients with sulfa allergy Ritonavir boosting required Has metabolic side effects
Efavirenz/emtricitabine/TDF (Atripla)	Single tablet once-a-day regimen Longest-term clinical experience Highly effective across broad range of initial CD4 counts and viral loads	Avoid in patients with transmitted *K103N* resistance Neuropsychiatric symptoms common and can be persistent
Rilpivirine/emtricitabine/TDF (Complera) or with emtricitabine/TAF (Odefsey)	Single tablet once-a-day regimen Noninferior to Atripla in patients with baseline viral load < 100,000/mcL Limited metabolic side effects	Requires taking with a meal Cannot be used with proton pump inhibitors Use only in patients with viral loads < 100,000 copies/mL and CD4 counts > 200 cells/mcL Do not use in patients with viral loads > 100,000 copies/mL or CD4 counts < 200 cells/mcL

[1] These recommended and alternative initial regimens are drawn from Saag MS et al. Antiretroviral drugs for treatment and prevention of HIV infection in adults: 2018 recommendations of the International Antiviral Society—USA Panel. JAMA. 2018;320(4):379–96.

[2] Usual medication doses are supplied when not part of a fixed-dose preparation.

TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate.

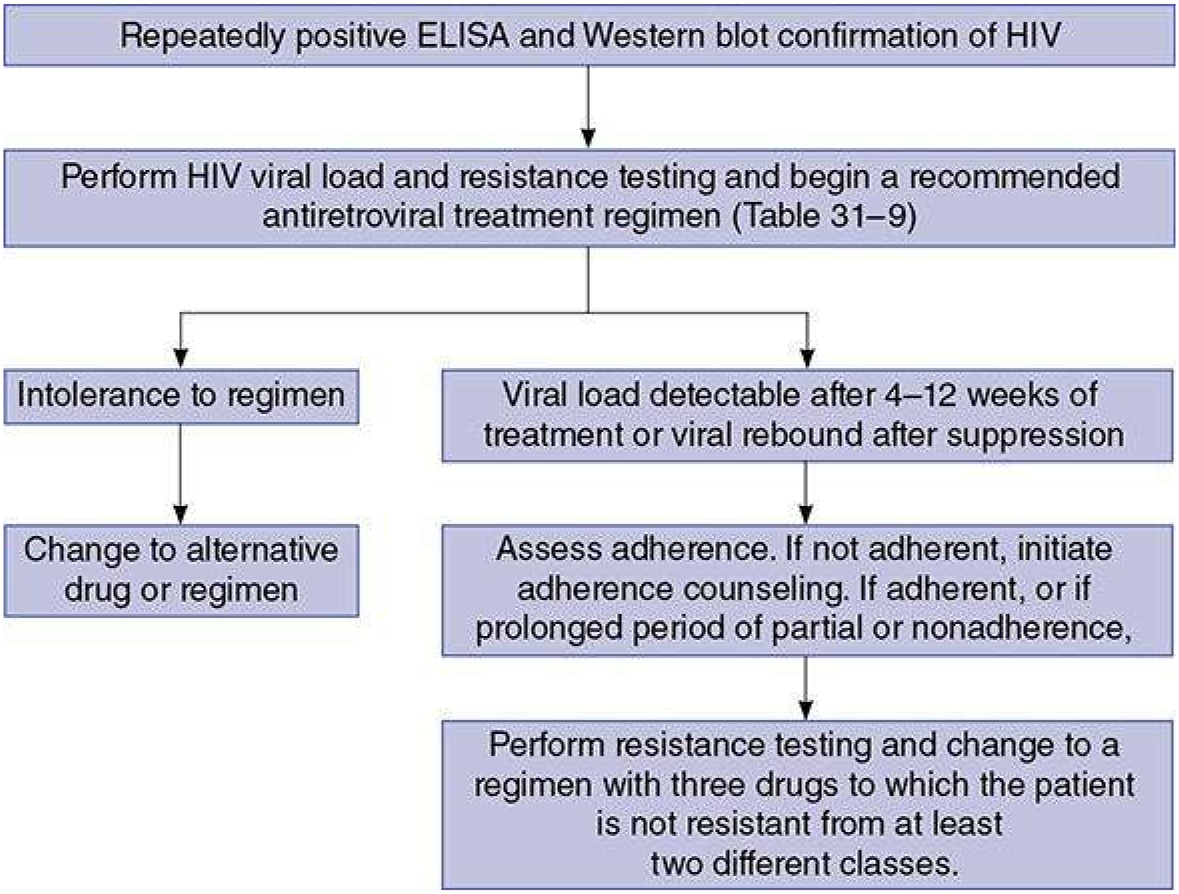
Studies have shown dolutegravir/abacavir/lamivudine to be superior to efavirenz/TDF/emtricitabine and have shown dolutegravir to be superior to ritonavir-boosted darunavir (both combined with either abacavir/lamivudine or TDF/emtricitabine). A network meta-analysis adjusting for NRTI backbone found that dolutegravir had superior efficacy in suppressing viral load compared with regimens containing ritonavir-boosted atazanavir, ritonavir-boosted darunavir, efavirenz, or ritonavir-boosted lopinavir. Discontinuation due to adverse events was also statistically lower in the dolutegravir regimens.

The drug combinations incorporating the integrase inhibitor raltegravir have done well in comparative studies. Among treatment-naïve patients, raltegravir in combination with TDF/emtricitabine is as effective as efavirenz/TDF/emtricitabine for daily treatment and has fewer side effects. In a 5-year follow-up to the double-blind trial, the raltegravir arm outperformed the efavirenz combination regimen largely due to better long-term tolerability. Furthermore, the CD4 response appeared better in patients treated with the raltegravir combination.

Neural tube defects have been reported in the offspring of women taking dolutegravir at conception, so the drug should be avoided in women who may become pregnant. For now, raltegravir is the integrase inhibitor recommended for women who are already pregnant. Elvitegravir/cobicistat and other drugs boosted with cobicistat should not be used during pregnancy and neither should bictegravir (because of lack of data regarding adverse effects). Recommended drugs in pregnancy include atazanavir/ritonavir, darunavir/ritonavir, efavirenz, and rilpivirine.

For patients who cannot take an integrase inhibitor, alternative regimens are recommended (Table 31–9).

Resistance testing should be performed prior to starting antiretroviral treatment. Of newly infected persons in some urban areas of the United States, 8–10% have NNRTI resistance (primarily K103N). Patients with NNRTI resistance would not be expected to respond fully to an efavirenz-based regimen. The most important determinant of treatment efficacy is adherence to the regimen. Therefore, it is vitally important that the regimen chosen be one to which the patient can easily adhere (Figure 31–7). In general, patients are more compliant with medication regimens (Table 31–9) that offer a complete regimen in one pill that needs to be taken only once or twice a day, do not require special timing with regard to meals, can be taken at the same time as other medications, do not require refrigeration or special preparation, and do not have bothersome side effects. Given the high level of effectiveness of recommended regimens, patients for whom the viral load does not fully suppress are likely noncompliant. Pharmacists and other specially trained clinicians can be very effective in helping patients improve their adherence by taking the time to understand why patients miss their medications and problem solve (eg, take medicine at same time every day, keep a supply in the car or at work in case they forget). For certain populations (eg, unstably housed individuals), specially tailored programs that include medication dispensing are needed.



Repeatedly positive ELISA and Western blot confirmation of HIV
Perform HIV viral load and resistance testing and begin a recommended antiretroviral treatment regimen (Table 31–9)
Intolerance to regimen
Viral load detectable after 4–12 weeks of treatment or viral rebound after suppression
Change to alternative drug or regimen
Assess adherence. If not adherent, initiate adherence counseling. If adherent, or if prolonged period of partial or nonadherence,
Perform resistance testing and change to a regimen with three drugs to which the patient is not resistant from at least two different classes.

Figure 31–7. Approach to monitoring initial and subsequent antiretroviral therapy.

E. Monitoring Antiretroviral Treatment

1. Goals of monitoring antiretroviral treatment—Monitoring of antiretroviral treatment (Figure 31–7) has two goals: evaluate for toxicity and measure efficacy using objective markers to determine whether to maintain or change regimens. Laboratory evaluation for toxicity depends on the specific medications in the combination but generally should be done approximately every 3–4 months once a patient is on a stable regimen. Patients who are intolerant of their initial regimen should be changed to one of the other initial recommended or alternative regimens in Table 31–9. The second aspect of monitoring is to measure objective markers of efficacy. The CD4 cell count and HIV viral load should be repeated 1–2 months after the initiation or change of antiretroviral regimen and every 3–6 months thereafter in clinically stable patients. With integrase regimens, approximately 80% of patients will have undetectable HIV viral load at 1 month. All patients should have undetectable viral loads by 3 months; if not, the usual problem is compliance (see next section). (Patients receiving antiretroviral treatment with undetectable viral load for 2 years and CD4 counts 300 cells/mcL or more may need CD4 testing only every 12 months.)

2. The challenge of compliance—In a patient who is adherent to an effective regimen, viral loads should be undetectable within 4–12 weeks. For patients in whom viral loads are not suppressed or who have viral rebound after suppression, the major question facing the clinician is whether the patient is nonadherent or has resistance to the regimen, or both. The issue is complicated because many patients report being more compliant than they really are. Patients who are having trouble adhering to their treatment should receive counseling on how to better comply with their treatment. In patients who are adherent or who have missed enough doses to make resistance possible, resistance testing should be performed. Based on the results of resistance testing, and assessment of the patient's ability to comply with complicated regimens or to tolerate predictable side effects, the clinician should prescribe a combination of three medications to which there is no or only minimal resistance.

Once antiretroviral treatment has been initiated, it is not advisable to stop the therapy unless there is a compelling reason (eg, toxicity, poor adherence, etc). So-called drug holidays or structured treatment interruptions have been shown to increase risk of AIDS-related complications, increase CD4 declines, and increase morbidity from non–AIDS-related complications (eg, myocardial infarctions and liver failure) and are not recommended.

3. The challenge of medication resistance—HIV-1 medication resistance limits the ability to fully control HIV replication and remains an important cause for antiretroviral regimen failure. Resistance has been documented for all currently available antiretrovirals including the newer classes of fusion inhibitor, CCR5 inhibitors, and integrase inhibitors. Although HIV medication resistance has been common historically, reports suggest that the degree of high-level resistance is declining in the past few years, which is likely related to better tolerated, easier to use, and more efficacious antiretroviral agents. Resistance also occurs in patients who are antiretroviral treatment-naïve, but who have been infected with a medication resistant strain—primary resistance or transmitted medication resistance. Cohort studies of antiretroviral treatment-naïve patients entering care in North America and Western Europe show that roughly 10–12% (and as high as 25%) of recently infected individuals have been infected with a medication-resistant strain of HIV-1.

In addition to being performed as part of a standard baseline, resistance testing is also recommended for patients who are receiving antiretroviral treatment and have suboptimal viral suppression (ie, viral loads greater than 200 copies/mL). Both genotypic and phenotypic tests are commercially available and in randomized controlled studies their use has been shown to result in improved short-term virologic outcomes compared to making treatment choices without resistance testing. Furthermore, multiple retrospective studies have conclusively demonstrated that resistance tests provide prognostic information about virologic response to newly initiated therapy that cannot be gleaned from standard clinical information (ie, treatment history, examination, CD4 count, and viral load tests).

Because of the complexity of resistance tests, many clinicians require expert interpretation of results. In the case of genotypic assays, results may show that the mutations that are selected for during antiretroviral treatment are medication-specific or contribute to broad cross-resistance to multiple medications within a therapeutic class. An example of a medication-specific mutation for the reverse transcriptase inhibitors would be the M184V mutation that is selected for by lamivudine or emtricitabine therapy—this mutation causes resistance only to those two medications. Conversely, the thymidine analog mutations ("TAMs") of M41L, D67N, K70R, L210W, T215Y/F, and T219Q/K/E are selected for by either zidovudine or stavudine therapy, but cause resistance to all the medications in the class and often extend to the nucleotide inhibitor tenofovir when three or more of these TAMs are present. Further complicating the interpretation of genotypic tests is the fact that some mutations that cause resistance to one medication can actually make the virus that contains this mutation more sensitive to another medication. The M184V mutation, for example, is associated with increased sensitivity to zidovudine, stavudine, and tenofovir. The most common mutations associated with medication resistance and cross-resistance patterns for NRTIs, NNRTIs, PIs, and integrase inhibitors can be found at https://hivdb.stanford.edu (see specific references below). Phenotypic tests also require interpretation in that the distinction between a resistant virus and sensitive one is not fully defined for all available medications.

Both methods of resistance testing are limited by the fact that they may measure resistance in only some of the viral strains present in an individual. Resistance results may also be misleading if a patient is not taking antiretroviral medications at the time of testing because the dominant virus is likely the wild-type, even if there are resistant viruses in the body that can become dominant with the selective pressure of antivirals. Thus, resistance results do not replace a careful history of what medications a patient has taken in the past and for how long. Also, the results of resistance testing should be viewed cumulatively—ie, if resistance is reported to an agent on one test, it should be presumed to be present thereafter even if subsequent tests do not give the same result.

Stanford University HIV Drug Resistance Database Home Page (https://hivdb.stanford.edu/) provides Genotypic Resistance Interpretation Algorithm, HIVdb Program, version 8.8, February 13, 2019

F. Constructing Alternative Antiretroviral Treatment Regimens

In designing second-line regimens for patients with resistance to initial therapy, the goal is to identify three medications from at least two different classes to which the virus is not resistant. Even without resistance testing, certain forms of cross-resistance between medications within a class can be assumed. For example, the resistance patterns of lopinavir/ritonavir and indinavir are overlapping, and patients with virus resistant to these agents are unlikely to respond to nelfinavir or saquinavir even though they have never received treatment with these agents. Similarly, the resistance patterns of nevirapine and efavirenz are overlapping—as are the resistance patterns between raltegravir and elvitegravir.

In constructing regimens, toxicities should be nonoverlapping and agents that are either virologically antagonistic or incompatible in terms of drug-drug interactions should be avoided. For example, the combination of stavudine plus didanosine should be avoided, since there is increased risk of toxicities, in particular in pregnant women because of the increased risk of lactic acidosis, which can be fatal. Moreover, the nucleoside pair of zidovudine and stavudine should be avoided because of increased toxicity and the potential for antagonism that results from intracellular competition for phosphorylation. The combination of didanosine with tenofovir should be avoided because of observed declines in CD4 counts. Etravirine should not be used with boosted tipranavir because of drug-drug interactions. Lamivudine and emtricitabine are essentially the same medication and so are not used together.

Given the availability of new class medications and new generation medications, a combination of antiretroviral treatment can successfully treat virtually all patients—no matter how much resistance is present.

Course & Prognosis

With improvements in therapy, patients who are compliant with treatment should have near normal life spans. A population-based study conducted in Denmark found that HIV-infected persons at age 25 years without hepatitis C had a life expectancy similar to that of an uninfected 25-year-old. Unfortunately, not all HIV-infected persons have access to treatment. Studies consistently show less access to treatment for blacks, the homeless, and injection drug users. For patients whose disease progresses even though they are receiving appropriate treatment, meticulous palliative care must be provided (see Chapter 5), with attention to pain control, spiritual needs, and family (biologic and chosen) dynamics.

When to Refer

- HIV-infected patients in whom viral loads cannot be fully suppressed on one of the initial recommended regimens should be referred to specialists.
- Specialty consultation is particularly important for those patients with detectable viral loads on antiretroviral treatment; those intolerant of standard medications; those in need of systemic chemotherapy; and those with complicated opportunistic infections, particularly when invasive procedures or experimental therapies are needed.

When to Admit

Patients with opportunistic infections who are acutely ill (eg, who are febrile, who have had rapid change of mental status, or who are in respiratory distress) or who require intravenous medications.

Cahn P et al; GEMINI Study Team. Dolutegravir plus lamivudine versus dolutegravir plus tenofovir disoproxil fumarate and emtricitabine in antiretroviral-naive adults with HIV-1 infection (GEMINI-1 and GEMINI-2): week 48 results from two multicentre, double-blind, randomised, non-inferiority, phase 3 trials. Viral & Rickettsial Infections

Wayne X. Shandera, MD
Eva Clark, MD, PhD

VIRAL DISEASES

HUMAN HERPESVIRUSES

1. Herpesviruses 1 & 2

ESSENTIALS OF DIAGNOSIS

- Spectrum of illness: stomatitis, urogenital lesions, Bell palsy, encephalitis.
- Variable intervals between exposure and clinical disease, since herpes simplex virus (HSV) causes both primary (often subclinical) and reactivation disease.

General Considerations

HSV-1 and HSV-2 affect primarily the oral and genital areas, respectively. Asymptomatic shedding of either virus is common, but it is more common with HSV-2 and from genital areas, with most infected individuals shedding virus at least once a month, which may be responsible for transmission. Asymptomatic HSV-2–infected individuals shed the virus less often than those with symptomatic infection. Clinical disease typically indicates reactivation. Total and subclinical shedding of HSV-2 virus decrease after the first year of initial infection, although viral shedding continues for years thereafter.

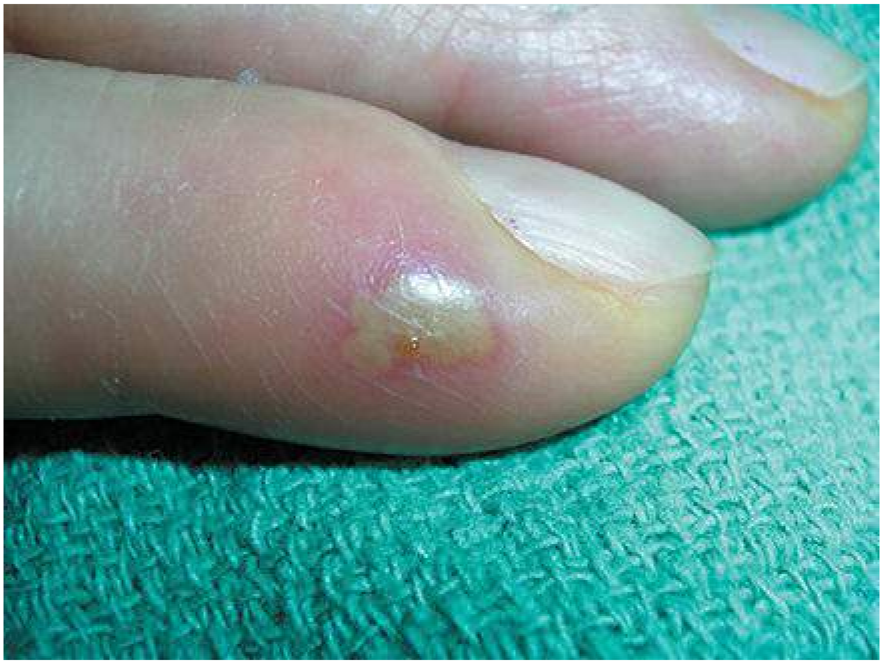
Although HSV-2 is the most common cause of genital ulcers in the developed world, epidemiologic studies show that HSV-1 is a more common cause of both genital and oral lesions than HSV-2 in young women in the United States. Most HSV-2–infected persons in the United States are unaware that they are infected.

HSV-2 seropositivity increases the risk of HIV acquisition (it is threefold higher among persons who are HSV-2 seropositive than among those who are HSV-2 seronegative), and HSV-2 reactivates more often in advanced HIV infection. HIV replication is increased by interaction with HSV proteins. Suppression of HSV-2 decreases HIV-1 plasma levels and genital tract shedding of HIV, which can contribute to a reduction in the sexual transmission of HIV-1.

Clinical Findings

A. Symptoms and Signs

1. Mucocutaneous disease—See Chapter 6 for HSV-1 mucocutaneous disease (“herpes labialis” or “gingivostomatitis”). Digital lesions (whitlows) (Figure 32–1) are an occupational hazard in medicine and dentistry. Contact sports (eg, wrestling) are associated with outbreaks of skin infections (“herpes gladiatorum”).



▲ **Figure 32–1. Herpetic whitlow**. (Used, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. The Color Atlas of Family Medicine, 2nd ed. McGraw-Hill, 2013.)

Vesicles form moist ulcers after several days and epithelialize over 1–2 weeks if untreated. Primary infection is usually more severe than recurrences but may be asymptomatic. Recurrences often involve fewer lesions, tend to be labial, heal faster, and are induced by stress, fever, infection, sunlight, chemotherapy (eg, fludarabine, azathioprine), or other undetermined factors.

HSV-2 lesions largely involve the genital tract, with the virus remaining latent in the presacral ganglia (see Chapter 6). Occasionally, lesions arise in the perianal region or on the buttocks and upper thighs. Dysuria, cervicitis, and urinary retention may occur in women. Urethritis may occur in men. Proctitis and extensive, ulcerating, weeping sacral lesions may be presenting symptoms in HIV-infected persons with CD4 cytopenia. Large ulcerations and atypical lesions suggest drug-resistant isolates.

2. Ocular disease—HSV can cause uveitis, keratitis, blepharitis, and keratoconjunctivitis (see Chapter 7). Lesions limited to the epithelium usually heal without affecting vision, whereas stromal involvement can cause uveitis, scarring, and eventually blindness. HSV is the second most common cause, after VZV, of acute retinal necrosis.

3. Neonatal and congenital infection—Both herpesviruses rarely infect the fetus and induce congenital malformations (organomegaly, bleeding, and central nervous system [CNS] abnormalities). The global rate of neonatal herpes is estimated to be about 10 cases per 100,000 live births. Maternal infection during the third trimester is associated with the highest risk of neonatal transmission, but about 70% of these infections are asymptomatic or unrecognized. Neonatal transmission during delivery, however, is more common than intrauterine infection. Invasive fetal monitoring and vacuum or forceps delivery increase the risk of herpesvirus transmission.

4. CNS disease—Traditionally, herpes simplex encephalitis is associated with HSV-1 infection and aseptic meningitis with HSV-2 infection. Both viruses, however, can cause encephalitis (and in one report, simultaneously). Encephalitis presents with nonspecific symptoms: a flu-like prodrome, followed by headache, fever, behavioral and speech disturbances, and focal or generalized seizures. The temporal lobe is often involved. Untreated disease and presentation with coma carry a high mortality. Ischemic stroke, although infrequent, can complicate the course of HSV meningitis or encephalitis. Many survivors suffer neurologic sequelae, which are observed more frequently among patients with HSV-1 infection. Both HSV-1 and HSV-2 can cause mild, nonspecific neurologic symptoms and are also associated with benign recurrent lymphocytic (Mollaret) meningitis.

5. Disseminated infection—Disseminated HSV infection occurs in the setting of immunosuppression, either primary or iatrogenic, or rarely with pregnancy. In disseminated disease, skin lesions are not always present. Disseminated skin lesions are a particular complication in patients with atopic eczema (eczema herpeticum) and burns. Pneumonia can occur regardless of immune status.

6. Bell palsy—HSV-1 is a cause of Bell palsy (facial nerve paralysis).

7. Esophagitis and proctitis—HSV-1 can cause esophagitis in immunocompromised patients, particularly those with AIDS. The lesions are smaller and deeper than those observed in patients with cytomegalovirus (CMV) esophagitis or with other herpesviruses known to cause esophagitis in immunocompromised persons. Proctitis occurs mainly in men who have sex with men.

8. Erythema multiforme—Herpes simplex viruses and certain drugs are a leading cause of erythema multiforme minor ("herpes-associated erythema multiforme") and of the more severe condition Stevens-Johnson syndrome/toxic epidermal necrolysis (see also Chapter 6).

9. Other—HSV is the cause of approximately 1% of cases of acute liver failure, particularly in pregnant women and immunosuppressed patients. The mortality of such rare fulminant hepatitis is nearly 75%. An HSV lower respiratory tract infection of unknown clinical significance is common in mechanically ventilated patients. Evidence suggests that this finding is usually an indicator rather than the cause of a poor clinical condition. HSV-1 pneumonia is associated with high morbidity in patients with solid tumors. HSV-1 is reported to be a cause of perinephric abscess, febrile neutropenia, chronic urticaria, and esophagitis and enteritis in systemic lupus erythematosus. HSV is also associated with Helicobacter pylori–negative upper gastrointestinal tract ulcers.

B. Laboratory Findings

1. Mucocutaneous disease—See Chapter 6.

2. Ocular disease—Herpes keratitis is diagnosed by branching (dendritic) ulcers that stain with fluorescein. The extent of epithelial injury in herpes keratitis correlates well with polymerase chain reaction (PCR) positivity. Uveitis from HSV is often diagnosed clinically, although PCR assays on anterior chamber aspirated material may assist in making the diagnosis.

3. Encephalitis and recurrent meningitis—Cerebrospinal fluid (CSF) pleocytosis is common, with a similar increase in the number of red cells although CSF findings may be atypical in immunosuppressed patients. HSV real-time DNA PCR of the CSF is a rapid, sensitive, and specific tool for early diagnosis and can be included in a multiple rapid array panel. Viral detection by this method can be used if the clinical picture is consistent, especially if initial studies are negative. Antibodies to HSV in CSF can confirm the diagnosis but appear late in disease. Viral culture shows a sensitivity of only 10%. MRI scanning is often a useful adjunct showing increased signal in the temporal and frontal lobes. Temporal lobe seizure foci may be shown on electroencephalograms (EEGs).

4. Esophagitis, proctitis, and other gastrointestinal disease—Esophagitis is diagnosed by endoscopic biopsy with real-time PCR and cultures. Proctitis may be diagnosed by rectal swab for PCR, culture, or both. Complicated cases may require biopsy. Concomitant hepatitis and colitis have been reported with herpes simplex.

5. Pneumonia—Pneumonia is diagnosed by clinical, pathologic, and radiographic findings. The CT findings include diffuse or multifocal areas of ground-glass attenuation or consolidative changes or both and are best confirmed by using high-resolution CT techniques.

Treatment & Prophylaxis

Medications that inhibit replication of HSV-1 and HSV-2 include trifluridine and vidarabine (both for keratitis), acyclovir and related compounds, foscarnet, and cidofovir (Table 32–1). Agents under study include helicase-primase inhibitors (amprenavir, fosamprenavir, and pritelivir) with promising preliminary (phase II) data.

Table 32–1. Agents for viral infections.[1]

Drug	Dosing[2]	Spectrum	Toxicities
Acyclovir	HSV and VZV infections: 200–800 mg orally five times daily; 250–500 mg/m^2 intravenously every 8 hours for 7 days Acute herpes encephalitis: 10 mg/kg intravenously every 8 hours for 14–21 days	HSV, VZV	Neurotoxic reactions, reversible kidney dysfunction, local reactions
Baloxavir	40 mg dose if patient is 40 to < 80 kg 80 mg if patient is 80 kg or more Only use for patients 12 years and older	Influenza A and B strains	Diarrhea and bronchitis
Cidofovir	5 mg/kg intravenously weekly for 2 weeks, then every other week	CMV	Neutropenia, kidney disease, ocular hypotonia
Famciclovir	500 mg orally three times daily for 7 days for acute VZV; 250 mg three times daily for 7–10 days for genital or cutaneous HSV-1/HSV-2 infection; 125 mg twice daily for 5 days for recurrences (500 mg twice daily for 7 days if HIV-infected)	HSV, VZV	Early angioedema; later rarely, gastrointestinal symptoms, headaches, rashes
Foscarnet	Induction: 90 mg/kg intravenously (90- to 120-minute infusion) every 12 hours or 60 mg/kg intravenously (minimum 1-hour infusion) every 8 hours over 2–3 weeks depending on clinical response Maintenance: 90–120 mg/kg intravenously (2-hour infusion) once daily	CMV, HSV resistant to acyclovir, VZV, HIV-1	Nephrotoxicity, genital ulcerations, calcium disturbances
Ganciclovir	Induction: 5 mg/kg intravenously every 12 hours for 14–21 days Maintenance: 6 mg/kg/day intravenously for 5 days each week	CMV	Neutropenia, thrombocytopenia, CNS side effects
Idoxuridine	Topical, 0.1% every 1–2 hours for 3–5 days (not available in the United States)	HSV keratitis	Local reactions
Interferon alfa-2b	HBV infection: 10 million international units subcutaneously three times weekly or 5 million units daily[1] Condylomata: 1 million international units intralesionally in up to five warts three times weekly for 3 weeks	HBV, HCV, HPV	Influenza-like syndrome, myelosuppression, neurotoxicity
Interferon alfa-n3	Refractory or recurring external condylomata acuminata: 0.05 mL (250,000 international units) per wart intralesionally twice weekly for up to 8 weeks; 0.5 mL (2.5 million international units) is the maximum dose per treatment session	HPV, HCV	Local reactions Influenza-like syndrome, myelosuppression, neurotoxicity
Oseltamivir	75 mg orally twice daily for 5 days	Influenza A and B	Dose needs to be adjusted for kidney dysfunction
Palivizumab	15 mg/kg intramuscularly every month in RSV season	RSV	Upper respiratory infection symptoms
Penciclovir	Topical 1% cream every 2 hours for 4 days	HSV	Local reactions
Peramivir	Intravenous, 600-mg single dose	Uncomplicated influenza A	Nausea, vomiting, diarrhea, neutropenia
Ribavirin	RSV infection: one vial (6 g) dissolved and delivered through a Small Particle Aerosol Generator (SPAG-2) over a continuous 12- to 18-hour period daily for 5 consecutive days	RSV, severe influenza A or B, Lassa fever	Wheezing, hemolytic anemia
Trifluridine	Topical, 1% drops every 2 hours to 9 drops/day	HSV keratitis	Local reactions
Valacyclovir	Acute VZV: 1 g orally three times daily for 7 days Primary genital HSV-1/HSV-2 infection: 1 g twice daily for 10 days Recurrent genital HSV-1/HSV-2 infection: 500 mg twice daily for 3 days Suppressive therapy: 1 g daily; 500 mg if fewer than 9 recurrences/year (Dose depends on immune status and number of recurrences.)	VZV, HSV	Thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome in AIDS
Valganciclovir	900 mg orally twice daily for 3 weeks; 900 mg daily as maintenance	CMV	See ganciclovir
Zanamivir	5 mg inhalations twice daily for 5 days	Uncomplicated influenza A and B	Bronchospasm in patients with asthma

Sources: Data from Drugs.com and Lexicomp Online.

[1] Agents used exclusively in the management of HIV infection and AIDS are found in Chapter 31. Agents used in the management of HBV and HCV infections are found in Chapter 16.

[2] Dosing varies considerably by indication and may require adjustment based on patient's clinical state and type of viral infection. Consultation with a pharmacist is recommended.

CMV, cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; HBV, hepatitis B virus; HCV, hepatitis C virus; HPV, human papillomavirus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

A. Mucocutaneous Disease

See Chapter 6.

B. Keratitis and Uveitis

For the treatment of acute epithelial keratitis, oral antiviral agents such as valacyclovir or famciclovir are first-line therapies (see Chapter 7). The usage of topical corticosteroids may exacerbate the infection, although systemic corticosteroids may help with selected cases of stromal infection. Long-term treatment (more than 1 year) with acyclovir at a dosage of 800 mg/day orally decreases recurrence rates of keratitis, conjunctivitis, or blepharitis due to HSV.

Uveitis is best managed with oral systemic (not topical) acyclovir, although HSV resistance among HIV-infected patients is reported because of the diversity of the HSV quasispecies often present.

C. Neonatal Disease

Counseling (but not serologic screening) should be offered to pregnant mothers. The use of maternal antenatal suppressive therapy with acyclovir (typically, 400 mg orally three times daily) beginning at 36 weeks' gestation decreases the presence of detectable HSV, the rates of recurrence at delivery, and the need for cesarean delivery. Cesarean delivery is recommended for pregnant women with active genital lesions or typical prodromal symptoms.

D. Encephalitis and CNS Meningitis

Because of the need for rapid treatment to decrease mortality and neurologic sequelae, intravenous acyclovir (10 mg/kg every 8 hours for 10 days or more, adjusting for kidney disease) should be started in those patients with suspected HSV encephalitis, stopping only if another diagnosis is established. If the PCR of CSF is negative but clinical suspicion remains high, treatment should be continued for 10 days because the false-negative rate for PCR can be as high as 25% (especially in children) and acyclovir is relatively nontoxic. HSV viral load does not appear to correlate with outcome of meningitis, and it is not recommended to follow viral load over time.

Long-term neurologic sequelae of HSV encephalitis are common, and late pediatric relapse is recognized. Acyclovir resistance in a case of herpes simplex encephalitis is reported. Aseptic meningitis may also require a course of intravenous acyclovir or valacyclovir. Long-term oral prophylaxis with valacyclovir, however, does not appear to prevent recurrences of aseptic meningitis with HSV-2.

E. Disseminated Disease

Disseminated disease responds best to parenteral acyclovir when treatment is initiated early.

F. Bell Palsy

Prednisolone, 25 mg orally twice daily for 10 days started within 72 hours of onset, significantly increases the rate of recovery. Data on antiherpes antiviral agents are equivocal and therefore HSV assays are not routinely recommended; according to one study, valacyclovir (but not acyclovir), 1 g orally daily for 5 days, plus corticosteroid therapy may be beneficial if started within 7 days of symptom onset. In patients with severe or complete facial paralysis, such antiviral therapy is often administered but without proof of efficacy.

G. Esophagitis and Proctitis

Patients with esophagitis should receive either intravenous acyclovir (5–10 mg/kg every 8 hours) or oral acyclovir (400 mg five times daily) through resolution of symptoms, typically 3–5 days; however, longer treatment may be necessary for immunosuppressed patients. Maintenance therapy for AIDS patients is also with acyclovir (400 mg orally three to five times daily). Proctitis is treated with similar dosages and usually responds within 5 days.

H. Erythema Multiforme

Suppressive therapy with oral acyclovir (400 mg twice a day for 6 months) decreases the recurrence rate of HSV-associated erythema multiforme. Valacyclovir (500 mg orally twice a day) may be effective in cases unresponsive to acyclovir.

Prevention

Besides antiviral suppressive therapy (see Erythema multiforme, above and in Chapter 6), prevention also requires counseling and the use of condom barrier precautions during sexual activity. Disclosure to sexual partners of HSV-seropositive status is associated with about a 50% reduction in HSV-2 acquisition. Male circumcision is associated with a lower incidence of acquiring HSV-2 infection.

Preventing spread to hospital staff and other patients from cases with mucocutaneous, disseminated, or genital disease requires isolation and usage of hand washing and gloving–gowning precautions. Staff with active lesions (eg, whitlows) should not have contact with patients. There is no approved herpes vaccine.

2. Varicella (Chickenpox) & Herpes Zoster (Shingles)

ESSENTIALS OF DIAGNOSIS

- **Varicella rash:** pruritic, centrifugal, papular changing to vesicular (“dew drops on a rose petal”), pustular, and finally crusting.
- **Zoster rash:** tingling, pain, eruption of vesicles in a dermatomal distribution, evolving to pustules and then crusting.

General Considerations

Varicella-zoster virus (VZV), or HHV-3, disease manifestations include chickenpox (varicella) and shingles (herpes zoster). Chickenpox generally presents during childhood; has an incubation period of 10–20 days (average 2 weeks); and is highly contagious, spreading by inhalation of infective droplets or contact with lesions.

The incidence and severity of herpes zoster (“shingles”), which affects up to 25% of persons during their lifetime, increases with age due to an age-related decline in immunity against VZV. More than half of all patients in whom herpes zoster develops are older than 60 years, and the incidence of herpes zoster reaches 10 cases per 1000 patient-years by age 80 (by which time 50% are infected with VZV). The annual incidence in the United States of 1 million cases is increasing as the population ages.

Populations at increased risk for varicella-zoster–related diseases include immunosuppressed persons and persons receiving biologic agents.

Clinical Findings

A. Varicella

1. Symptoms and signs—Fever and malaise are mild in children and more marked in adults. The pruritic rash begins prominently on the face, scalp, and trunk, and later involves the extremities (Table 32–2). Maculopapules change within a few hours to vesicles that become pustular and eventually form crusts (Figures 32–2 and 32–3). New lesions may erupt for 1–5 days, so that different stages of the eruption are usually present simultaneously. The crusts slough in 7–14 days. The vesicles and pustules are superficial and elliptical, with slightly serrated borders. Pitted scars are frequent. Although the disease is often mild, complications (such as secondary bacterial infection, pneumonitis, and encephalitis) occur in about 1% of cases and often lead to hospitalization.

Table 32–2. Diagnostic features of some acute exanthems.

Disease	Prodromal Signs and Symptoms	Nature of Eruption	Other Diagnostic Features	Laboratory Tests
Atypical measles	Same as measles.	Maculopapular centripetal rash, becoming confluent.	History of measles vaccination.	Measles antibody present in past, with titer rise during illness.
Chikungunya fever	2–4 (sometimes 1–12) days, fever, headaches, abdominal complaints, myalgias, arthralgias.	Maculopapular, centrally distributed, pruritus, can be bullous with sloughing in children, occasional facial edema and petechiae.	History of mosquito bites, epidemiologic factors.	ELISA-based IgM or IgG (fourfold increase in titers); PCR and cultures are infrequently available.
Eczema herpeticum	None.	Vesiculopustular lesions in area of eczema.		Herpes simplex virus isolated in cell culture. Multinucleate giant cells in smear of lesion.
Ehrlichiosis	Headache, malaise.	Rash in one-third, similar to Rocky Mountain spotted fever.	Pancytopenia, elevated liver biochemical tests.	Polymerase chain reaction, immunofluorescent antibody.
Enterovirus infections	1–2 days of fever, malaise.	Maculopapular rash resembling rubella, rarely papulovesicular or petechial.	Aseptic meningitis.	Virus isolation from stool or cerebrospinal fluid; complement fixation titer rise.
Erythema infectiosum (erythrovirus)	None. Usually in epidemics.	Red, flushed cheeks; circumoral pallor; maculopapules on extremities.	"Slapped face" appearance.	White blood cell count normal.
Exanthema subitum (HHV-6, 7; roseola)	3–4 days of high fever.	As fever falls, pink maculopapules appear on chest and trunk; fade in 1–3 days.		White blood cell count low.
Infectious mononucleosis (EBV)	Fever, adenopathy, sore throat.	Maculopapular rash resembling rubella, rarely papulovesicular.	Splenomegaly, tonsillar exudate.	Atypical lymphocytes in blood smears; heterophile agglutination (Monospot test).
Kawasaki disease	Fever, adenopathy, conjunctivitis.	Cracked lips, strawberry tongue, maculopapular polymorphous rash, peeling skin on fingers and toes.	Edema of extremities. Angiitis of coronary arteries.	Thrombocytosis, electrocardiographic changes.

Measles (rubeola)	3–4 days of fever, coryza, conjunctivitis, and cough.	Maculopapular, brick red; begins on head and neck; spreads downward and outward, in 5–7 days rash brownish, desquamating. See Atypical measles, above.	Koplik spots on buccal mucosa.	White blood cell count low. Virus isolation in cell culture. Antibody tests by hemagglutination inhibition or neutralization.
Meningococcemia	Hours of fever, vomiting.	Maculopapules, petechiae, purpura.	Meningeal signs, toxicity, shock.	Cultures of blood, cerebrospinal fluid. White blood cell count high.
Rocky Mountain spotted fever	3–4 days of fever, vomiting.	Maculopapules, petechiae, initial distribution centripetal (extremities to trunk, including palms).	History of tick bite.	Indirect fluorescent antibody; complement fixation.
Rubella	Little or no prodrome.	Maculopapular, pink; begins on head and neck, spreads downward, fades in 3 days. No desquamation.	Lymphadenopathy, postauricular or occipital.	White blood cell count normal or low. Serologic tests for immunity and definitive diagnosis (hemagglutination inhibition).
Scarlet fever	One-half to 2 days of malaise, sore throat, fever, vomiting.	Generalized, punctate, red; prominent on neck, in axillae, groin, skin folds; circumoral pallor; fine desquamation involves hands and feet.	Strawberry tongue, exudative tonsillitis.	Group A beta-hemolytic streptococci in cultures from throat; antistreptolysin O titer rise.
Smallpox	Fever, malaise, prostration.	Maculopapules to vesicles to pustules to scars (lesions develop at the same pace).	Centrifugal rash; fulminant sepsis in small percentage of patients, gastrointestinal and skin hemorrhages.	Contact CDC[1] for suspicious rash; EM and gel diffusion assays.
Typhus	3–4 days of fever, chills, severe headaches.	Maculopapules, petechiae, initial distribution centrifugal (trunk to extremities).	Endemic area, lice.	Complement fixation.
Varicella (chickenpox)	0–1 day of fever, anorexia, headache.	Rapid evolution of macules to papules, vesicles, crusts; all stages simultaneously present; lesions superficial, distribution centripetal.	Lesions on scalp and mucous membranes.	Specialized complement fixation and virus neutralization in cell culture. Fluorescent antibody test of smear of lesions.

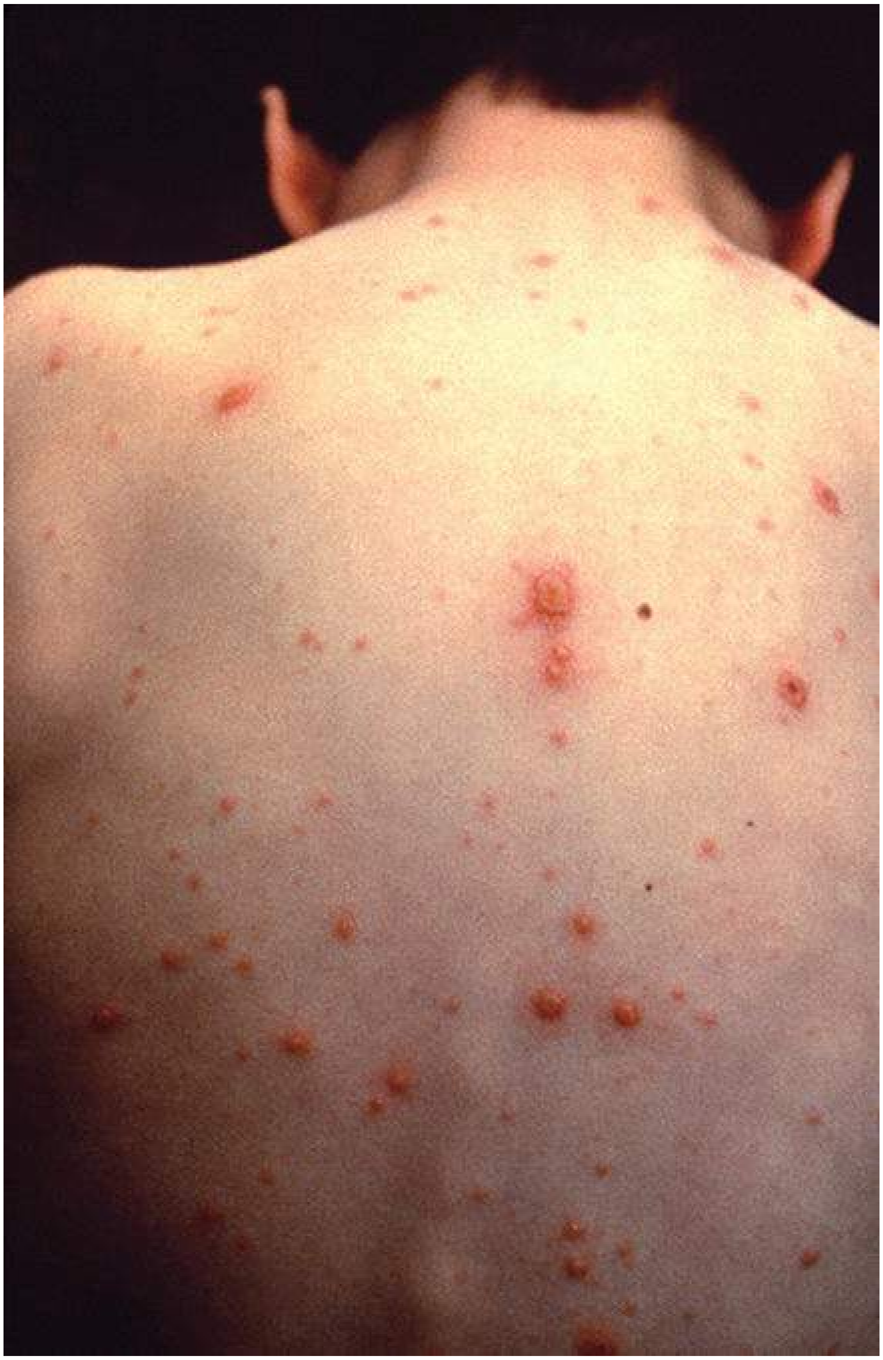
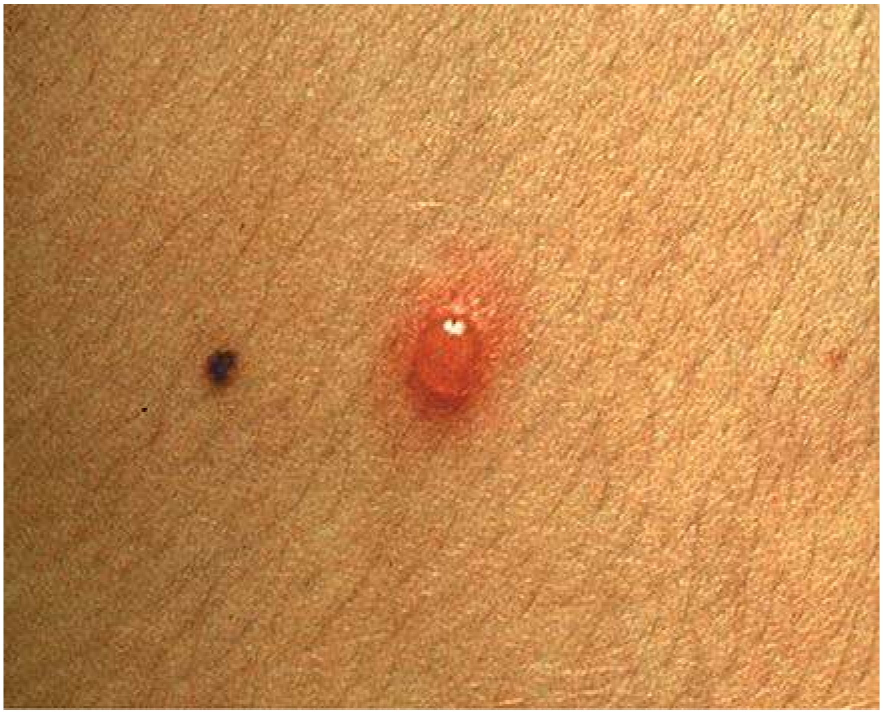
CDC, Centers for Disease Control and Prevention; EBV, Epstein-Barr virus; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; HHV, human herpesvirus; Ig, immunoglobulin; PCR, polymerase chain reaction.



▲ **Figure 32–2.** **Primary varicella (chickenpox) skin lesions**. (Public Health Image Library, CDC.)



▲ Figure 32–3. **Chickenpox (varicella) with classic “dew drop on rose petal” appearance**. (Used, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. The Color Atlas of Family Medicine, 2nd ed. McGraw-Hill, 2013.)

Varicella is more severe in older patients and immunocompromised persons. In the latter, atypical presentations, including widespread dissemination in the absence of skin lesions, are often described. After the primary infection, the virus remains dormant in cranial nerve sensory ganglia and spinal dorsal root ganglia. Latent VZV will reactivate as herpes zoster in about 10–30% of persons. There is a small increased risk of Guillain-Barré syndrome for at least 2 months after an acute herpes zoster attack.

2. Laboratory findings—Diagnosis is usually made clinically, with confirmation by direct immunofluorescent antibody staining or PCR of scrapings from lesions, both of which are more sensitive than culture. Multinucleated giant cells are usually apparent on a Tzanck smear of material from the vesicle base. Leukopenia and subclinical transaminase elevation are often present, and thrombocytopenia occasionally occurs. Although elevation of varicella IgM is occasionally used to diagnose a primary VZV infection, the assay has poor performance and is generally not recommended. The exception is that varicella antibody tested in the CSF is useful for identifying CNS involvement if VZV vasculopathy is suspected but CSF VZV DNA PCR is negative. A varicella skin test and interferon-gamma enzyme-linked immunospot (ELISPOT) can screen for VZV susceptibility.

B. Herpes Zoster

Herpes zoster (**"shingles"**) usually occurs among adults, but cases are reported among infants and children. Shingles incidence rises markedly with age because of immunosenescence and loss of specific immunity to VZV, with rates of 8 to 12 per 1000 person-years in individuals older than 80 years. Skin lesions resemble those of chickenpox. Pain is often severe and commonly precedes the appearance of rash. Lesions follow a dermatomal distribution, with thoracic and lumbar roots being the most common. In most cases, a single unilateral dermatome is involved, but occasionally, neighboring and distant areas are involved. Lesions on the tip of the nose, inner corner of the eye, and root and side of the nose (Hutchinson sign) indicate involvement of the trigeminal nerve (herpes zoster ophthalmicus). Facial palsy and lesions of the external ear with or without tympanic membrane involvement, vertigo and tinnitus, or deafness signify geniculate ganglion involvement (Ramsay Hunt syndrome or herpes zoster oticus). Shingles is a particularly common and serious complication among immunosuppressed patients.

Complications

A. Varicella

Secondary bacterial skin superinfections, particularly with group A Streptococcus and Staphylococcus aureus, are the most common complications. Cellulitis, erysipelas, and scarlet fever are described. Bullous impetigo and necrotizing fasciitis are less often seen. Other associations with varicella include epiglottitis, necrotizing pneumonia, osteomyelitis, septic arthritis, epidural abscess, meningitis, endocarditis, pancreatitis, giant cell arteritis, inflammatory bowel disease, and purpura fulminans. Toxic shock syndrome can also develop.

Interstitial VZV pneumonia is more common in adults (especially smokers, HIV-infected patients, and pregnant women) and may result in acute respiratory distress syndrome (ARDS). After healing, numerous densely calcified lesions are seen throughout the lung fields on chest radiographs.

Historically, neurologic complications developed in about 1 in 2000 children. Cerebellar ataxia occurs at a frequency of 1:4000 in the young. A limited course and complete recovery are the rule. Encephalitis is similarly infrequent, occurs mostly in adults, and is characterized by delirium, seizures, and focal neurologic signs. The rates for both mortality and long-term neurologic sequelae are about 10%. Ischemic strokes in the wake of acute VZV infection present at a mean of 4 months after rashes and may be due to an associated vasculitis. Multifocal encephalitis, ventriculitis, myeloradiculitis, arterial aneurysm formation, and arteritis are also described in immunosuppressed, especially HIV-infected, patients.

Clinical hepatitis is uncommon and mostly presents in the immunosuppressed patient but can be fulminant and fatal. Reye syndrome (fatty liver with encephalopathy) also complicates varicella (and other viral infections, especially influenza B virus), usually in childhood, and is associated with aspirin therapy (see Influenza, below).

When contracted during the first or second trimesters of pregnancy, varicella carries a very small risk of congenital malformations, including cicatricial lesions of an extremity, growth retardation, microphthalmia, cataracts, chorioretinitis, deafness, and cerebrocortical atrophy. If varicella develops around the time of delivery, the newborn is at risk for disseminated disease.

B. Herpes Zoster

Postherpetic neuralgia occurs in 60–70% of patients who have herpes zoster and are older than 60 years. The pain can be prolonged and debilitating. Risk factors for postherpetic neuralgia include advanced age, female sex, the presence of a prodrome, and severity of rash or pain but not family history.

Other complications include the following: (1) bacterial skin superinfections; (2) herpes zoster ophthalmicus, which occurs with involvement of the trigeminal nerve, is a sight-threatening complication (especially when it involves the iris), and is a marker for stroke over the ensuing year (Hutchinson sign is a marker of ocular involvement in the HIV-positive population); (3) rarely, unilateral ophthalmoplegia; (4) involvement of the geniculate ganglion of cranial nerve VII as well as cranial nerves V, VIII, IX, and X; (5) aseptic meningitis; (6) peripheral motor neuropathy; (7) transverse myelitis; (8) encephalitis; (9) acute cerebellitis; (10) stroke; (11) vasculopathy; (12) acute retinal necrosis; (13) progressive outer retinal necrosis (largely among HIV infected persons); (14) temporal arteritis; and (15) sacral meningoradiculitis (Elsberg syndrome). VZV is a major cause of Bell palsy in patients who are HSV seronegative.

Diagnosis of neurologic complications requires the detection of VZV DNA in CSF or the detection of VZV DNA in tissue. Diagnosis by examination of saliva may be possible. Zoster sine herpete (pain without rash) can also be associated with most of the above complications.

Treatment

A. General Measures

In general, patients with varicella should be isolated until primary lesions have crusted. The skin is kept clean. Pruritus can be relieved with antihistamines, calamine lotion, and colloidal oatmeal baths. Fever can be treated with acetaminophen (not aspirin). Fingernails can be closely cropped to avoid skin excoriation and infection.

B. Antiviral Therapy

1. Varicella—Uncomplicated disease in otherwise healthy children and adolescents does not require antiviral therapy. Acyclovir, 20 mg/kg (up to 800 mg per dose) orally four times daily for 5–7 days, should be given within the first 24 hours after the onset of varicella rash and should be considered for patients older than 12 years, secondary household contacts (disease tends to be more severe in secondary cases), patients with chronic cutaneous and cardiopulmonary diseases, and children receiving long-term therapy with salicylates (to decrease the risk of Reye syndrome). Acyclovir hastens defervescence and healing of lesions but does not impact complication rates. Experience with valacyclovir and famciclovir in these settings is scant and while these agents are often used, their use is not FDA-approved in the United States. Nonsteroidal anti-inflammatory drug (NSAID) use in varicella-infected children appears to be associated with an increase in bacterial infections.

In immunocompromised patients, in pregnant women during the third trimester, and in patients with extracutaneous disease (encephalitis, pneumonitis), antiviral therapy with high-dose acyclovir (30 mg/kg/day in three divided doses intravenously for at least 7 days) should be started once the diagnosis is suspected. Corticosteroids may be useful in the presence of pneumonia. Prolonged prophylactic acyclovir is important to prevent VZV reactivation in profoundly immunosuppressed patients.

2. Herpes zoster—For uncomplicated herpes zoster, valacyclovir or famciclovir is preferable to acyclovir due to dosing convenience and higher drug levels in the body (Table 32–1). Therapy should start within the first 72 hours of the onset of the lesions and be continued for 7 days or until the lesions crust over. Amenamevir is an oral helicase-primase inhibitor given as a single dose that was approved to treat shingles in Japan in 2017 but is not yet available in the United States. Antiviral therapy reduces the duration of herpetic lesions and associated episodes of acute pain but does not in all studies decrease the risk of postherpetic neuralgia. Corticosteroids (a tapering course starting at 60 mg/day, for 2–3 weeks) are safe in immunocompetent patients and may be useful in the acute management of disease to hasten the resolution of acute lesions. Corticosteroids do not prevent the development of postherpetic neuralgia.

Intravenous acyclovir is used for extradermatomal complications of zoster. Adjunctive therapy may be considered in retinal disease (foscarnet) and acute herpes zoster (sorivudine, a topical antiviral). In cases of prolonged or repeated acyclovir use, immunosuppressed patients may require a switch to foscarnet due to the development of acyclovir-resistant VZV infections. VZV associated with the Ramsay Hunt syndrome is more resistant to antiviral therapy.

C. Treatment of Postherpetic Neuralgia

Once established, postherpetic neuralgia is difficult to treat, and less than half of patients achieve adequate pain relief. This condition may respond to neuropathic pain agents such as gabapentin or lidocaine patches. Tricyclic antidepressants, opioids, and capsaicin cream are also widely used and effective. The epidural injection of corticosteroids and local anesthetics appears to modestly reduce herpetic pain at 1 month but, as with oral corticosteroids, is not effective for prevention of long-term postherpetic neuralgia. There is reported success using transcutaneous electrical nerve stimulation.

Prognosis

The total duration of varicella from onset of symptoms to disappearance of crusts rarely exceeds 2 weeks. Fatalities are rare except in immunosuppressed patients.

Herpes zoster resolves in 2–6 weeks. Antibodies persist longer and at higher levels than with primary varicella. Eye involvement with herpes zoster necessitates periodic future examinations.

Prevention

Health care workers should be screened for varicella and vaccinated if seronegative. Patients with active varicella or herpes zoster are promptly separated from seronegative patients. For patients with varicella, airborne and contact isolation is recommended, whereas for those with zoster, contact precautions are sufficient. For immunosuppressed patients with zoster, precautions should be the same as if the patient had varicella. Exposed serosusceptible patients should be placed in isolation and exposed serosusceptible employees should stay away from work for 8–21 days after exposure. Health care workers with zoster should receive antiviral agents during the first 72 hours of disease and withdraw from work until lesions are crusted. The need for postexposure prophylaxis should be assessed.

A. Varicella

1. Vaccination—Universal childhood vaccination against varicella is effective. The varicella vaccine is live and attenuated, safe, and over 98.1% effective when given after 13 months of age. A single antigen live attenuated vaccine (VARIVAX, VARILRIX) or a quadrivalent measles, mumps, rubella, and varicella (MMRV) vaccine (ProQuad) is available (the combination is immunogenic). The first dose of the single antigen vaccine should be administered at 12–18 months of age and the second at 4–6 years. Alternatively, the MMRV vaccine can be given as a first dose at 12–15 months of age and the second dose before elementary school entry. Aspirin should be avoided for at least 6 weeks after vaccination because of the risk of Reye syndrome. The single antigen vaccine is safe and well tolerated, but the quadrivalent MMRV vaccine is associated with a small risk of febrile seizures 5–12 days after vaccination among infants aged 12–23 months. Because of this risk, the Centers for Disease Control and Prevention (CDC) recommends using separate varicella and measles, mumps, and rubella (MMR) vaccines for the first dose in children younger than 48 months old. Rashes, when secondary to the varicella vaccine, appear 15–42 days after vaccination. Rare cases of keratitis are associated with zoster and varicella vaccines.

For serosusceptible individuals older than 13 years, two doses of varicella vaccine (single antigen) administered 4–8 weeks apart are recommended. For those who received a single dose in the past, a catch-up second dose is advised, especially in the epidemic setting (where it is effective when it can be given during the first 5 days postexposure). Household contacts of immunocompromised patients should adhere to these recommendations. Susceptible pregnant women (who should not be vaccinated with live varicella or zoster vaccines during pregnancy) need to receive the first dose of single antigen vaccine before discharge after delivery and the second dose 4–8 weeks later. The Advisory Committee on Immunization Practices (ACIP) recommends administration of the single agent varicella vaccine as two doses 3 months apart to HIV-infected children aged 12 months or older with CD4 lymphocyte percentage greater than 15% and adolescents and adults with CD4 lymphocyte counts 200 cells/mcL or higher.

The vaccine may also be given to patients with impaired humoral immunity, to patients receiving corticosteroids, to pediatric oncology patients receiving chemotherapy, and to patients with juvenile rheumatoid arthritis who receive methotrexate. Patients receiving high doses of corticosteroids for over 2 weeks may be vaccinated a month after discontinuation of the therapy. Patients with leukemia, lymphoma, or other malignancies whose disease is in remission and who have not undergone chemotherapy for at least 3 months may be vaccinated. Kidney and liver transplant patients should be vaccinated if they are susceptible to varicella.

The incidence of varicella in the United States is significantly reduced with the varicella vaccine. Although uncommon, the varicella vaccine, like any of the live varicella-zoster vaccines, has the potential to reactivate and cause clinical disease. It is thought that vaccination against varicella provides less protection against future zoster than does natural varicella infection. The incidence of varicella-associated group A streptococcal infection and varicella neurologic complications are both diminished with the advent of varicella vaccination.

The FDA no longer maintains a registry for exposed pregnant women because of the low rate of such incidents and the general safety of varicella vaccines. Incidents can be reported to Merck (877-888-4231) or through the Vaccine Adverse Events Registry System Vaccine (https://vaers.hhs.gov/index).

2. Postexposure—Postexposure vaccination is recommended for unvaccinated persons without other evidence of immunity. Varicella-zoster immune globulin available in the United States only as VariZIG should be considered for susceptible exposed patients (for up to 10 days after exposure but as soon as feasible) who cannot receive the vaccine, including immunosuppressed patients, neonates from mothers with varicella around the time of delivery, exposed premature infants born from serosusceptible mothers at greater than 28 weeks of gestation, neonates born at less than 28 weeks of gestation regardless of maternal serostatus, and nonimmune pregnant women. No controlled studies have evaluated the use of acyclovir in this setting. VariZIG is given by intramuscular injection in a dosage of 125 international units/10 kg, to a maximum of 625 international units with a weight-based (2-kg cutoff) minimum dose of 62.5 or 125 international units), with a repeat identical dose in 3 weeks if a high-risk patient remains exposed. VariZIG has no place in therapy of established disease; however, it reduces severity of varicella in high-risk children or adults (ie, those with impaired immunity, pregnant women, and infants exposed peripartum) if given within 4 days of exposure. Varicella vaccination should be delayed at least 5 months after VariZIG administration. If VariZIG is not available, standard pooled intravenous immunoglobulin (IVIG) (400 mg/kg given in one dose) can be given. Acyclovir (40–80 mg/kg) for 5 days or the varicella vaccine (if not contraindicated) can also be given as postexposure prophylaxis within 3 days of exposure. Either of these options offers an efficacy of 70–85% compared to 90% efficacy for VariZIG.

Further information may be obtained by calling the Centers for Disease Control and Prevention's Immunization Information Hotline (800-232-2522).

B. Herpes Zoster

Shingrix, HZ/su (GlaxoSmithKline Biologics), an adjuvanted recombinant subunit vaccine, was approved in 2017 by the FDA for VZV and is recommended for individuals 50 years of age and older. Unlike the older live attenuated VZV vaccine (ZOSTAVAX, see below), Shingrix is particularly effective in reducing the incidence of herpes zoster infection and postherpetic neuralgia in adults 70 years of age and older; immunosenescence to the vaccine does not appear to occur in older patients. It can also be used in immunosuppressed patients. Two doses of the vaccine given 2 months apart had 97% efficacy in preventing herpes zoster. Shingrix also appears to be safe in HIV-infected persons with CD4 counts above 50 cells/mcL, recipients of autologous stem cell transplants, and adults with autoimmune disease taking immunosuppressive therapy.

The older live attenuated VZV vaccine, ZOSTAVAX (19,400 plaque forming units [pfu] of Oka/Merck strain) contains at least 14 times the concentration of varicella virus found in VARIVAX. It is recommended for persons 60 years and older because it reduces the incidence of herpes zoster by 33–55% in the first 3 years after vaccination and reduces the incidence of postherpetic neuralgia by 55–67%. The efficacy of

ZOSTAVAX wanes over time, from 69% in the first year after vaccination to 45% by the third year.

Even if the person has had a prior episode of herpes zoster, either of the two zoster vaccines has efficacy and can be administered. No specific recommendations exist regarding how long to wait between a zoster outbreak and administering the vaccine; the CDC recommends waiting at least until the outbreak has resolved. The attenuated VZV vaccine is safe, but only moderately immunogenic among HIV-infected persons with a CD4 count of at least 200 cells/mcL. Decreased efficacy occurs in patients older than 70, and this vaccine should not be given to immunosuppressed persons. Nonetheless, hematologic oncology patients taking anti-CD20 monoclonal antibodies may be successfully vaccinated. An increased risk of herpes zoster during a 6-week interval following vaccination is reported among patients taking immunosuppressant medications. This vaccine provides protection for about 3 years.

Concurrent administration of the adjuvanted recombinant subunit vaccine or the live attenuated VZV vaccine with pneumococcal vaccine is safe. If a varicella vaccine is mistakenly administered to an adult instead of a live attenuated zoster vaccine, the dose should be considered invalid and the patient should be administered a dose of zoster vaccine at the same visit. The zoster vaccine cannot be used in children in place of varicella vaccine; if the vaccine is accidentally given to a child, the event should be reported to the CDC.

3. Epstein-Barr Virus & Infectious Mononucleosis

ESSENTIALS OF DIAGNOSIS

- Malaise, fever, and (exudative) sore throat.
- Palatal petechiae, lymphadenopathy, splenomegaly, and, occasionally, a maculopapular rash.
- Positive heterophile agglutination test (Monospot).
- Atypical large lymphocytes in blood smear; lymphocytosis.
- **Complications:** hepatitis, myocarditis, neuropathy, encephalitis, airway obstruction from adenitis, hemolytic anemia, thrombocytopenia.

General Considerations

Epstein-Barr virus (EBV, or human herpes virus-4 [HHV-4]) is one of the most ubiquitous human viruses, infecting more than 95% of the adult population worldwide and persisting for the lifetime of the host. Infectious mononucleosis is a common manifestation of EBV and may occur at any age. In the United States the incidence of EBV infection is declining although prevalence of EBV remains high for those aged 12–19 years. In the developing world, infectious mononucleosis occurs at younger ages and tends to be less symptomatic. Rare cases in older adults occur usually without the full symptomatology. EBV is largely transmitted by saliva but can also be recovered from genital secretions. Saliva may remain infectious during convalescence, for 6 months or longer after symptom onset. The incubation period lasts several weeks (30–50 days). Patients with immunodeficiency disorders are at risk for the full spectrum of EBV-associated disorders.

Clinical Findings

A. Symptoms and Signs

Fever, sore throat, fatigue, malaise, anorexia, and myalgia typically occur in the early phase of the illness. Physical findings include lymphadenopathy (discrete, nonsuppurative, slightly painful, especially along the posterior cervical chain), transient bilateral upper lid edema (Hoagland sign), and splenomegaly (in up to 50% of patients and sometimes massive). A maculopapular or occasionally petechial rash occurs in less than 15% of patients unless ampicillin is given (in which case rash was thought to occur in more than 90% of patients; however, recent data indicates that the incidence of drug hypersensitivity is much lower than previously reported). Conjunctival hemorrhage, exudative pharyngitis, uvular edema, tonsillitis, or gingivitis may occur and soft palatal petechiae may be noted. Complications of acute disease are more common among older adults.

Other manifestations include hepatitis, interstitial pneumonitis (sometimes with pleural involvement), cholestasis, gastritis, kidney disease (mostly interstitial nephritis), epiglottitis, and nervous system involvement in 1–5% (mononeuropathies and occasionally aseptic meningitis, encephalitis, cerebellitis, peripheral and optic neuritis, transverse myelitis, or Guillain-Barré syndrome). Vaginal ulcers are rare but may be present. Airway obstruction from lymph node enlargement can occur.

B. Laboratory Findings

An initial phase of granulocytopenia is followed within 1 week by lymphocytic leukocytosis (greater than 50% of all leukocytes) with atypical lymphocytes (larger than normal mature lymphocytes, staining more darkly, and showing vacuolated, foamy cytoplasm and dark nuclear chromatin) comprising more than 10% of the leukocyte count. Hemolytic anemia, with antibodies, occurs occasionally as does thrombocytopenia (at times marked and life-threatening).

Diagnosis is made based on characteristic manifestations and serologic evidence of infection (the heterophile sheep cell agglutination [HA] antibody tests or the correlated mononucleosis spot test [Monospot]). These tests usually become positive within 4 weeks after onset of illness and are specific but often not sensitive in early illness. Heterophile antibodies may be absent in young children and in as many as 20% of adults. During acute illness, there is a rise and fall in immunoglobulin M (IgM) antibody to EB virus capsid antigen (VCA) and a rise in immunoglobulin G (IgG) antibody to VCA, which persists for life. Antibodies (IgG) to EBV nuclear antigen (EBNA) appear after 4 weeks of onset and also persist. Absence of IgG and IgM VCA or the presence of IgG EBNA should make one reconsider the diagnosis of acute EBV infection.

PCR for EBV DNA is useful in the evaluation of malignancies associated with EBV. For instance, detection of EBV DNA in CSF shows a sensitivity of 90% and specificity of nearly 100% for the diagnosis of primary CNS lymphoma in patients with AIDS.

Differential Diagnosis

CMV infection, toxoplasmosis, acute HIV infection, secondary syphilis, HHV-6 infection, rubella, and drug hypersensitivity reactions may be indistinguishable from infectious mononucleosis due to EBV, but exudative pharyngitis is usually absent and the heterophile antibody tests are negative. With acute HIV infection, rash and mucocutaneous ulceration are common but atypical lymphocytosis is much less common. Heterophile-negative infectious mononucleosis with nonsignificant lymphocytosis (especially if rash or mucocutaneous ulcers are present) should prompt investigation for acute HIV infection. CMV, toxoplasmosis and, on occasion, EBV can cause heterophile-negative infectious mononucleosis with atypical lymphocytosis. Mycoplasma infection may also present as pharyngitis, though lower respiratory symptoms usually predominate. A hypersensitivity syndrome induced by carbamazepine or phenytoin may mimic infectious mononucleosis.

The differential diagnosis of acute exudative pharyngitis includes gonococcal and streptococcal infections, and infections with adenovirus and herpes simplex. Head and neck soft tissue infections (pharyngeal and tonsillar abscesses) may occasionally be mistaken as the lymphadenopathy of mononucleosis.

Complications

Secondary bacterial pharyngitis can occur and is often streptococcal. Splenic rupture (0.5–1%) is a rare but dramatic complication, and a history of preceding trauma can be elicited in 50% of the cases. Acalculous cholecystitis, fulminant hepatitis with massive necrosis, pericarditis and myocarditis are also infrequent complications.

Treatment

A. General Measures

Over 95% of patients with acute EBV-associated infectious mononucleosis recover without specific antiviral therapy. Treatment is symptomatic with NSAIDs or acetaminophen and warm saline throat irrigations or gargles three or four times daily. Acyclovir decreases viral shedding but shows no clinical benefit. Corticosteroid therapy, although widespread, is not recommended in uncomplicated cases; its use is reserved for impending airway obstruction from enlarged lymph nodes, hemolytic anemia, and severe thrombocytopenia. The value of corticosteroid therapy in impending splenic rupture, pericarditis, myocarditis, and nervous system involvement is less well established. If a throat culture grows beta-hemolytic streptococci, a 10-day course of penicillin or azithromycin is indicated. Ampicillin and amoxicillin are avoided because of the frequent association with rash, although one recent study indicates that the incidence of drug hypersensitivity is much lower than previously reported.

EBV infections in solid organ transplant recipients are difficult to prevent and treat, although recent data suggest possible utility of pretransplant rituximab for high-risk transplant recipients. The role of antiviral prophylaxis for preventing posttransplantation EBV infection and sequelae, including posttransplant lymphoproliferative disorders (PTLD) in patients who are donor organ EBV-positive and recipient negative (the main risk factor for both early PTLD [less than 1 year posttransplantation] and late PTLD [more than 1 year]). One recent retrospective study indicated that prophylaxis with acyclovir, valacyclovir, ganciclovir, or valganciclovir delayed primary EBV infection at 100 days posttransplant. A decreased incidence of late-onset PTLD and EBV-related neoplasias in treated patients was also noted. Finally, new therapies are being developed to protect hematopoietic stem cell transplant recipients from many viruses, including EBV.

B. Treatment of Complications

Hepatitis, myocarditis, and encephalitis are treated symptomatically. Rupture of the spleen requires splenectomy and is most often caused by deep palpation of the spleen or vigorous activity. Patients should avoid contact or collision sports for at least 4 weeks to decrease the risk of splenic rupture (even if splenomegaly is not detected by physical examination, which can be insensitive).

Prognosis & Prevention

In uncomplicated cases, fever disappears in 10 days and lymphadenopathy and splenomegaly in 4 weeks. The debility sometimes lingers for 2–3 months.

Death is uncommon and is usually due to splenic rupture, hypersplenic phenomena (severe hemolytic anemia, thrombocytopenic purpura), or encephalitis.

4. Other EBV-Associated Syndromes

EBV viral antigens are found in more than 90% of patients with endemic (African) Burkitt lymphoma and nasopharyngeal carcinoma (among whom quantified EBV DNA can be used to follow disease). Risk factors for Burkitt lymphoma include a history of malaria (which may decrease resistance to EBV infection) while risk factors for nasopharyngeal carcinoma include long-term heavy cigarette smoking and seropositive EBV serologies (VCA and deoxyribonuclease [DNase]). VCA-IgA in peripheral blood is a sensitive and specific predictor for nasopharyngeal carcinoma in an endemic area.

Among Hodgkin lymphoma patients, EBV seropositivity is common when the disease is found in the developing world or is associated with HIV infection, when pathologic specimens show mixed cellularity, and when patients are younger than 10 years or older than 45 years at onset of the lymphoma. The EBV-seropositive have a worse prognosis for early stages of Hodgkin lymphoma.

Chronic EBV infection is associated with aberrant cellular immunity (a low frequency of EBV-specific $CD8^+$ T cells), an X-linked lymphoproliferative syndrome (Duncan disease), lymphomatoid granulomatosis, and a fatal T-cell lymphoproliferative disorder in children.

EBV is an important trigger for hemophagocytic lymphohistiocytosis among immunodeficient patients and causes B-cell lymphomas (such as primary CNS lymphoma in HIV-infected individuals), natural killer/T-cell lymphoma, and posttransplant lymphoproliferative disorders. CD30 and EBV viral loads are prognostic markers for EBV-associated lymphoproliferative disease. PTLD are commonly associated with EBV, especially in children. EBV-naïve patients who receive a donor organ from an EBV-infected donor are at the highest risk for the development of PTLD. EBV serostatus, however, is not associated with overall survival among patients with PTLD. Decreasing the iatrogenic immunosuppression given to prevent graft rejection is the initial step in managing such patients, while rituximab (CD20 monoclonal antibody) is effective in treating more than two-thirds of cases. Oral mucocutaneous ulcerative disease in the HIV-infected may be due to EBV.

Age is a major determinant of the type of tumor associated with EBV. T and NK cell lymphoma caused by chronic active EBV infections are more frequent in childhood while peripheral T-cell lymphomas and diffuse large B-cell lymphomas are more common in older patients due to waning immunity. EBV is also associated with leiomyomas in children with AIDS and with nasal T-cell lymphomas.

When to Admit

Presence of severe complications of EBV disease including the following:

- Acute meningitis, encephalitis, or Guillain-Barré syndrome.
- Severe thrombocytopenia; significant hemolysis.
- Potential splenic rupture.
- Airway obstruction from severe adenitis.
- Pericarditis.
- Abdominal findings mimicking an acute abdomen.

5. Cytomegalovirus Disease

ESSENTIALS OF DIAGNOSIS

- Mononucleosis-like syndrome.
- Frequent pathogen seen in transplant populations.
- Diverse clinical syndromes in HIV (retinitis, esophagitis, pneumonia, encephalitis).

General Considerations

Most cytomegalovirus (CMV) infections are asymptomatic. After primary infection, the virus remains latent in most body cells. Seroprevalence in adults of Western developed countries is about 60–80% but is higher in developing countries. The virus can be isolated from a variety of tissues under nonpathogenic conditions. Transmission occurs through sexual contact, breastfeeding, blood products, or transplantation; it may also occur person-to-person (eg, day care centers) or be congenital. Serious disease occurs primarily in immunocompromised persons, including those with inflammatory bowel disease.

There are three recognizable clinical syndromes: (1) perinatal disease and CMV inclusion disease, (2) diseases in immunocompetent persons, and (3) diseases in immunocompromised persons. Congenital CMV infection is the most common congenital infection in developed countries (about 0.6% of live births, with higher rates in underdeveloped areas and among lower socioeconomic groups). Transmission is much higher from mothers with primary disease than those with reactivation (40% vs 0.2–1.8%). About 10% of infected newborns will be symptomatic with CMV inclusion disease.

In immunocompetent persons, acute CMV infection is the most common cause of the mononucleosis-like syndrome with negative heterophile antibodies. In critically ill immunocompetent adults, CMV reactivation is associated with prolonged hospitalization and death. CMV appears to be involved in the malignant manifestations of glioblastoma multiforme.

In immunocompromised persons, solid organ and bone marrow transplant patients are at highest risk for a year after allograft transplantation (but especially during the first 100 days afterward) and in particular when graft-versus-host disease is present or when the donor is CMV seropositive and the recipient is seronegative. Depending on the serostatus of the donor and recipient, disease may present as primary infection or reactivation. The risk of CMV disease is proportionate to the degree of immunosuppression and manifestations may differ by the cause. CMV may contribute to transplanted organ dysfunction, which often mimics organ rejection. CMV retinitis may develop after solid organ or bone marrow transplantation. CMV disease in HIV-infected patients (retinitis, serious gastrointestinal disease) occurs most prominently when the CD4 count is less than 50 cells/mcL and can be a marker for increased mortality. Antiretroviral therapy (ART) reduces the frequency of retinitis and may reverse active disease. Patients with immune recovery with CD4 cell count greater than 100 cells/mcL show decreased mortality. CMV retinitis associated with intravitreal delivery of corticosteroids (injections or implants) or systemic anti-TNF antibodies is also described. Occasionally, CMV retinitis presents in immunocompetent persons. Serious gastrointestinal CMV disease also occurs after organ transplantation, cancer chemotherapy, or corticosteroid therapy. CMV may exist alongside other pathogens, such as Cryptosporidium, in up to 15% of patients with AIDS cholangiopathy. CMV pneumonitis occurs in transplant recipients (mainly bone marrow and lung) with a mortality rate up to 60–80%, and less often in AIDS patients. CMV pneumonitis in hematologic malignancies (eg, lymphoma) is increasingly reported. Neurologic CMV in patients with advanced AIDS is usually associated with disseminated CMV infection.

Clinical Findings

A. Symptoms and Signs

1. Perinatal disease and CMV inclusion disease—CMV inclusion disease in infected newborns is characterized by hepatitis, thrombocytopenia, microcephaly, periventricular CNS calcifications, mental retardation, and motor disability. Hearing loss develops in more than 50% of infants who are symptomatic at birth. Most infected neonates are asymptomatic, but neurologic deficits may ensue later in life, including hearing loss in 15% and mental retardation in 10–20%. Perinatal infection acquired through breastfeeding or blood products typically shows a benign clinical course.

2. Disease in immunocompetent persons—Acute CMV infection is characterized by fever, malaise, myalgias, arthralgias, and splenomegaly. Exudative pharyngitis or cervical lymphadenopathies are uncommon, but cutaneous rashes (including the typical maculopapular rash after exposure to ampicillin) are common. The mean duration of symptoms is 7–8 weeks. Complications include mucosal gastrointestinal damage, encephalitis, severe hepatitis, thrombocytopenia (on occasion, refractory), the Guillain-Barré syndrome, pericarditis, and myocarditis. A mononucleosis-like syndrome due to CMV can also occur post splenectomy, often years later and associated with a protracted fever, marked lymphocytosis, and impaired anti-CMV IgM response.

3. Disease in immunocompromised persons—Distinguishing between CMV infection (with evidence of CMV replication) and CMV disease (evidence for systemic symptoms or organ invasion by pathologic diagnosis) is important. In addition to patients infected with HIV, those who have undergone transplantation (solid organ or hematopoietic stem cell) show a wide spectrum of disease including gastrointestinal (eg, acute cholecystitis), kidney, and CNS disease, as outlined above. CMV viral loads serve as an important predictor of disease presence.

A. CMV RETINITIS—A funduscopic examination reveals neovascular, proliferative lesions ("pizza-pie" retinopathy). Immune restoration with ART is associated with CMV vitritis and cystoid macular edema.

B. GASTROINTESTINAL AND HEPATOBILIARY CMV—Esophagitis presents with odynophagia. Gastritis can occasionally cause bleeding, and small bowel disease may mimic inflammatory bowel disease or may present as ulceration or perforation. Colonic CMV disease causes diarrhea, hematochezia, abdominal pain, fever, and weight loss and may mimic inflammatory bowel disease. CMV hepatitis commonly complicates liver transplantation and appears to be increased in those with hepatitis B or hepatitis C viral infection.

C. RESPIRATORY CMV—CMV pneumonitis is characterized by cough, dyspnea, and relatively little sputum production. Concomitant infection with Pneumocystis jirovecii occurs among patients regardless of HIV status.

D. NEUROLOGIC CMV—Neurologic syndromes associated with CMV include polyradiculopathy, transverse myelitis, ventriculoencephalitis (suspected with ependymitis), and focal encephalitis. These manifestations are more prominent in patients with advanced AIDS in whom the encephalitis has a subacute onset.

B. Laboratory Findings

1. Mothers and newborns—Pregnant women should be tested for CMV viremia every 3 months if found to be seropositive during the first trimester. Congenital CMV disease is confirmed by presence of the virus in amniotic fluid or an IgM assay from fetal blood. Amniocentesis is less reliable before 21 weeks of gestation (due to inadequate fetal urinary development and release into the amniotic fluid), but amniocentesis is attendant with greater risk when performed after 21 weeks of gestation. PCR assays of dried blood samples from newborns, micro-enzyme-linked immunosorbent assay (ELISA), shell-vial culture, or culture of urine, saliva, or blood specimens obtained during the first 3 weeks of life are used to diagnose congenital CMV infection.

2. Immunocompetent persons—The acute mononucleosis-like syndrome is characterized by initial leukopenia; within 1 week, it is followed by absolute lymphocytosis with atypical lymphocytes. Abnormal liver biochemical tests are common in the first 2 weeks of the disease (often 2 weeks after the fever). Detection of CMV DNA, specific IgM, or a fourfold increase of specific IgG levels support the diagnosis of acute infection.

3. Immunocompromised persons—CMV retinitis is diagnosed on the basis of the characteristic ophthalmoscopic findings. In HIV-infected patients, negative CMV serologies lower the possibility of the diagnosis but do not eliminate it. Cultures alone are of little use in diagnosing AIDS-related CMV infections, since viral shedding of CMV is common. Detection of CMV by quantitative DNA PCR should be used to diagnose CNS infection since cultures are not specific for disease.

Detection of CMV by quantitative DNA PCR is also used in posttransplant patients to guide both treatment and prevention and should be interpreted in the context of clinical and pathologic findings. CMV viral loads are internationally standardized and have replaced conventional CMV antigenemia tests in many settings. The PCR is sensitive in predicting clinical disease. Serial PCR should be performed and compared using the same specimen type (ie, whole blood or plasma). To assist in the diagnosis CMV pneumonia, bronchoalveolar lavage fluid can be tested to quantify CMV viral load. Rapid shell-vial cultures detect early CMV antigens with fluorescent antibodies in 24–48 hours. Shell-vial cultures are more useful on bronchoalveolar lavage fluid than in routine blood monitoring. CMV colitis can occur in the absence of a detectable viremia.

C. Imaging

The chest radiographic findings of CMV pneumonitis are consistent with interstitial pneumonia.

D. Biopsy

Tissue confirmation is especially useful in diagnosing CMV pneumonitis and CMV gastrointestinal disease; the diagnosis of colonic CMV disease is made by mucosal biopsy showing characteristic CMV histopathologic findings of intranuclear (“owl’s eye”) and intracytoplasmic inclusions. In situations where histopathologic or immunohistochemical findings are not seen but CMV colitis is suspected, CMV DNA PCR can be used to identify additional cases.

Treatment

In immunocompetent persons, CMV infection is usually self-limited, and no specific antiviral therapy is needed. In immunocompromised persons, treatment of CMV disease is necessary. Treatment of **CMV retinitis** is discussed in Chapter 7. The role of ART in HIV infections in reducing the need for CMV antiviral agents is essential. Because recurrence occurs even at high CD4 cell counts, ongoing ophthalmologic surveillance is necessary. CMV disease in patients with solid organ transplants, AIDS, and invasive end-organ disease is typically treated initially with intravenous ganciclovir (recommended dose is 5 mg/kg every 12 hours, although this needs to be adjusted for kidney function) until two CMV PCRs 1 week apart are negative (usually 14–21 days). Oral valganciclovir (900 mg every 12 hours), which also needs to be adjusted for kidney function, is an acceptable alternative in patients with non–life-threatening disease.

Pneumonia due to CMV in hematopoietic stem cell transplant recipients is treated even more aggressively, with 5 mg/kg of ganciclovir intravenously every 12 hours for 21 days followed by 5 mg/kg daily for 3–4 weeks plus CMV immunoglobulin (500 mg/kg) or CMV immunoglobulin (150 mg/kg) twice per week for 2 weeks and then once weekly for an additional 4 weeks.

Reduction of immunosuppression should be attempted when possible (especially for muromonab, azathioprine, or mycophenolate mofetil). Secondary prophylaxis is typically maintained until immune restoration (with two CD4 T-cell counts greater than 100 cells/mcL present for at least 6 months in the setting of HIV infection). Prolonged prophylaxis may be necessary in other immunosuppressed patients, such as those receiving TNF inhibitors.

Foscarnet and cidofovir are reserved for treatment of resistant infections. Other agents that may be useful in resistant CMV infections include CMV immunoglobulin, leflunomide, sirolimus-based therapy, artesunate, and adoptive immunotherapy. New anti-CMV drugs under development include brincidofovir and maribavir.

Prevention

A major source of CMV for pregnant women is their own young children, particularly those in childcare. These women can decrease their risk of contracting primary CMV just before pregnancy or during pregnancy by practicing hand hygiene after changing diapers and after contact with respiratory secretions; avoiding kissing young children on the face; and avoiding sharing utensils, food, and cleansing objects that have been in contact with children's secretions.

ART is effective in preventing CMV infections in HIV-infected patients. Primary prevention is best accomplished by good hand hygiene and use of barrier methods during sexual contacts with persons who are members of high-prevalence groups (ie, men who have sex with men, injection drug users, and those who have exposure to children in child care).

The use of leukocyte-depleted blood products effectively reduces the incidence of CMV disease in patients who have undergone transplantation. Prophylactic and preemptive strategies (eg, antiviral agents only when antigen detection or PCR assays show evidence of active CMV replication) appear equally effective in preventing invasive disease and mortality after hematopoietic stem cell transplant. The appropriate management of transplant patients is based on the serostatus of the donor and the recipient. All effective anti-CMV agents can serve as prophylactic agents for CMV-seropositive transplants or for CMV-seronegative recipients of CMV-positive organ transplants, although starting CMV prophylaxis 14 days after transplant may help reduce late-onset CMV end-organ disease. The typical dose for valganciclovir prophylaxis is 450 mg orally twice daily, although a recent prospective trial in kidney transplant recipients indicated that prophylaxis with low-dose valganciclovir (450 mg/day, three times a week for 6 months) seemed to be effective. Acyclovir may also be used. Recommended duration of CMV prophylaxis in posttransplant patients and in other immunocompromised patients varies by the type of transplant. Letermovir is useful in prophylaxis against CMV infections in adult allogenic hematopoietic stem cell transplant recipients. It is given as 480 mg orally daily with dose adjustments for cyclosporine administration and for advanced kidney dysfunction (less than a creatinine clearance of 10 mL/min). Major side effects reported to date include cough, diarrhea, headache, nausea, stomach pain, weakness, and vomiting.

CMV immune globulin may also be useful in reducing the incidence of bronchiolitis obliterans in the bone marrow transplant population and is used in some centers as part of the prophylaxis in kidney, liver, and lung transplantation patients. CMV immune globulin as prophylaxis is not recommended in hematopoietic stem cell transplant recipients.

When to Refer

- AIDS patients with retinitis, esophagitis, colitis, hepatobiliary disease, or encephalitis.
- Organ and hematopoietic stem cell transplants with suspected reactivation CMV.

When to Admit

- Escalating CMV viral load at the onset of illness.
- Risk of colonic perforation.
- Evaluation of unexplained, advancing encephalopathy.
- Initiation of treatment with intravenous anti-CMV agents.

6. Human Herpesviruses 6, 7, & 8

HHV-6 is a B-cell lymphotropic virus that is the principal cause of exanthema subitum (roseola infantum, sixth disease). Primary HHV-6 infection occurs most commonly in children under 2 years of age and is a major cause of infantile febrile seizures (21% in one recent series). HHV-6 is also associated with encephalitis (symptoms may include insomnia, seizures, and hallucinations), Hashimoto thyroiditis, myocarditis, and acute liver failure. Primary infection in immunocompetent adults is not common but can produce a mononucleosis-like illness. Pathologically, HHV-6 is associated with mesial temporal sclerosis, which may lead to mesial temporal lobe epilepsy. Reactivation of HHV-6 in immunocompetent adults is rare and can present as encephalitis. Imaging studies in HHV-6 encephalitis typically show lesions in the hippocampus, amygdala, and limbic structures.

Infection during pregnancy and congenital transmission is recognized. Most cases of reactivation occur in immunocompromised persons. Reactivation is associated with graft rejection, graft-versus-host disease, and bone marrow suppression in transplant patients and with encephalitis and pneumonitis in AIDS patients. In recipients of hematopoietic stem cell transplants, HHV-6 may cause fever. It is also associated with an HHV-6–induced encephalitis (diagnosed with multiplex PCR assays) that is correlated strongly with umbilical cord hematopoietic cell transplants (although HHV-6 is not associated with survival in such patients and surveillance for the virus may not be needed).

HHV-6 is on occasion also associated with drug-induced hypersensitivity syndromes. HHV-6 may cause fulminant hepatic failure and acute decompensation of chronic liver disease in children. Purpura fulminans and corneal inflammation are reported with HHV-6 infection. Two variants (A and B) of HHV-6 have been identified. HHV-6B is the predominant strain found in both normal and immunocompromised persons. Ganciclovir, cidofovir, and foscarnet (but not acyclovir) appear to be clinically active against HHV-6. Adoptively transferred virus-specific T cell therapy is also being developed for treatment of HHV-6 infections in hematopoietic stem cell transplant recipients.

HHV-7 is a T-cell lymphotropic virus that is associated with roseola seizures and, rarely, encephalitis, even in immunocompetent adults. Pregnant women are often infected. Infection with HHV-7 is synergistic with CMV in kidney transplant recipients.

HHV-8 (see also Chapter 31) is associated with Kaposi sarcoma, multicentric Castleman disease, and primary effusion (body cavity) lymphoma. HHV-8 infection is endemic in Africa; transmission seems to be primarily horizontal in childhood from intrafamilial contacts and continues through adulthood possibly by nonsexual routes.

MAJOR VACCINE-PREVENTABLE VIRAL INFECTIONS

1. Measles

ESSENTIALS OF DIAGNOSIS

- Exposure 7–18 days before onset of prodrome in an unvaccinated patient.
- Prodrome: fever, coryza, cough, conjunctivitis, malaise, irritability, photophobia, Koplik spots.
- Rash: brick red, maculopapular; appears 3–4 days after onset of prodrome; begins on the face and proceeds "downward and outward," affecting the palms and soles last.
- Leukopenia.

General Considerations

Measles is a reportable acute systemic paramyxoviral infection transmitted by direct contact with infectious droplets or by airborne spread. It is highly contagious with communicability greatest during the preeruptive and catarrhal stages but continues 4 days after the appearance of rash. Measles elimination is defined as the absence of endemic measles virus transmission in an area for 12 months or longer. Measles remains a major cause internationally of mortality with nearly 90,000 estimated deaths per year.

Between 2000 and 2016, the annual incidence of measles decreased by 87%, although in recent years the global tally of cases has increased, with the World Health Organization (WHO) estimating 7 million infections for 2016, the year with most recently compiled complete data. The WHO previously considered measles eradicated in the Americas. Major outbreaks, however, continue throughout the world (countries with over 1000 suspected cases in 2019 include Bangladesh, Cameroon, Chad, China, the Democratic Republic of the Congo, Georgia, Kazakhstan, Kyrgyzstan, India, Indonesia, Japan, Madagascar, Malaysia, Myanmar, Nigeria, the Philippines, Russian, Thailand, the Ukraine, and possibly Venezuela) and in the United States.

Most measles cases in the United States are due to either travel to endemic areas or exposure to individuals who have not been vaccinated against measles. A large 2015 outbreak at a California Disney theme park developed into a multistate outbreak involving 147 people. A 2017 outbreak in New York included 17 reported cases among unvaccinated Orthodox Jews and developed into a tristate outbreak. Additionally, 65 confirmed cases were identified in 2017 in a Somali-American community from Minnesota due to a decline in MMR vaccination coverage. The 2019 outbreak of measles includes 704 cases documented between January 1, 2019 and April 26, 2019 in 13 outbreaks occurring in 22 states with major outbreaks in California, New Jersey, New York, and Washington State. Previously, the highest number of reported measles cases was 667 in 27 states in 2014 followed by 372 in 2018. Intentional undervaccination continues to undermine measles elimination programs.

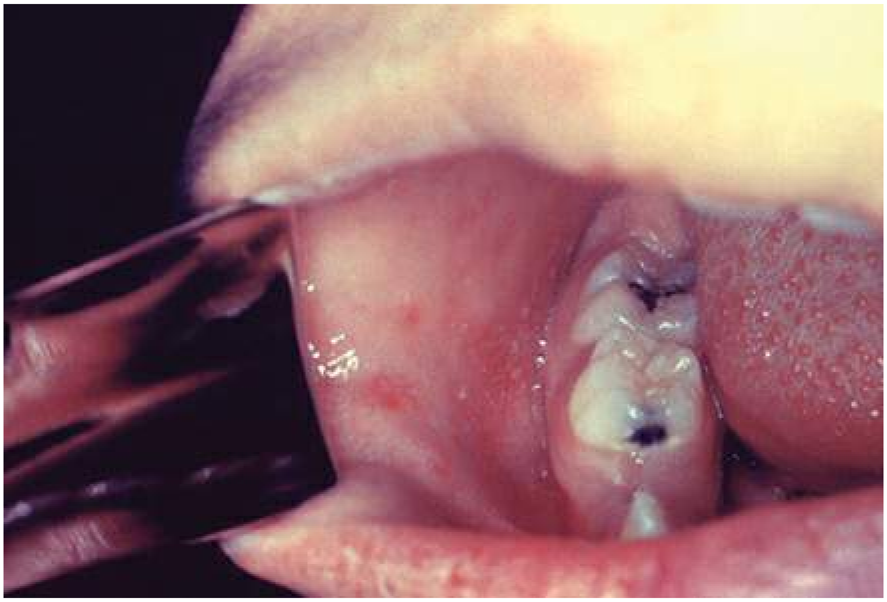
Clinical Findings

A. Symptoms and Signs

The incubation period for measles is 10–14 days. The illness starts with a prodromal phase manifested by high-grade fever (often as high as 40–40.6°C), malaise, coryza (nasal obstruction, sneezing, and sore throat resembling upper respiratory infections), persistent cough, and conjunctivitis (redness, swelling, photophobia, and discharge). These symptoms intensify over 2–4 days before onset of the rash and peak on the first day of the rash. The fever persists through the early rash (about 5–7 days) (Table 32–2).

The characteristic measles rash appears on the face and behind the ears. Initial lesions are pinhead-sized papules that coalesce to form a brick red, irregular, blotchy maculopapular rash. The rash spreads to the trunk and extremities, including the palms and soles. It lasts for 3–7 days and fades in the same manner it appeared. Other findings include pharyngeal erythema, tonsillar exudate, moderate generalized lymphadenopathy and, at times, splenomegaly.

Koplik spots (small, irregular, and red with whitish center on the mucous membranes) are pathognomonic of measles (Figure 32–4). They appear about 2 days before the rash and last 1–4 days as tiny “table salt crystals” on the palatal or buccal mucosa opposite the molars.



▲ Figure 32–4. **Very small, bright red spots on the buccal mucosa indicative of Koplik spots.** (Public Health Image Library, CDC.)

B. Laboratory Findings

Leukopenia is usually present unless secondary bacterial complications exist. A lymphocyte count under 2000/mcL is a poor prognostic sign. Thrombocytopenia is common. Proteinuria is often observed.

Detection of IgM measles antibodies with ELISA or a fourfold rise in serum hemagglutination inhibition antibody supports the diagnosis. IgM assays can be falsely negative the first few days of infection and falsely positive in the presence of rheumatoid factor or with acute rubella, erythrovirus (formerly parvovirus B19), or HHV-6 infection.

Measles virus is technically difficult to culture. Real-time reverse transcriptase-PCR (RT-PCR), available from the CDC and some public health laboratories, can help establish a diagnosis promptly.

Differential Diagnosis

Measles is usually diagnosed clinically but may be mistaken for Kawasaki disease and other exanthematous infections (Table 32–2). Frequent difficulty in establishing a diagnosis suggests that measles may be more prevalent than is recognized.

Complications

A. Respiratory Tract Disease

Early in the course of the disease, bronchopneumonia or bronchiolitis due to the measles virus may occur in up to 5% of patients and result in serious respiratory difficulties. Bronchiectasis may occur in up to a quarter of nonvaccinated children. The incidence of severe respiratory disease may be increased among immunocompromised children and pregnant women.

B. Central Nervous System

Postinfectious encephalomyelitis occurs in 0.05–0.1% of cases, with higher rates occurring in adolescents. It is an acute demyelinating disease that usually starts 3–7 days after the rash. Seizures, coma, and other neurologic symptoms and signs may develop. Treatment is symptomatic and supportive. Virus isolation from the CNS is uncommon. There is an appreciable mortality (10–20%) and morbidity (33% of survivors are left with neurologic deficits).

Measles inclusion body encephalitis is another form of neurologic complication that results in neurologic deterioration and death within months of the acute illness among patients with impaired cellular immunity. Treatment is supportive, including stopping immunosuppressants when feasible. Interferon and ribavirin are variably successful.

Subacute sclerosing panencephalitis is a very rare, and fatal CNS complication that occurs 5–15 years after infection. It is characterized by progressive deterioration of motor and cognitive function leading to death. It is more common in boys of rural backgrounds who are infected with measles before 2 years of age.

C. Other Complications

Immediately following measles, secondary bacterial infection, particularly cervical adenitis, otitis media (the most common complication), and pneumonia, occurs in about 15% of patients. Keratoconjunctivitis is a serious complication that caused blindness before the widespread use of measles vaccine and vitamin A supplementation. Diarrhea and protein-losing enteropathy (prodromal rectal Koplik spots may occur) are significant complications among malnourished children, although the mortality associated with diarrhea is primarily 1 week prior to and 4 weeks after the measles rash, with no longer-term mortality shown with measles-associated diarrhea. Some data implicate the measles virus in the pathogenesis of rheumatoid arthritis.

Treatment

Treatment is symptomatic, including antipyretics and fluids as needed. Vitamin A supplementation for children reduces pediatric morbidity and measles-associated mortality. Data are less substantial for adult supplementation, although many advocate megadose vitamin A at the time of delivery in order to boost infant levels of the vitamin.

Measles virus is susceptible to ribavirin and other antivirals in vitro. Ribavirin is used in selected severe cases of pneumonitis, but insufficient data prevent recommending antiviral use. Zinc has a role in the maintenance of normal immune functions, but routine zinc supplementation to children with measles is not recommended, again for lack of data.

Prognosis

It is estimated that 20.4 million deaths were prevented by use of measles vaccination. In the United States, the case fatality rate is around 2 per 1000 reported cases, with deaths principally due to respiratory and neurologic complications. Deaths in the developing world are mainly related to acute diarrhea and protein-losing enteropathy. Pregnant women with measles may be at increased risk for death. Historically famines are particularly associated with high measles mortality.

Prevention

Because measles is highly contagious, the vaccine coverage rates must exceed 95% to prevent outbreaks. Illness confers permanent immunity. One vaccine dose is about 93% effective. Two doses of vaccine are estimated to be 97% protective. Migrants and asylum seekers are thought to be at higher risk because their antibody levels often are lower than needed for adequate protection. The CDC currently recommends that all individuals embarking on international travel assure that they have been vaccinated. Infants under 1 year of age should have a first dose with boosters at 12–15 months and at age 4–6, children 1 year or older should receive two doses separated by 28 days, and teens and adults without evidence of immunity similarly should receive two doses separated by 28 days.

Vaccine site reactions appear to differ by the manufacturer.

In the United States, based on the 2016 National Immunization Survey, 91.1% of children aged 19–35 months received one or more doses of MMR and 90.9% of adolescents aged 13–17 years received two or more doses. These data suggest considerable geographic disparity. Clustering of unvaccinated individuals increases the likelihood of an outbreak.

At 6 months of age, more than 99% of infants of vaccinated women and 95% of infants of naturally immune women lose maternal antibodies. The susceptibility to measles is 2.4-fold higher if the vaccine is given prior to 15 months (with impact of waning maternal antibody levels). Thus, in the United States, children receive their first vaccine dose at 12–15 months of age. The second dose is given at age 4–6 years, prior to school entry. For individuals born before 1957, herd immunity is assumed. All adults born after 1957, without evidence of immunity should receive at least one dose of MMR vaccine. Persons at high risk for measles exposure (teachers, health care workers, post–high school students, travelers to developing countries) should receive two vaccination doses at least 28 days apart. Immigrants and refugees should be screened and vaccinated if necessary. Combination MMRV vaccines may be used in place of the traditional MMR vaccine.

MMR and MMRV vaccine should not be administered to pregnant women, patients with anaphylactic reactions to neomycin, and patients with known primary or acquired immunodeficiency. Asymptomatic patients living with HIV with CD4 counts higher than 200 cells/mcL should receive MMR vaccine but not MMRV (without a varicella component) vaccine.

Repeated studies fail to show an association between vaccination and autism. MMR vaccine can cause fever and transient rash. Severe allergic reactions are rare. Quadrivalent MMRV vaccine is associated with an increased risk of febrile seizures that appears to be age-related; the risk is highest when MMRV is given to infants between 12 and 23 months of age. Postimmunization seizures appear in whole genome studies to be associated with an interferon receptor and a measles receptor. Immune thrombocytopenia is a documented side effect. Rare cases of postimmunization encephalitis are reported.

In case of an outbreak, when susceptible individuals are exposed to measles, MMR vaccine can prevent disease if given within 3 days of exposure. Immunoglobulin should be administered within 6 days of exposure in any high-risk person exposed to measles, followed by active immunization 3 months later. All infants less than 1 year of age should receive intramuscular immunoglobulin (0.5 mL/kg, maximum dose 15 mL). For infants between 6 months and 12 months, MMR vaccination with repeat at 15 months can be given in place of intramuscular immunoglobulin. Pregnant women and severely immunocompromised persons who are exposed to active measles cases should receive IVIG (400 mg/kg).

Patients with measles should be isolated for 4 days after the onset of rash. In the hospital setting, patients with measles should be placed under air-borne precautions.

An aerosolized measles vaccine remains under study. Future vaccines for a variety of infectious agents may utilize measles vectors, thereby augmenting immunity to measles.

When to Refer

- Any suspect cases should be reported to public health authorities.
- HIV infection.

- Pregnancy.

When to Admit

- Meningitis, encephalitis, or myelitis.
- Severe pneumonia.
- Diarrhea that significantly compromises fluid or electrolyte status.

2. Mumps

ESSENTIALS OF DIAGNOSIS

- Exposure 12–25 days before onset.
- Painful, swollen salivary glands, usually parotid.
- Frequent involvement of testes, pancreas, and meninges in unvaccinated individuals.
- Mumps can occur in appropriately vaccinated persons in highly vaccinated

communities.

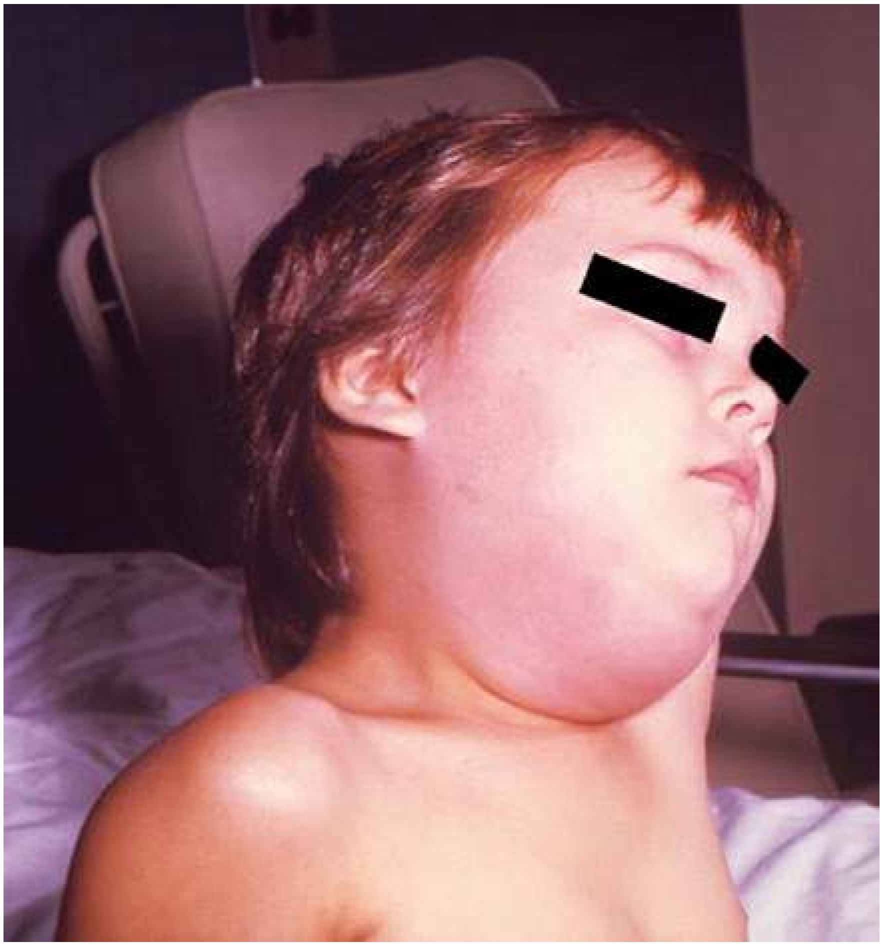
General Considerations

Mumps is a paramyxoviral disease spread by respiratory droplets. Children are most commonly affected; however, in outbreaks, infection can affect patients in their second or third decades of life. Mumps can spread rapidly in congregate settings, such as colleges and schools. The incubation period is 12–25 days (average, 16–18 days). The mumps virus spreads through direct contact with respiratory secretions or saliva or infected surfaces. Transmission can also be airborne or via droplets. Up to one-third of affected individuals have subclinical infection, which is still transmissible. Despite high vaccination rates, several mumps outbreaks were reported over the past few years in an increasing number. In 2016 and 2017, mumps cases surged to about 6000/year, with the largest outbreak occurring at a college in northwest Arkansas, which involved 3000 cases. A combination of factors contributes to outbreaks, including efficacy of vaccines; waning individual immunity; and crowded conditions, which promote transmission.

Clinical Findings

A. Symptoms and Signs

Mumps is more serious in adults than in children and appears to occur more commonly in males. Parotid tenderness and overlying facial edema (Figure 32–5) are the most common physical findings and typically develop within 48 hours of the prodromal symptoms. Usually, one parotid gland enlarges before the other, but unilateral parotitis occurs in 25% of patients. The parotid duct (orifice of Stensen) may be red and swollen. Trismus may result from parotitis. The parotid glands return to normal within 1 week. Involvement of other salivary glands (submaxillary and sublingual) occurs in 10% of cases. Fever and malaise are variable but often minimal in young children. The entire course of mumps rarely exceeds 2 weeks.



[redacted]

Figure 32–5. **Mumps**. (Public Health Image Library, CDC.)

The testes are the most common extra salivary disease site in adults. High fever, testicular swelling, and tenderness (unilateral in 75% of cases) denote orchitis, which usually develops 7–10 days after the onset of parotitis. In recent outbreaks in the United States, complications from mumps were rare; 3.3–10% of adolescent and adult males developed orchitis (which occurred less frequently in persons who have received two doses of vaccine). Lower abdominal pain and ovarian enlargement suggest oophoritis, which is usually unilateral and occurs in less than 1% of postpubertal women.

Other rare complications, occurring in less than 1% of cases, are meningitis, encephalitis, Guillain-Barré syndrome, hearing loss, priapism or testicular infarction from orchitis, pancreatitis, thyroiditis, keratitis, neuritis, hepatitis, myocarditis, thrombocytopenia, migratory arthralgias, and nephritis. No mumps-related deaths have occurred in the United States in recent outbreaks. A rare cause of mumps is iodine exposure in medical procedures (“iodide mumps”).

Some epidemiologic studies have suggested an association between mumps and risk of type 1 diabetes mellitus. Further studies do not provide evidence of this association.

B. Laboratory Findings

Mild leukopenia with relative lymphocytosis may be present. Elevated serum amylase usually reflects salivary gland involvement rather than pancreatitis. Mild kidney injury is found in up to 60% of patients.

The characteristic clinical picture usually suffices for diagnosis. An elevated serum IgM is considered diagnostic. Repeat testing 2–3 weeks after the onset of symptoms is recommended if the first assay is negative because the rise in IgM may be delayed, especially in vaccinated persons. A fourfold rise in complement-fixing antibodies to mumps virus in paired serum IgG also confirms infection. Anti-mumps IgM and IgG in the CSF can confirm the diagnosis of meningitis. Nucleic acid amplification techniques, such as real-time RT-PCR, are more sensitive than viral cultures and are available from some commercial laboratories, selected state laboratories, and the CDC. Diagnostic yield is highest if collected during the first 3 days of illness. Confirmatory diagnosis of mumps is also made by isolating the virus preferably from a swab of the duct of the parotid or other affected salivary gland. The virus can also be isolated from CSF early in aseptic meningitis. Vaccinated persons may shed virus for shorter periods of time compared to those who are unvaccinated.

Differential Diagnosis

Swelling of the parotid gland may be due to calculi in the parotid ducts, tumors, or cysts. Other causes include sarcoidosis, cirrhosis, diabetes, bulimia, pilocarpine usage, and Sjögren syndrome. Parotitis may be produced by pyogenic organisms (eg, S aureus, gram-negative organisms [particularly in debilitated individuals with poor oral intake]), drug reaction (phenothiazines, propylthiouracil), and other viruses (HIV, influenza A, parainfluenza, EBV infection, coxsackieviruses, adenoviruses, HHV-6). Swelling of the parotid gland must be differentiated from inflammation of the lymph nodes located more posteriorly and inferiorly than the parotid gland.

Treatment

Treatment is symptomatic. Topical compresses may relieve parotid discomfort. Some clinicians advocate IVIG for complicated disease (eg, thrombocytopenia), although its definitive role is unproven. There is no specific treatment for orchitis.

Prevention

Vaccination is the most effective way to prevent mumps.

Monovalent mumps vaccine is no longer available in the United States. Mumps vaccine is now administered as combined vaccine in MMR or MMRV vaccine. The vaccination schedule, indications, and contraindications are described in the measles section. The mumps vaccine component of the MMR is less effective than the measles and rubella components. One dose is 78% (range: 49–92%) protective. Two doses of the vaccine are 88% (range: 66–95%) effective. Rare reported complications of mumps vaccination include immune thrombocytopenic purpura and aseptic meningitis.

A 2017 study, evaluating the effect of a third dose of MMR vaccine after a mumps outbreak, showed that the attack rate was significantly lower among students who received a third dose compared with two doses, especially if the second dose was given more than 13 years prior to the outbreak. The CDC recommends a third dose of vaccine in case of an outbreak.

The patient should be isolated. For outbreak control, the most important step is to vaccinate all susceptible individuals. MMR vaccine is not effective in preventing the disease in unvaccinated patients who already have been exposed to the virus. In the healthcare setting, the following steps should be taken: implement droplet and standard precaution, isolate patients until swelling subsides (about 9 days from onset), and provide vaccination to healthcare workers with no evidence of immunity.

When to Refer

Any suspect cases should be reported to public health authorities.

When to Admit

- Trismus; meningitis; encephalitis; myocarditis; pancreatitis.
- Severe testicular pain; priapism.
- Severe thrombocytopenia.

3. Rubella

ESSENTIALS OF DIAGNOSIS

- Exposure 14–21 days before onset.
- No prodrome in children, mild prodrome in adults; mild symptoms (fever, malaise, coryza) coincide with, or precede by up to 5 days, the eruption of rash.
- Posterior cervical and postauricular lymphadenopathy 5–10 days before rash.
- Fine maculopapular rash of 3 days' duration; face to trunk to extremities.
- Leukopenia, thrombocytopenia.

General Considerations

Rubella is a systemic disease caused by a togavirus transmitted by inhalation of infective droplets. It is moderately communicable. Infection usually confers permanent immunity. The incubation period is 14–21 days. The disease is transmissible from 1 week before the rash appears until 15 days afterward.

The last cases of endemic rubella and congenital rubella syndrome were reported in 2009 from the Americas region. Each year in the United States, fewer than 10 cases of rubella are reported, all of which are due to the arrival of infected persons from other countries. In 2015, the WHO declared the Americas region free of rubella and congenital rubella syndrome. Some European countries are facing a challenge with lower immunization coverage among refugees and migrants. Worldwide, cases are decreasing due to widespread implementation of rubella-containing vaccines; as of 2016, the vaccine was added to the national vaccine schedule in 152 of 194 (78%) countries, though it is important to note that extensive variation in the rate of national coverage exists. On the other hand, the number of cases of congenital rubella syndrome remains high, particularly in Africa and Southeast Asia. The increase in congenital rubella syndrome may be secondary to an increase in surveillance and reporting of congenital rubella cases. The WHO set a goal to eliminate rubella in at least five of the six WHO regions (all but the Western Pacific region, which includes China) by 2020, although plans for rubella control are inadequate in 42 countries, especially in Africa and the Eastern Mediterranean regions.

Clinical Findings

A. Postnatal Rubella

Rubella is a common childhood disease; the majority of the cases are asymptomatic. The clinical picture of rubella is difficult to distinguish from other viral illnesses, such as infectious mononucleosis, measles, echovirus infections, and coxsackievirus infections. Fever and malaise, usually mild, accompanied by tender suboccipital adenitis, may precede the eruption by 1 week. Early posterior cervical and postauricular lymphadenopathy is common. A fine, pink maculopapular rash appears and fades from the face, trunk, and extremities in rapid progression (2–3 days), usually lasting 1 day in each area (Table 32–2).

B. Congenital Rubella

The principal importance of rubella lies in its devastating effects on the fetus in utero causing fetal death, preterm delivery, and teratogenic effects. The severity of symptoms is directly related to the gestational age; fetal infection during the first trimester leads to congenital rubella in at least 80% of fetuses; however, an infection during the fourth month can lead to 10% risk of a single congenital defect. In the second trimester of pregnancy, deafness is the primary complication.

C. Laboratory Findings

When rubella is suspected, the diagnosis requires serologic confirmation. Diagnosis of acute rubella infection is based on elevated IgM antibody, fourfold or greater rise in IgG antibody titers, or isolation of the virus. Serosensitivity to rubella is thought to change with subsequent pregnancies, although data from Hong Kong (lower immunity) and the United Kingdom (higher immunity) differed in their findings.

IgM is detectable in 50% of persons on day 1 of the rash but in most on day 5 after rash onset. Antibody testing can be performed on sera or saliva. An isolated IgM-positive test does not necessarily imply acute infection. IgM antibodies can persist after an infection or could be false-positive due to cross-reactivity with other antigens such as EBV, CMV, erythrovirus, and rheumatoid factor. This distinction is very important to make when infection is suspected in pregnancy. High-avidity anti-rubella IgG assays can distinguish between recent and remote infection. Low-avidity IgG is observed in acute rubella infections and lasts up to 3 months postinfection. After 3 months, low-avidity antibodies are replaced by high-avidity antibodies indicating remote infection.

The CDC can test for virus by RT-PCR from throat swabs, oral fluids, or nasopharyngeal secretions. The timing of sample collection is important and is best if collected within the first 3 days of an acute illness and within 3 months in case of congenital rubella syndrome. After 3 months of age, up to 50% of infants with congenital rubella syndrome will not shed the virus.

Complications

Complications of rubella are rare. Polyarticular arthritis and arthralgia occur more commonly in adult women; involve the fingers, wrists, and knees; and usually subside within 7 days but may persist for weeks. Hemorrhagic manifestations due to thrombocytopenia and vascular damage occur more commonly in children, unlike other complications. Hepatitis has been reported. Encephalitis, another rare complication, occurs more commonly in adults and has a high mortality rate.

Treatment

Rubella infection, including complications, is treated symptomatically.

Prevention

Patients with rubella should be isolated for 7 days after rash onset.

In the United States, monovalent rubella vaccine is no longer produced. Live attenuated rubella virus vaccine is primarily given as combination with the MMR vaccine or in combination with MMRV vaccine. It is recommended that the first dose be given between 12 months and 15 months. The second dose is given between age 4 and 6 years, prior to school entry. More details on scheduling, side effects, and contraindications are explained in the measles section. It is important that girls are immune to rubella prior to menarche. In the United States, about 80% of 20-year-old women are immune to rubella.

Rubella vaccine is safe and highly efficacious; a single dose of MMR vaccine is about 97% effective at preventing rubella.

The immune status of pregnant women should be evaluated because antibody titers fall in about 10% of vaccinated individuals within 12 years of vaccination. There is no evidence of adverse outcomes with MMR immunization of pregnant women, yet it is still recommended that women avoid pregnancy for at least 3 months after vaccination. Opportunities should be made available to vaccinate all women of childbearing age.

The administration of live vaccines to immunocompromised patients is controversial. In patients receiving immunosuppressive therapy as well as in patients who have undergone solid organ or bone marrow transplantation, seroconversion is higher to rubella compared with measles, mumps, and varicella. In addition, response to live attenuated vaccines may be lessened due to presence of antibodies from IVIG or other blood products. Safety is another concern when administering live attenuated vaccines to immunocompromised patients. Because MMR vaccine is contraindicated in solid organ transplant recipients, current evidence recommends that seronegative patients receive one or two doses of the MMR vaccine at least 4 weeks prior to solid organ transplantation. Patients who have undergone bone marrow transplant lose antigen-specific antibodies and should be revaccinated regardless of their vaccination history. The revised guidelines recommend MMR and varicella vaccines be given to seronegative patients without graft-versus-host disease 2 years after hematopoietic stem cell transplantation.

Prognosis

Rubella is a mild illness and rarely lasts more than 3–4 days. Congenital rubella has a high fetal mortality rate, and the associated congenital defects are largely permanent.

When to Refer

- Pregnancy.
- Meningitis/encephalitis.
- Significant vaccination reactions.
- Any suspect cases should be reported to public health authorities.

4. Poliomyelitis

ESSENTIALS OF DIAGNOSIS

- Incubation period 7–14 days from exposure.
- Headache, stiff neck, fever, vomiting, sore throat.
- Lower motor neuron lesion (flaccid paralysis) with decreased deep tendon reflexes and muscle wasting.

General Considerations

Poliomyelitis virus, an enterovirus, is highly contagious through fecal-oral route, especially during the first week of infection. There are three wild poliovirus serotypes; however, only wild poliovirus type 1 has remained endemic since 2012. Pakistan and Afghanistan currently are the only countries with endemic wild type poliovirus transmission. In 2017, there were only 22 cases of wild type polio (14 in Afghanistan and 8 in Pakistan), and as of October 2018, only 20 cases of polio in these two endemic countries have been reported. In 2017, there were 96 vaccine-derived poliovirus infections, and as of October 2018, 68 vaccine-derived poliovirus cases (most of these type 2) had been reported in five countries, including The Democratic Republic of the Congo, Niger, Nigeria, Papa New Guinea, and Somalia.

Cases of acute flaccid paralysis resembling polio with residual weakness are increasingly being reported throughout Africa (20 countries), the Eastern Mediterranean region (5 countries), intermittently in Europe (Germany and France), and the United States (a California outbreak in 2012–2014, surge in 2018).

In 2018, an increase in acute flaccid paralysis was noted in the United States, with 80 confirmed cases between January 1, 2018, and November 1, 2018. All but one of the 2018 cases (79, 99%) had a preceding viral illness in the month before presentation of neurologic signs. These signs most commonly involved the upper limbs (38, 47.5%) or all four limbs (23, 28.8%). The most commonly associated viruses (among 50 with virus isolation) were enterovirus A71 and enterovirus D68. In all instances, poliomyelitis was ruled out but an exact etiology for the acute flaccid paralysis was not always determined.

Clinical Findings

A. Symptoms and Signs

At least 95% of infections are asymptomatic. Patients who become symptomatic can present with abortive poliomyelitis, nonparalytic poliomyelitis, or paralytic poliomyelitis. **Post-poliomyelitis syndrome** is the constellation of symptoms that affect polio survivors and is not infectious.

1. Abortive poliomyelitis—Nonspecific symptoms of this minor illness include fever, headache, vomiting, diarrhea, constipation, and sore throat lasting 2–3 days.

2. Nonparalytic poliomyelitis—In addition to the above symptoms, signs of meningeal irritation and muscle spasm occur in the absence of frank paralysis.

3. Paralytic poliomyelitis—Characterized as a flaccid asymmetric paralysis affecting mostly the proximal muscles of the lower extremities; the febrile period is present over 2–3 days. Sensory loss is very rare. Paralytic poliomyelitis is divided into two forms, which may coexist: (1) spinal poliomyelitis involving the muscles innervated by the spinal nerves, and (2) bulbar poliomyelitis involving the muscles supplied by the cranial nerves (especially nerves IX and X) and of the respiratory and vasomotor centers. The most life-threatening aspect of bulbar poliomyelitis is respiratory paralysis. The incidence of paralytic poliomyelitis is higher when infections are acquired later in life.

4. Post-poliomyelitis syndrome—The syndrome presents with signs of chronic and new denervation. The most frequent symptoms are progressive muscle limbs paresis with muscle atrophy, with fasciculations and fibrillation during rest activity. The restless leg syndrome is also reported.

B. Laboratory Findings

The virus may be recovered from throat washings (early) and stools (early and late) and PCR of washings, stool, or CSF can also facilitate diagnosis. CSF findings include the following: (1) normal or slightly increased pressure and protein, (2) glucose is not decreased, and (3) white blood cells usually number less than 500/mcL and are principally lymphocytes after the first 24 hours. CSF findings are normal in 5% of patients. Neutralizing and complement-fixing antibodies appear during the first or second week of illness. Serologic testing cannot distinguish between wild type and vaccine-related virus infections.

Differential Diagnosis

Acute inflammatory polyneuritis (Guillain-Barré syndrome), Japanese encephalitis virus infection, West Nile virus infection, and tick paralysis may resemble poliomyelitis. In Guillain-Barré syndrome (see Chapter 24), the weakness is more symmetric and ascending in most cases, but the Miller Fisher variant of Guillain-Barré is similar to bulbar poliomyelitis. Paresthesia is uncommon in poliomyelitis but common in Guillain-Barré syndrome. The CSF usually has high protein content but normal cell count in Guillain-Barré syndrome. Acute flaccid paralysis resembling polio with residual weakness are increasingly recognized with no evidence of polio infection. Enterovirus is isolated in some of these cases.

Treatment

In the acute phase of paralytic poliomyelitis, patients should be hospitalized. In cases of respiratory weakness or paralysis, intensive care is needed. Intensive physiotherapy may help recover some motor function with paralysis. Attention to psychological disorders in longstanding disease is also important.

Immunodeficient individuals have prolonged excretion of poliovirus leading to virus circulation and threatening the polio eradication efforts. Pocapavir, an experimental capsid inhibitor antiviral agent, was tested in healthy adults given monovalent live oral poliovirus vaccine (OPV) type 1 and was shown to be safe and effective in reducing the duration of viral excretion in stool, but resistance emerged in 44% of treated participants in this study.

Immune modulators, such as prednisone, interferon, and IVIG, do not show any clear benefit in the treatment of post-poliomyelitis syndrome.

Prognosis

The death-to-case ratio for paralytic polio ranges between 2% and 30%, depending on age. Bulbar poliomyelitis carries a mortality rate of up to 75%.

Prevention

Given the epidemiologic distribution of poliomyelitis and the continued concern about vaccine-associated disease with the trivalent live OPV, the inactive (Salk) parenteral vaccine is currently used in the United States for all four recommended doses (at ages 2 months, 4 months, 6–18 months, and at 4–6 years). Inactivated vaccine is also routinely used elsewhere in the developed world where one dose is often administered, although immunogenicity is improved with additional doses.

Because most of circulating vaccine-derived poliovirus and vaccine-associated poliomyelitis are live OPV type 2, the WHO replaced worldwide the trivalent live OPV (containing types 1, 2, and 3) with the bivalent live OPV (type 1 and 3) in 2016. The goal is to replace all live OPV with inactive parenteral vaccination to eliminate poliovirus circulation. The advantages of oral vaccination are the ease of administration, low cost, effective local gastrointestinal and circulating immunity, and herd immunity. Monovalent OPV type 2 (mOPV2) as well as the trivalent OPV are used for control in countries with vaccine-derived type 2 outbreaks.

Routine immunization of adults in the United States is no longer recommended because of the low incidence of the disease. Vaccination should be considered for adults not vaccinated within the prior decade who are exposed to poliomyelitis or who plan to travel to endemic areas and adults engaged in high-risk activities (eg, laboratory workers handling stools).

When to Refer

Any suspicious cases should be referred to public health authorities.

OTHER NEUROTROPIC VIRUSES

1. Rabies

ESSENTIALS OF DIAGNOSIS

- History of animal bite.
- Paresthesias, hydrophobia, rage alternating with calm.
- Convulsions, paralysis, thick tenacious saliva.

General Considerations

Rabies is a viral (rhabdovirus) encephalitis transmitted by infected saliva that enters the body by an animal bite or an open wound. Worldwide, over 17 million cases of animal bites are reported every year, and it is estimated that about 60,000 deaths annually are attributable to rabies. Rabies is endemic in over 150 countries; on the basis of interviews, it is estimated that over 40% of the world's population lives in areas without rabies surveillance. Most cases of rabies occur in rural areas of Africa and Asia. India has the highest incidence, accounting for 36% of global deaths (http://www.who.int/rabies/epidemiology/en/). In developing countries, more than 90% of human cases and 99% of human deaths from rabies are secondary to bites from infected dogs. Rabies among travelers to rabies-endemic areas is usually associated with animal injuries (including dogs in North Africa and India, cats in the Middle East, and nonhuman primates in sub-Saharan Africa and Asia), with most travel-associated cases occurring within 10 days of arrival. Rare but related viruses are the Australian lyssavirus, transmitted by bats including one referred to as the black flying fox, and which has caused 3 deaths over the last 20 years, and the European lyssavirus, with cases from Germany and the United Kingdom.

In the United States, domestically acquired rabies cases are rare (approximately 92% of cases are associated with wildlife) but probably underreported. Reports largely from the East Coast show an increase in rabies among cats, with about 1% of tested cats showing rabies seropositivity. The annual caseload in the United States is 1–3 cases (https://www.cdc.gov/rabies/location/usa/surveillance/human_rabies.html). Surveillance for animal rabies in 2015 showed 5508 cases occurring in 49 states and Puerto Rico. Wildlife reservoirs, with each species having its own rabies variant(s), follow a unique geographic distribution in the United States: raccoons on the East Coast; skunks in the Midwest, Southwest, and California; and foxes in the Southwest and in Alaska. However, some areas have all three wildlife reservoirs (eg, the hill country of Texas). Hawaii is the only rabies-free state to date. Most of Western Europe and much of Oceania is rabies-free.

Raccoons, bats, and skunks account for 84% of the rabid animals found in the United States; other rabid animals include foxes, cats, cattle, and dogs. Rodents and lagomorphs (eg, rabbits) are unlikely to spread rabies because they cannot survive the disease long enough to transmit it (woodchucks and groundhogs are exceptions). Wildlife epizootics present a constant public health threat in addition to the danger of reintroducing rabies to domestic animals. Vaccination is the key to controlling rabies in small animals and preventing rabies transmission to human beings.

The virus enters the salivary glands of dogs 5–7 days before their death from rabies, thus limiting their period of infectivity. Less common routes of transmission include contamination of mucous membranes with saliva or brain tissue, aerosol transmission, and corneal transplantation. Recognized mutations in rabies virus proteins can subvert the host immune system. Transmission through solid organ and vascular segment transplantation from donors with unrecognized infection is also reported. A number of transplantation-associated cases are reported, including two clusters in the United States. Postexposure prophylaxis can be administered in these patients and may prevent development of disease.

The incubation period may range from 10 days to many years but is usually 3–7 weeks depending in part on the distance of the wound from the CNS. The virus travels in the nerves to the brain, multiplies there, and then migrates along the efferent nerves to the salivary glands. Rabies virus infection forms cytoplasmic inclusion bodies similar to Negri bodies. These Negri bodies are thought to be the sites of viral transcription and replication.

Clinical Findings

A. Symptoms and Signs

While there is usually a history of animal bite, bat bites may not be recognized. The prodromal syndrome consists of pain at the site of the bite in association with fever, malaise, headache, nausea, and vomiting. The skin is sensitive to changes of temperature, especially air currents (aerophobia). Percussion myoedema (a mounding of muscles after a light pressure stimulus) can be present and persist throughout the disease. The CNS stage begins about 10 days after the prodrome and may be either encephalitic (“furious”) or paralytic (“dumb”). The encephalitic form (about 80% of the cases) produces the classic rabies manifestations of delirium alternating with periods of calm, extremely painful laryngeal spasms on attempting drinking (hydrophobia), autonomic stimulation (hypersalivation), and seizures. In the less common paralytic form, an acute ascending paralysis resembling Guillain-Barré syndrome predominates with relative sparing of higher cortical functions initially. Both forms progress relentlessly to coma, autonomic nervous system dysfunction, and death.

B. Laboratory Findings

Biting animals that appear well should be quarantined and observed for 10 days. Sick or dead animals should be tested for rabies. A wild animal, if captured, should be sacrificed and the head shipped on ice to the nearest laboratory qualified to examine the brain for evidence of rabies virus. When the animal cannot be examined, raccoons, skunks, bats, and foxes should be presumed to be rabid.

Direct fluorescent antibody testing of skin biopsy material from the posterior neck (where hair follicles are highly innervated) has a sensitivity of 60–80%.

Quantitative RT-PCR, nucleic acid sequence-based amplification, direct rapid immunohistochemical test, and viral isolation from the CSF or saliva are advocated as definitive diagnostic assays. Antibodies can be detected in the serum and the CSF. Pathologic specimens often demonstrate round or oval eosinophilic inclusion bodies (Negri bodies) in the cytoplasm of neuronal cells, but the finding is neither sensitive nor specific. MRI signs are diffuse and nonspecific.

Treatment & Prognosis

Management requires intensive care with attention to the airway, maintenance of oxygenation, and control of seizures. Universal precautions are essential. Corticosteroids are of no use. Survival is rare, and data are insufficient to provide estimate of success.

If postexposure prophylaxis (discussed below) is given expediently, before clinical signs develop, it is nearly 100% successful in prevention of disease. Once the symptoms have appeared, death almost inevitably occurs after 7 days, usually from respiratory failure. Most deaths occur in persons with unrecognized disease who do not seek medical care or in individuals who do not receive postexposure prophylaxis. The very rare cases in which patients recover without intensive care are referred to as “abortive rabies.”

Prevention

Immunization of household dogs and cats and active immunization of persons with significant animal exposure (eg, veterinarians) are important. The most important decisions, however, concern animal bites. Animals that are frequent sources of infection to travelers are dogs, cats, and nonhuman primates.

In the developing world, education, surveillance, and animal (particularly dog) vaccination programs (at recurrent intervals) are preferred over mass destruction of dogs, which is followed typically by invasion of susceptible feral animals into urban areas. In some Western European countries, campaigns of oral vaccination of wild animals led to the elimination of rabies in wildlife.

A. Local Treatment of Animal Bites and Scratches

Thorough cleansing, debridement, and repeated flushing of wounds with soap and water are important. Rabies immune globulin or antiserum should be given as stated below. Wounds caused by animal bites should not be sutured.

B. Postexposure Immunization

The decision to treat should be based on the circumstances of the bite, including the extent and location of the wound, the biting animal, the history of prior vaccination, and the local epidemiology of rabies. Any contact or suspect contact with a bat, skunk, or raccoon is usually deemed a sufficient indication to warrant prophylaxis. Consultation with state and local health departments is recommended. Postexposure treatment including both immune globulin and vaccination should be administered as promptly as possible when indicated.

For patients who had not received rabies vaccination prior to possible exposure, the optimal form of **passive immunization** is human rabies immune globulin (HRIG; 20 international units/kg), administered once. As much as possible of the full dose should be infiltrated around the wound, with any remaining injected intramuscularly at a site distant from the wound. Finger spaces can be safely injected without development of a compartment syndrome. If HRIG is not available and appropriate tests for horse serum sensitivity are done, equine rabies antiserum (40 international units/kg) can be used.

Two vaccines are licensed and available for use in humans in the United States: a human diploid cell vaccine (HDCV, Immovax) and a purified chick embryo cell vaccine (PCEC, RabAvert). There are several postexposure prophylaxis strategies. The most commonly used one is the “abbreviated Essen” strategy, where either of the current vaccines is given as four intramuscular injections of 1 mL in the deltoid or, in small children, into the anterolateral thigh muscles on days 0, 3, 7, and 14 after exposure. (The fifth dose at 28 days after exposure is no longer recommended except among immunosuppressed patients.) The vaccine should not be given in the gluteal area due to suboptimal response. An alternative intramuscular vaccination strategy that takes only 1 week, with injections on days 0, 3, and 7 after exposure with a Vero cell vaccine (Verorab) is reportedly successful in achieving adequate neutralizing titers at days 14 and 28 in a study from Thailand; this vaccine is not currently available in the United States.

The WHO supports an intradermal vaccination strategy using Verorab and the inactivated rabies virus vaccine Rabipur (an alternative formulation of the PCEC [purified chick embryo cell]) (0.1 mL per intradermal injection) for regions of the world where vaccine is in short supply; either vaccine can be given at two sites on days 0, 3, 7, and 28.

Rabies vaccines and HRIG should never be given in the same syringe or at the same site. Allergic reactions to the vaccine are rare and include a report of sudden unilateral sensorineural hearing loss and immune thrombocytopenic purpura, although local reactions (pruritus, erythema, tenderness) occur in about 25% and mild systemic reactions (headaches, myalgias, nausea) in about 20% of recipients. Intradermal vaccines appear to be better tolerated than intramuscular vaccines, especially among young children. Adverse reactions to HRIG seem to be more frequent in women and rare in young children. The vaccines are commercially available or can be obtained through health departments.

In patients with history of past vaccination, the need for HRIG is eliminated (HRIG is in short supply worldwide), but postexposure vaccination is still required. The vaccine should be given 1 mL in the deltoid twice (on days 0 and 3). Neither the passive nor the active form of postexposure prophylaxis is associated with fetal abnormalities and thus pregnancy is not considered a contraindication to vaccination. Peripartum rabies transmission occurs but is rare. Neonates may also receive both forms of postexposure prophylaxis at birth.

The WHO has a program to eliminate dog-transmitted human rabies by 2030.

C. Preexposure Immunization

Preexposure prophylaxis with three injections of human diploid cell vaccine intramuscularly (1 mL on days 0, 7, and 21 or 28) is recommended for persons at high risk for exposure: veterinarians (who should have rabies antibody titers checked every 2 years and be boosted with 1 mL intramuscularly); animal handlers; laboratory workers; Peace Corps workers; and travelers with stays over 1 month to remote areas in endemic countries in Africa, Asia, and Latin America. An intradermal route is also available (0.1 mL on days 0, 7, and 21 over the deltoid) but not in the United States. Immunosuppressive illnesses and agents including corticosteroids as well as antimalarials—in particular chloroquine—may diminish the antibody response. A single-dose booster at 10 years after initial immunization increases the level of antibody titers. Unfortunately, data from travel services indicate that only a small proportion of travelers with anticipated lengthy stays in rabies-impacted areas receive the vaccine as recommended.

When to Refer

Suspicion of rabies requires contact with public health personnel to initiate appropriate passive and active prophylaxis and observation of suspect cases.

When to Admit

- Respiratory, neuromuscular, or CNS dysfunction consistent with rabies.
- Patients with suspect rabies require initiation of therapy until the disease is ruled out in suspect animals, and this requires coordination of care based on likelihood of patient compliance, availability of inpatient and outpatient facilities, and response of local public health teams.

2. Arbovirus Encephalitides

ESSENTIALS OF DIAGNOSIS

- Fever, malaise, stiff neck, sore throat, and vomiting, progressing to stupor, coma, and convulsions.
- Upper motor neuron lesion signs: exaggerated deep tendon reflexes, absent superficial reflexes, and spastic paralysis.
- CSF opening pressure and protein are often increased with lymphocytic pleocytosis.

General Considerations

The arboviruses are arthropod-borne viral pathogens carried by mosquitoes or ticks that produce clinical manifestations in humans. The **mosquito-borne pathogens** include togaviruses (causing Western, Eastern, and Venezuelan equine encephalitis), flaviviruses (causing West Nile fever, St. Louis encephalitis, Japanese encephalitis, and

Murray Valley encephalitis; dengue, Zika, and yellow fever can present with encephalitis), bunyaviruses (the California serogroup of viruses, including the Jamestown Canyon [seen largely in Northern states] and the La Crosse viruses [seen in the upper Midwest and mid-Atlantic primarily]), and the alphavirus chikungunya. The **tick-borne** causes of encephalitis include the flavivirus of the Powassan encephalitis (North American Northeast and Great Lakes), tick-borne encephalitis virus (Europe and Asia), and the Colorado tick fever reovirus. Only those viruses causing primarily encephalitis in the United States are discussed here. The most commonly encountered arboviruses from 2017 in the United States are West Nile virus (2097 cases, 89% of arboviral neuroinvasive disease), Jamestown Canyon virus (75 cases), the La Crosse virus (63 cases), and Powassan virus (34 cases). Rare causes of domestic arboviruses were St. Louis encephalitis virus (11 cases) and eastern equine encephalitis virus disease (5 cases, 3 via organ transplantation).

West Nile virus is the leading cause of domestically acquired arboviral disease in the United States. West Nile virus disease is a nationally notifiable condition. Among the 2291 cases of domestic arboviral disease from 2017, cases were reported to the CDC from 48 states and the District of Columbia, 1425 (68%) were classified as neuroinvasive disease, and 32% were classified as non-neuroinvasive disease. Most cases are identified in Texas and California. Asymptomatic seroconversion is the norm and is not reported. Epidemiologic studies from the Dallas-Fort Worth area show consistency through time of the percentage of neuroinvasive disease.

Outbreaks with West Nile infection tend to occur between mid-July and early September. Climatic factors, including elevated mean temperatures and rainfall, correlate with increased West Nile infection. West Nile virus circulates between mosquitoes (mainly Culex species) and birds. In case of West Nile virus outbreak, infected birds develop high levels viremia that lead to substantial avian mortality and a high incidence of mosquito infection. Infected mosquitoes bite and infect people and other mammals. However, humans and other mammals are “dead end” hosts, since they do not transmit the virus on to other biting mosquitoes; only dengue and Venezuelan equine encephalitis viruses produce viremias high enough to allow continued transmission to other mosquitoes and ticks between humans and vectors. Human-to-human transmission is usually related to blood transfusion and organ transplantation. Since 2003, all blood donations in the United States are screened with nucleic acid amplification assays for West Nile virus. Eastern equine encephalitis is now also shown to be transmitted by organ transplantation.

Clinical Findings

A. Symptoms and Signs

West Nile virus infection has an incubation period of 2–14 days. The infection is symptomatic in no more than 10% of the cases; of those, about 10% progress to neuroinvasive disease, including meningitis, encephalitis, and flaccid paralysis. The case fatality rate is about 10%.

Symptoms include acute febrile illness, and a nonpruritic maculopapular rash is variably present. Meningitis is indistinguishable from other viral meningitis. West Nile virus encephalitis presents with fever and altered mental status. Other signs include tremors, seizures, cranial nerve palsies, and pathologic reflexes. Acute flaccid (poliomyelitis-like) paralysis, which is asymmetric and can involve facial and respiratory muscles, is a well-known complication and is less commonly seen with other arboviruses infection. West Nile virus can also present as Guillain-Barré syndrome with radiculopathy. The disease manifestations associated with West Nile virus infection are strongly age-dependent: the acute febrile syndrome and mild neurologic symptoms are more common in the young, aseptic meningitis and poliomyelitis-like syndromes are seen in middle-aged persons, and frank encephalopathy is seen more often in older adults. All forms of disease tend to be severe in immunocompromised persons in whom neuroinvasive manifestations and associated high mortality are more apt to develop. Other risk factors for development of neuroinvasive disease and increased mortality include black race, diabetes, chronic kidney disease, and hepatitis C virus infection.

Host genetic variation in the interferon response pathway is associated with both risk for symptomatic West Nile virus infection and increased likelihood of West Nile virus disease progression.

B. Laboratory Findings

The peripheral white blood cell count is usually normal. Usually a CSF lymphocytic pleocytosis is present, and polymorphonuclear cells predominate early. The diagnosis of arboviral encephalitides depends on serologic tests. For West Nile virus, an IgM capture ELISA in serum or CSF is almost always positive by the time the disease is clinically evident, and the presence of IgM in CSF indicates neuroinvasive disease. Documentation of a fourfold increase in acute/convalescent IgG titers is confirmatory for all arboviruses. Antibodies to arboviruses persist for life, and the presence of IgG in the absence of a rising titer of IgM may indicate past exposure rather than acute infection. Serologic tests are available commercially and through local and state health departments. Cross-reactivity exists among the different flaviviruses, so a plaque reduction assay may be needed to definitively distinguish between West Nile fever, St. Louis encephalitis, and others. PCR assays (available through state laboratories and the CDC) can be used to detect viral RNA in serum, CSF, or tissue early after illness onset and may be particularly useful in immunocompromised patients with abnormal antibody responses. Individuals with chronic symptoms after West Nile virus infection may show persistent kidney infection for up to 6 years with West Nile virus RNA present in urine. Blood products are best screened using nucleic acid assays. MRI of the brain may reveal leptomeningeal, basal ganglia, thalamic, or periventricular enhancement.

Differential Diagnosis

Mild forms of encephalitis must be differentiated from aseptic meningitis, lymphocytic choriomeningitis, and nonparalytic poliomyelitis.

Severe forms of arbovirus encephalitides are to be differentiated from other causes of viral encephalitis (HSV, mumps virus, poliovirus or other enteroviruses, HIV), encephalitis accompanying exanthematous diseases of childhood (measles, varicella, infectious mononucleosis, rubella), encephalitis following vaccination or infection (a demyelinating type seen after rabies, measles, pertussis vaccination), toxic encephalitis (from drugs, poisons, or bacterial toxins such as Shigella dysenteriae type 1), Reye syndrome, and severe forms of stroke, brain tumors, brain abscess, autoimmune processes such as lupus cerebritis, and intoxications. In the California Encephalitis Project, anti-N-methyl-D-aspartate receptor (anti-NMDAR) encephalitis is a more common cause of encephalitis than viral diseases, especially in the young, with 65% of cases of encephalitis due to anti-NMDAR occurring among patients 18 or younger.

Complications

Bronchial pneumonia, urinary retention and infection, prolonged weakness, and pressure injuries may occur. Retinopathy occurs in 24% of patients with a history of West Nile virus infection and is associated with increased risk in those with encephalitis. Few studies suggest that West Nile virus infection can persist in the kidneys, but in a subset of patients following West Nile virus infection, kidney infection may lead to progressive renal pathology.

Treatment

Although specific antiviral therapy is not available for most causative entities, vigorous supportive measures can be helpful. Some studies suggest improved outcomes with the use of IVIG enriched with West Nile virus antibody; however, a randomized, controlled trial of IVIG did not show a benefit.

Prognosis

Although most infections are mild or asymptomatic, the prognosis is always guarded, especially at the extremes of age. Most fatalities occur with neuroinvasive disease. Most patients with non-neuroinvasive West Nile virus disease or West Nile virus meningitis recover completely, but a syndrome of fatigue, malaise, and weakness can linger for weeks or months. Patients who recover from West Nile virus encephalitis or poliomyelitis often have residual neurologic deficits. The recovery of persons with severe neurologic compromise may take 6 months or longer. The sequelae of West Nile virus infection include a poliomyelitis-like syndrome, cognitive complaints, movement disorders, epilepsy, and depression; and they may become apparent late in the course of what appears to be a successful recovery.

Another entity, nonprimary infection, characterized by elevated serum IgG, absent serum IgM, and occasional detection of West Nile virus RNA in blood or CSF, is associated with underlying psychiatric disorders, hospitalization during times not associated with peak West Nile transmission, fever, and increased in-hospital mortality.

The long-term prognosis is generally better for Western equine than for Eastern equine or St. Louis encephalitis.

Prevention

Mosquito avoidance (repellents, protective clothing, and insecticide spraying) is effective prevention. Laboratory precautions are indicated for handling all these pathogens. No human vaccine is currently available for the arboviruses prevalent in North America. A chimeric live attenuated West Nile virus vaccine is tested in phase I clinical trials and is shown to be safe and immunogenic in healthy adults.

3. Japanese Encephalitis

ESSENTIALS OF DIAGNOSIS

- Most important vaccine-preventable cause of encephalitis in the Asia-Pacific region.
- The virus is transmitted by mosquitoes, especially Culex species.
- Wide symptom spectrum; most infections asymptomatic.

General Considerations

The Japanese encephalitis virus is a flavivirus akin to those causing West Nile infection and St. Louis encephalitis. It is the most common cause of encephalitis in East Asia with over 68,000 estimated annual cases and up to 20,400 annual deaths. It is geographically contained to East Asia. Most cases occur in the summer and late fall, although in tropical and subtropical areas transmission occurs throughout the year. Major outbreaks every 2–15 years often correlate with patterns of agricultural development. The virus is transmitted by mosquitoes, especially Culex species. Areas with high endemicity tend to be warm-temperate, semitropical or tropical areas with high annual rainfalls. Wading birds (such as herons) and pigs more commonly sustain the infection as reservoirs in nature, since the viremia in humans is transient and not usually high enough to sustain transmission. In endemic countries, Japanese encephalitis is primarily a disease of children. Travelers to major urban areas for less than 1 month are at minimal risk for Japanese encephalitis. Transmission by blood transfusion is documented.

Clinical Findings

A. Symptoms and Signs

The median incubation period is 5–15 days. Most persons asymptomatically seroconvert. The 1% of patients in whom disease develops report sudden-onset headaches, nausea, and vomiting, followed by mental status changes, parkinsonian movement disorders, and in a smaller percentage, seizures, typically in children.

Japanese encephalitis most closely resembles St. Louis encephalitis and West Nile encephalitis, although epidemiologic data readily distinguish these infections in most instances. The clinical course is less severe in patients with a history of dengue virus infection.

B. Laboratory Findings and Diagnosis

The disease should be suspected in persons with symptoms of CNS infection who recently visited or who reside in an endemic area.

Common laboratory abnormalities include leukocytosis, mild anemia, and hyponatremia. CSF typically has a mild to moderate pleocytosis with a lymphocytic predominance, slightly elevated protein, and normal glucose.

Diagnosis is confirmed by finding anti-Japanese encephalitis IgM in CSF or serum using ELISA. Definitive diagnosis requires fourfold increase in virus-specific IgG confirmed by plaque reduction neutralization assay. Because of low levels of viremia in humans, RT-PCR is not recommended.

In severe disease, brain imaging reveals thalamic lesions, with the hippocampus, midbrain, basal ganglia, and cerebral cortex affected to varying degrees.

Complications

A variety of cognitive, neurologic, and psychiatric complications, including memory impairment and intellectual impairment in adults and children, are recognized to occur in as many as 50% of survivors and to persist at least 1–2 years after the acute infection. Rare reported complications include the opsoclonus myoclonus syndrome and the Kasabach-Merritt phenomenon of consumptive coagulopathy. The mortality is reportedly as high as 30%.

Treatment

Treatment is supportive, including antipyretics, analgesics, bed rest, and fluids. Corticosteroids may be needed for rare complications, such as the opsoclonus myoclonus syndrome.

Prevention

Using mosquito repellents; wearing long sleeves, long pants, and socks; and using air-conditioned facilities and bed nets are essential means of protection.

In the United States, inactivated Vero-cell culture-derived Japanese encephalitis vaccine (IXIARO) is licensed for the prevention of Japanese encephalitis in persons 2 months of age and older. Travelers who plan to spend more than 1 month in rural East Asia during Japanese encephalitis virus transmission season should receive the vaccine. Primary vaccination requires two doses administered 28 days apart, to be completed more than 1 week before travel. For adults, a booster dose is recommended in case of potential reexposure or of continued risk for infection if the primary series of the vaccine was administered over a 1 year before.

Four effective types of vaccine against Japanese encephalitis are available worldwide, including live attenuated and inactivated vaccines. The risk of serious reactions, including potential encephalitis, with live vaccines is low and decreases with age. Rare reported neurologic reactions are not definitively associated with vaccination. There are no studies about the safety of IXIARO in pregnant women. Therefore, administration of this vaccine to pregnant women should be deferred, unless the risk of infection outweighs the risk of vaccine complications.

4. Tick-Borne Encephalitis

ESSENTIALS OF DIAGNOSIS

- Flaviviral encephalitis found in Eastern, Central, and occasionally Northern Europe and Asia.
- Transmitted via ticks or ingestion of unpasteurized milk.
- Long-term neurologic sequelae in 2–25% of cases.
- Therapy is largely supportive.
- Prevention: avoid tick exposure, pasteurize milk, and vaccinate.

General Considerations

Tick-borne encephalitis (TBE) is a flaviviral infection caused by TBE virus with three subtypes: European, Siberian, and Far Eastern. The principal reservoirs and vectors for TBE virus are ticks with small rodents as the amplifying host; humans are an accidental host. The vectors for most cases are Ixodes ricinus (European subtype) and Ixodes persulcatus (Siberian and Far Eastern subtype). Infection results from tick bites during outdoor activities in forested areas, predominantly in the late spring through fall. Ingestion of unpasteurized milk from viremic livestock (goats, sheep, and cattle) is also a recognized mode of transmission. Transmission by transplantation of solid organs is reported leading to fatal outcomes. TBE is endemic in certain parts of Europe (reported recent foci include northeastern France and Bulgaria) and Asia (principally China but a few cases from Japan as well). The number of cases reported annually fluctuates significantly depending on surveillance, human activities, socioeconomic factors, ecology, and climate. Modeling studies from Prague suggests several superimposed cycles of variable year duration. The incubation period is 7–14 days for tick-borne exposures but only 3–4 days for milk ingestion.

Powassan virus is the only North American member of the tick-borne encephalitides. Its vector is several Ixodes species ticks. Most cases occur in older men (median age, 62; all deaths have occurred in persons over age 50), primarily from Northeast and North Central states (especially Minnesota, New York, and Wisconsin). Most reported cases are neuroinvasive with presentations including acute encephalitis and aseptic meningitis. The incubation period can range from 1 to 5 weeks, although pinpointing the date of actual exposure is often difficult.

Clinical Findings

A. Symptoms and Signs

Most cases are subclinical, and many resemble an influenza-like syndrome with 2–10 days of fever (usually with malaise, headache, and myalgias). In some cases, the disease is biphasic where the initial flu-like period is followed by a 1- to 21-day symptom-free interval followed by a second phase with fevers and neurologic symptoms (cases from Asia appear not to show this biphasic pattern). The neurologic manifestations range from febrile headache to aseptic meningitis and encephalitis with or without myelitis (preferentially of the cervical anterior horn) and spinal paralysis (usually flaccid). A myeloradiculitic form can also develop but is less common. Peripheral facial palsies, sometimes bilateral, tend to occur infrequently late in the course of infection, usually after encephalitis and usually are associated with a favorable outcome within 30–90 days. The main sequela of disease is paresis. Other causes of long-term morbidity include protracted cognitive dysfunction and persistent spinal nerve paralysis. The **post-encephalitic syndrome** is characterized by headache, difficulties concentrating, balance disorders, dysphasia, hearing defects, and chronic fatigue. A progressive motor neuron disease and partial continuous epilepsy are complications. Longstanding psychiatric complications are reported and include attention deficits, slowness of thought and learning impairment, depression, lability, and mutism.

Mortality in TBE is usually a consequence of brain edema or bulbar involvement.

B. Laboratory Findings and Diagnosis

Leukocytosis and neutrophilia are common. Abnormal CSF findings include an inconsistent pleocytosis that may persist for up to 4 months. Hyponatremia is more commonly seen than with other viral encephalitides. Neuroimaging might show hyperintense lesions in the thalamus, brainstem, and basal ganglia, and cerebral atrophy.

When neurologic symptoms develop, the TBE virus is typically no longer detectable in blood and CSF samples. Virus detection by RT-PCR in ticks from TBE patients, if available, can help with the diagnosis. TBE virus IgM and IgG are detected by ELISA when neurologic symptoms occur.

Cross-reactivity with other flaviviruses or a vaccinated state may require confirmation by detection of TBE virus–specific antibodies by plaque-reduction neutralization tests.

Differential Diagnosis

The differential diagnosis includes other causes of aseptic meningitis, such as enteroviral infections; poliomyelitis (no longer reported from Eastern Europe); herpes simplex encephalitis; and a variety of tick-borne pathogens, including tularemia, the rickettsial diseases, babesiosis, Lyme disease, and other flaviviral infections. Coinfections are documented with Anaplasma, Babesia, and Borrelia infections.

Treatment

There is no specific antiviral treatment, and therapy is largely supportive.

Prognosis

The three subtypes of TPE have different prognoses. The European subtype is usually milder with up to 2% mortality and 30% neuroinvasive disease. The Siberian subtype is associated with 3% mortality and chronic, progressive disease. The Far Eastern subtype is usually more severe with up to 40% mortality and higher likelihood of neurologic involvement. All three subtypes are more severe among elderly adults compared with children. Coinfection with Borrelia burgdorferi (the agent of Lyme disease; transmitted by the same tick vector) may result in more severe disease.

Prevention

There is no available TBE vaccine in the United States. There are four different inactivated TBE virus vaccines for adults and children licensed in Europe (two in Austria and Germany and two in Russia) and one available in China. The vaccine is safe and effective and should provide cross-protection against all three TBE virus subtypes. The initial vaccination schedule requires two to three doses given over 6 or more months with boosters every 1–5 years, the interval dependent on the vaccine and national guidelines. Breakthrough TBE in vaccinated individuals is reported, especially among recipients who are over 50 years of age and among persons who are immunosuppressed, such as those receiving anti-TNF therapy or methotrexate, indicating the need for a modified immunization strategy in such patients. Neuritis and neuropathies of peripheral nerves (plexus neuropathy—paresis of lower limb muscles, polyradiculopathy) are recognized complications of TBE vaccination.

The low popular support for the vaccine in endemic countries is responsible for limited abilities to control the disease. Other prevention recommendations include avoidance of tick exposure and pasteurization of cow and goat milk.

5. Lymphocytic Choriomeningitis

ESSENTIALS OF DIAGNOSIS

- “Influenza-like” prodrome of fever, chills, and cough, followed by a meningeal phase.
- Aseptic meningitis: stiff neck, headache, vomiting, lethargy.
- CSF: slight increase of protein, lymphocytic pleocytosis (500–3000/mcL).
- Complement-fixing antibodies within 2 weeks.

General Considerations

The lymphocytic choriomeningitis virus is an arenavirus (related to the pathogen causing Lassa fever, discussed below) that primarily infects the CNS. Its main reservoir is the house mouse (Mus musculus). Other rodents (such as rats, guinea pigs, and even pet hamsters), monkeys, dogs, and swine are also potential reservoirs. The infected animal sheds lymphocytic choriomeningitis virus in nasal secretions, urine, and feces; transmission to humans probably occurs through aerosolized particles and mucosal exposure, percutaneous inoculation, direct contact, or animal bites. The disease in humans is underdiagnosed and occurs most often in autumn. The lymphocytic choriomeningitis virus is typically not spread person to person, although vertical transmission is reported, and it is considered to be an underrecognized teratogen. Rare cases related to solid organ transplantation and autopsies of infected individuals are also reported. All reported cases were donor derived. Outbreaks are uncommon, and usually occur in laboratory settings among those workers with significant rodent exposure.

The ubiquitous nature of its reservoir and the large distribution of the reported cases suggest a widespread geographic risk of lymphocytic choriomeningitis virus infection. Serologic surveys in the southern and eastern United States suggest past infection in approximately 3–5% of those tested, although later data from upstate New York showed less than 1% seroprevalence. Infection risk can be reduced by limiting contact with pet rodents and rodent trappings.

Clinical Findings

A. Symptoms and Signs

The incubation period is 8–13 days to the appearance of systemic manifestations and 15–21 days to the appearance of meningeal symptoms. Symptoms are biphasic, with a prodromal illness characterized by fever, chills, headache, myalgia, cough, and vomiting, occasionally with lymphadenopathy and maculopapular rash. After 3–5 days the fever subsides only to return after 2–4 days alongside the meningeal phase, characterized by headache, nausea and vomiting, lethargy, and variably present meningeal signs. Arthralgias can develop late in the course. Transverse myelitis, deafness, Guillain-Barré syndrome, and transient and permanent hydrocephalus are reported. Lymphocytic choriomeningitis virus is a well-known, albeit underrecognized, cause of congenital infection frequently complicated with obstructive hydrocephalus and chorioretinitis. In fetuses and newborns with ventriculomegaly or other abnormal neuroimaging findings, screening for congenital lymphocytic choriomeningitis may be considered; mothers are asymptomatic half the time. In over one-third of cases, rodent exposure is reported retrospectively. Occasionally, a syndrome resembling the viral hemorrhagic fevers is described in transplant recipients of infected organs and in patients with lymphoma.

B. Laboratory Findings

Leukocytosis or leukopenia and thrombocytopenia may be initially present. During the meningeal phase, CSF analysis frequently shows lymphocytic pleocytosis (total count is often 500–3000/mcL) alongside a slight increase in protein, while a low to normal glucose is seen in at least 25%. The virus may be recovered from the blood and CSF by mouse inoculation. Complement-fixing antibodies appear during or after the second week. Detection of specific IgM by ELISA is widely used. Detection of lymphocytic choriomeningitis virus by PCR is available in research settings.

Differential Diagnosis

The influenza-like prodrome and latent period may distinguish this from other aseptic meningitides, and bacterial and granulomatous meningitis. A history of exposure to mice or other potential vectors is an important diagnostic clue.

Treatment

Treatment is supportive. In several survivors of transplant-associated outbreaks, ribavirin (which is effective against other arenaviruses) has been used successfully along with decreasing immunosuppression.

Prognosis

Complications and fatalities are rare in the general population. The illness usually lasts 1–2 weeks, though convalescence may be prolonged. Lymphocytic choriomeningitis in solid organ transplant recipients is associated with a poor prognosis; of reported cases, the mortality rate is more than 80%.

Prevention

Pregnant women should be advised of the dangers to their unborn children inherent in exposure to rodents.

6. Prion Diseases

ESSENTIALS OF DIAGNOSIS

- Rare in humans.
- Cognitive decline.
- Myoclonic fasciculations, ataxia, visual disturbances, pyramidal and extrapyramidal symptoms.
- Variant form presents in younger persons with prominent psychiatric or sensory symptoms.
- Specific EEG patterns.

General Considerations

The transmissible spongiform encephalopathies are a group of fatal neurodegenerative diseases affecting humans and animals. They are caused by proteinaceous infectious particles or prions. These agents show slow replicative capacity and long latent intervals in the host. They induce the conformational change (“misfolding”) of a normal brain protein (prion protein; PrP[C]) into an abnormal isoform (PrP[Sc]) that accumulates and causes neuronal vacuolation (spongiosis), reactive proliferation of astrocytes and microglia, and, in some cases, the deposition of beta-amyloid oligomeric plaques.

Prion disease can be hereditary, sporadic, or transmissible in humans. Hereditary disorders are caused by germ line mutations in the PrP[C] gene causing familial Creutzfeldt–Jakob disease (fCJD), Gerstmann-Sträussler-Scheinker syndrome (GSS), and fatal familial insomnia. Another uncommon hereditary disorder is PrP systemic amyloidosis.

Sporadic Creutzfeldt-Jakob disease (sCJD) is the most common of the human prion diseases, accounting for approximately 85% of cases; it has no known cause. Transmissible prion disease is described only for kuru and Creutzfeldt-Jakob disease in its iatrogenic (iCJD) and variant (vCJD) form. Iatrogenic transmission of CJD is associated with prion contaminated human corneas, dura mater grafts, growth hormone, gonadotropins, stereotactic electroencephalography, electrodes, and neurosurgical instruments. Abnormal prion proteins have been detected in the nasal mucosa and urine of patients with Creutzfeldt-Jakob disease, raising health concerns about possibility of transmission.

Kuru, once prevalent in central New Guinea, is now rare, a decline in prevalence that started after the abandonment of cannibalism in the late 1950s (a protective allele of the PrP gene is now identified at codon 127).

More than 200 cases of vCJD (bovine spongiform encephalopathy [BSE] or “mad cow disease”) were reported in the United Kingdom since the first documented cases there in the mid-1990s. It is far less common in North America, with only four cases reported in the United States (the last one in 2015) and two deaths in Canada from definite or probable vCJD. Of the US-reported cases, none are confirmed to have acquired the disease locally (two of them acquired the infection in the United Kingdom, one in Saudi Arabia, one possibly in a Middle Eastern or Eastern European country). This disease is characterized by its bovine-to-human transmission through ingestion of meat from cattle infected with BSE. There is no animal-to-animal spread of BSE, and milk and its derived products are not considered infectious. Reports of secondary transmission of vCJD due to blood transfusions from asymptomatic donors are reported in the United Kingdom. Although iCJD and vCJD are not associated with a known PrP gene mutation, a polymorphism in codon 129 is prevalent and seems to determine susceptibility and expression of clinical disease.

The overall annual incidence of prion disease worldwide is approximately 1–2/1 million person-years. In the United States, among the 4085 cases reported through September 18, 2018, to the US National Prion Disease Pathology Surveillance Center, 3656 (89.5%) were sporadic, 400 (9.8%) familial, 12 (0.3%) iatrogenic, and 4 (0.1%) vCJD.

A **chronic wasting disease** also due to a transmissible spongiform encephalopathic agent is occurring among deer, elk, and moose and has been reported from 24 states including most of Wyoming and parts of Colorado but present in the East and South as well. Although there are no documented of transmission to humans, the CDC recommends refraining from killing bizarrely acting animals, not handling or eating roadkill, and wearing gloves when dressing wild game. Testing for the virus in game animals may be useful, but its efficacy is not established.

Clinical Findings

A. Symptoms and Signs

Both sCJD and fCJD usually present in the sixth or seventh decade of life, whereas the iCJD form tends to occur in a much younger population. Clinical features of these three forms of disease usually involve mental deterioration (dementia, behavioral changes, loss of cortical function) that is progressive over several months, as well as myoclonus and extrapyramidal (hypokinesia) and cerebellar manifestations (ataxia, dysarthria). Finally, coma ensues, usually associated with an akinetic state and less commonly decerebrate/decorticate posturing. Like iCJD, vCJD usually affects younger patients (averaging ~28 years), but the duration of disease is longer (about 1 year). The degree of organ involvement is often extensive, and the clinical symptoms are unique, mainly characterized by prominent psychiatric and sensory symptoms.

B. Laboratory Findings

CJD should be considered as a diagnosis in the proper clinical scenario, in the absence of alternative diagnoses after routine investigations. Abnormalities in CSF are subtle and rarely helpful. The detection of 14-3-3 protein in the CSF is helpful for the diagnosis of sCJD but not in vCJD and fCJD. Its sensitivity and specificity are widely variable among different studies and may be increased with use of tau protein assays. CSF detection of total PrP can differentiate CJD from atypical Alzheimer disease with 82% sensitivity and 91% specificity.

A blood-based assay and PCR in CSF may help with the diagnosis of vCJD with high specificity but 71% sensitivity. The assay as well as 14-3-3 protein assay and a “quaking induced conversion” assay are all available through the National Prion Disease Surveillance Center at Case Western University in Cleveland. Other referral laboratories with variable availability of assays include state health departments, academic centers, and the National Prion Clinics in the United Kingdom. It is also recognized that the presence of a variant with low titers (“very low peripheral prion colonization”) in peripheral tissue, including frequently biopsied tonsillar tissue, may be responsible for the underrecognition of vCJD.

Probable diagnosis requires the presence of rapidly progressive dementia plus two of four clinical features (myoclonus, visual or cerebellar signs, pyramidal/extrapyramidal signs, and akinetic mutism) as well as a positive laboratory assay (typical EEG, positive 14-3-3 CSF assay with duration under 2 years) and MRI high signal in the caudate and/or putamen on diffusion-weighted imaging (DWI) or fluid-attenuated inversion recovery (FLAIR) imaging. In sCJD, the EEG typically shows a pattern of paroxysms with high voltages and slow waves, while the MRI is characteristic for bilateral areas of increased signal intensity, predominantly in the caudate and putamen. An MRI can improve early diagnosis of sCJD because clinical findings are often missed. When an experienced neuroradiologist or a prion disease expert reviews the MRI, diagnostic sensitivity of MRI for sCJD increases to 91%.

Differential Diagnosis

Autoimmune encephalitis can have a similar clinical picture. The presence of high titer autoantibodies (eg, to the NMDA receptor) in the CSF is consistent with autoimmune encephalitis.

Treatment & Prevention

There is no specific treatment for CJD. Once symptoms appear, the infection invariably leads to death. Flupirtine (an analgesic drug) is sometimes useful in slowing the associated cognitive decline but does not affect survival. Quinacrine (mepacrine) was evaluated as an oral treatment option but was not shown to improve survival for people with sCJD. Antibodies against PrP is also proposed as a therapeutic strategy. Studies are in progress to identify epitopes for vaccine development, but no promising candidates exist to date.

Iatrogenic CJD can be prevented by limiting patient exposure to potentially infectious sources as mentioned above. Prevention of vCJD relies on monitoring livestock for possible infection. The American Red Cross does not accept blood donations from persons with a family history of CJD or with a history of dural grafts or pituitary-derived growth hormone injections.

An international referral and database for CJD is available at http://www.cjdsurveillance.com.

Reference centers are available at Case Western Reserve University in the United States and the University College London Hospitals in the United Kingdom.

7. Progressive Multifocal Leukoencephalopathy (PML)

PML is a rare demyelinating CNS disorder caused by the reactivation of the JC virus (John Cunningham virus or JCV). This polyomavirus usually causes its primary infection during childhood with about 80% of adults typically being seropositive. The virus remains latent in the kidneys, lymphoid tissues, epithelial cells, peripheral blood leukocytes, bone marrow, and possibly brain until reactivation occurs and symptoms become evident. This reactivation is usually seen in adults with impaired cell-mediated immunity, especially AIDS patients (5–10% of whom develop PML), as well as those with idiopathic CD4 lymphopenia syndrome. It is also reported among those with lymphoproliferative and myeloproliferative disorders; in those with granulomatous, inflammatory, and rheumatic diseases (systemic lupus erythematosus and rheumatoid arthritis in particular); in those who have undergone solid and hematopoietic cell transplantation; and occasionally in those who have other medical states, including cirrhosis and kidney disease.

Diagnostic criteria that use clinical, imaging, pathologic, and virologic manifestations of JCV are available from the American Academy of Neurology.

Medication-associated PML is described with the use of natalizumab, rituximab, infliximab (one case), azathioprine with corticosteroids (one case), and mycophenolate mofetil. Natalizumab, a monoclonal antibody used in the treatment of multiple sclerosis, is associated with the risk of PML developing in 4 per 1000 treated patients, with the rate increasing with duration of therapy. The risk of clinical PML appears to increase up to 36 months of therapy and levels off thereafter. The mean interval between use of the drug to the diagnosis of PML is 5.5 months. The virus is detected in the CSF of up to one-half of all patients treated with natalizumab. An immune reconstitution inflammatory state (IRIS) may follow cessation of natalizumab or other monoclonal antibody therapy, although the JCV presence and the residual neurologic deficits may not clear for years after therapy is stopped. The risk of developing PML associated with rituximab is at least 1 in 25,000 exposed patients with cases reported in various autoimmune conditions treated with rituximab (systemic lupus erythematosus, rheumatoid arthritis, multiple sclerosis). Although the exact relationship between latent JCV and frank PML remains unclear, higher JC viral loads are detected among patients who are immunosuppressed and among those who have HIV infection with lower CD4 counts.

Smoking is reportedly associated with an increased risk of PML.

Clinical Findings

A. Symptoms and Signs

JCV causes lytic infection of oligodendrocytes in the white matter and symptoms presenting subacutely reflect the diverse areas of CNS involvement. Symptoms include altered mental status, aphasia, ataxia, hemiparesis or hemiplegia, and visual field disturbances. Seizures occur in about 18%. Involvement of cranial nerves and the cervical spine is rare.

B. Laboratory Findings

Quantitative PCR for JCV in CSF is used for diagnosis in patients with compatible clinical and radiologic findings. Persistent JC viremia and increasing urinary JCV DNA may be predictive of PML. An anti-JCV IgG was higher 6 months before diagnosis but was not predictive of PML in a cohort of HIV-infected persons.

MRI of the brain shows multifocal areas of white matter demyelination without mass effect or, usually, contrast enhancement. These findings may not be distinguishable from IRIS. Increased uptake of methionine with concomitant decreased uptake of fluorodeoxyglucose in positron emission tomography may be helpful for diagnosis. In HIV-infected patients, a syndrome of cerebellar degeneration is described.

Treatment & Prevention

Limiting the immunosuppressed state without inducing an IRIS represents the mainstay of therapy for PML. Treatment of HIV with ART reduces the incidence of PML, improves the clinical symptoms, reverses some of the radiographic abnormalities, and improves the 1-year mortality rate, regardless of baseline CD4 count. Immune recovery can induce worsening of the clinical picture in a small number of cases. Immune reconstitution syndromes do not alter mortality but are associated with a form of PML called non-determined leukoencephalopathy associated with a chemokine polymorphism. Significant neurologic sequelae to PML infections are the rule and deficits may persist for years.

Decreasing immunosuppression in non-AIDS patients with PML (eg, multiple sclerosis or transplant patients) is also important. Cidofovir may be beneficial in non–AIDS-related cases, while corticosteroids may be useful with immune reconstitution. Because the JCV infects cells through serotonin receptors, some clinicians recommend the use of risperidone and mirtazapine. Anecdotal reports show that premature stopping of natalizumab in multiple sclerosis may itself lead to IRIS states. Plasma exchange, which theoretically reduces the plasma level of agents associated with PML, may be useful in natalizumab-associated PML but is associated with a high risk of IRIS. In kidney transplant patients, a preinduction regimen with IVIG and rituximab and transplantation with lymphocyte- depleted cells appears to reduce the risk of PML. Similarly, titers of JC antibody are not shown to significantly increase prior to clinical onset of PML.

8. Human T-Cell Lymphotropic Virus (HTLV)

HTLV-1 and -2 are retroviruses that infect CD4 and CD8 T cells, respectively, where they persist as a lifelong latent infection. HTLV-1 currently infects approximately 20 million individuals worldwide. It is endemic to many regions in the world including southern Japan, the Caribbean, much of sub-Saharan Africa, South America, Eastern Europe, and Oceania. The Caribbean basin and southwestern Japan show the highest prevalence of infection (4–37%). Conversely, HTLV-2 is mainly found in native populations of South (1–58%), Central (8–10%), and North America (2–13%) as well as African pygmy tribes. In some areas of Africa (eg, Malawi), HTLV-2 seroprevalence is higher than HTLV-1 seroprevalence.

In the United States, studies done in blood donors show a seroprevalence of HTLV-1 of 0.005% and HTLV-2 of 0.014%, a decline since the early 1990s. The virus is transmitted horizontally (sex), vertically (intrauterine, peripartum, and prolonged breastfeeding), and parenterally (injection drug use and blood transfusion). Hence, a higher prevalence is seen among injection drug users. Coinfection with HIV-1 occurs but is often underrecognized. Transmission via organ transplant has been reported. Disease may flare when biologic agents are used for rheumatoid conditions.

Clinical Findings

A. Symptoms and Signs

HTLV-1 infection is associated with HTLV-1 adult T-cell lymphoma/leukemia (ATL) and HTLV-1 associated myelopathy/tropical spastic paraparesis (HAM/TSP). In contrast, HTLV-2 is significantly less pathogenic, with few reported cases of HAM/TSP as well as other neurologic manifestations. The causative association of HTLV-1 with ATL, attributed to the virally encoded oncoprotein tax, is well established. The lifetime risk of developing ATL among seropositive persons is estimated to be 3% in women and 7% in men, with an incubation period of at least 15 years. The mean age at diagnosis of ATL is 40–50 years in Central and South America and 60 years in Japan.

ATL clinical syndromes may be classified as chronic, acute (leukemic), smoldering, or lymphomatous. A primary cutaneous tumor is also described and shows a worse prognosis compared with the smoldering type. Clinical features of ATL include diffuse lymphadenopathy, maculopapular skin lesions that may evolve into erythroderma, a bronchoalveolar disorder, organomegaly, lytic bone lesions, and hypercalcemia. Opportunistic infections, such as P jirovecii pneumonia and cryptococcal meningitis, are common.

HAM/TSP, associated with both HTLV-1 and HTLV-2, develops in 0.3–4% of seropositive individuals and is more common in women and in older individuals. A chronic inflammation of the spinal cord leads to intense and progressive motor weakness and symmetric spastic paraparesis, bilateral facial palsies, falls, nociceptive low back pain, and paraplegia with hyperreflexia. Bladder and sexual disorders (eg, dyspareunia, erectile dysfunction), sensory disturbances, and constipation are also common. Both viruses can also induce motor abnormalities, such as leg weakness, impaired tandem walk, and vibration sense, without overt HTLV-associated myelopathy.

HTLV-1 seropositivity is associated with an increased risk of tuberculosis, Strongyloides stercoralis hyperinfection, crusted scabies, and infective dermatitis. Inflammatory states associated with HTLV-1 infection include arthropathy, recurrent facial palsies, polymyositis, uveitis, and sicca, but inconsistently Sjögren syndrome, vasculitis, cryoglobulinemia, infiltrative pneumonitis, and ichthyosis. Bronchioloalveolar carcinoma is increased in frequency in the presence of HTLV-1.

HTLV-2 appears to cause a myelopathy that is milder and slower to progress than HAM. All-cause and cancer mortality are higher among HTLV-2 seropositive patients.

HTLV-1/HIV coinfection is associated both with higher CD4 counts and a higher risk of HAM.

B. Laboratory Findings

The peripheral smear can show atypical lymphoid cells with basophilic cytoplasm and convoluted nuclei (flower cells) but the diagnostic standard is evidence of clonal integration of the proviral DNA genome into tumor cell. The identification of HTLV-1 antibodies supports the diagnosis. Serum neopterin levels may indicate disease activity. An HTLV-1 provirus load in peripheral blood mononuclear cells and CSF cells and an HTLV-1 mRNA load are proposed as markers of HAM risk and progression. HTLV positivity is associated with erythrocytosis, lymphocytosis (HTLV-2), and thrombocytosis (HTLV-1).

Treatment, Prevention, & Prognosis

No vaccine or antiviral therapy currently exists for the prevention and treatment of HTLV infections.

Management of ATL consists mainly of chemotherapy, with allogeneic stem cell transplantation and the use of monoclonal antibodies (anti-CCR4 and anti-CD25). A chemotherapy regimen in Japan using eight different agents shows a higher response rate than traditional biweekly CHOP (40% vs 25%). Combination therapy with interferon-alpha has been used with success. Nivolumab is being studied as a novel therapy. Prophylaxis against infections is needed in ATL because patients show a profound immunodeficiency. Patients who are coinfected with HIV-1 and HTLV reportedly do respond to ART for HIV.

HAM is treated with a variety of immune-modulating agents (including corticosteroids) without consistent results. Combination therapy with antiretrovirals does not show benefit, although several trials evaluating raltegravir alone or in combination with zidovudine are underway. Interferon-alpha may be of some efficacy. A significant response is reported with the combined regimen of prednisolone, pegylated interferon, and sodium valproate. Clinical trials also are currently underway to assess the efficacy of pentoxifylline, cyclosporine, and the retinoid tamibarotene in the treatment of HAM. Small, uncontrolled studies suggest plasmapheresis results in improvement in gait and sensory disturbance among some patients and improvement in muscle pain with pulsed methylprednisolone. In general, however, no agent is effective.

Screening of the blood supply for HTLV-1 is required in the United States. There is significant cross-reactivity between HTLV-1 and HTLV-2 by serologic studies, but PCR can distinguish the two. Improved assays to screen organ donors for HTLV-1 and -2 infections are needed, although such screening is not currently required.

Boostani R et al. Triple therapy with prednisolone, pegylated interferon and sodium valproate improves clinical outcome and reduces human T-cell leukemia virus type 1 (HTLV-1) proviral load, tax and HBZ mRNA expression in patients with HTLV-1-associated myelopathy/tropical spastic paraparesis. VIRAL HEMORRHAGIC FEVERS

1. Ebola Viral Disease (EVD)

ESSENTIALS OF DIAGNOSIS

- **Early stage EVD:** a nonspecific febrile illness.
- **Later stage EVD:** severe gastrointestinal symptoms, then neurologic symptoms and hypovolemic shock.
- Hemorrhagic manifestations are late mani-festations.
- Uveitis is a prominent ocular finding.
- Travel and contact history from an Ebola-affected country raise suspicion.
- Virus is detected with a real-time RT-PCR.

General Considerations

Genus Ebolavirus is a single-stranded RNA virus in the Filoviridae family. Four different species of Ebolavirus have been identified to cause human disease. Fruit bats are possible reservoir for Ebolavirus. Zoonotic transmission to humans occurs via contact with the reservoir or an infected primate. Ebolavirus can continue to be transmitted among humans who have direct contact with infected body fluids. To acquire EVD, the virus must enter the body via mucous membranes, nonintact skin, sexual intercourse, breastfeeding, or needlesticks. Traditional burial practices in Africa (which entail considerable contact with the corpse) and unprotected direct care of persons with EVD are associated with highest transmission risk. Ebolavirus has been detected in semen up to 9 months after recovery from infection.

EVD has a 2–21-day incubation period. Prior to manifestation of symptoms, Ebolavirus is not transmissible. Even at symptom onset, the risk of transmission is low but increases over time.

The first Ebola outbreak occurred in 1976 as a simultaneous epidemic in the Democratic Republic of Congo and South Sudan. Subsequent outbreaks were confined to the Democratic Republic of Congo, Uganda, and Sudan until March 2014 when the first Ebola case in West Africa was identified in Guinea. Zaire ebolavirus was the associated species. This Ebola outbreak grew to be larger than all prior Ebola outbreaks combined. The number of EVD cases spread rapidly; there were at least 10 affected countries, especially Guinea, Liberia, and Sierra Leone. Many cases and deaths in these countries occurred among healthcare workers. In the United States, 11 persons were treated for Ebola. Most were healthcare workers who were evacuated to the United States and 4 patients were diagnosed in the United States. Sierra Leone contained its last EVD outbreak as of March 2016. Guinea was declared free of EVD transmission in June 2016. Liberia declared the end of its last outbreak in June 2016. The WHO reports that the West African Ebola outbreak was associated with 28,616 cases and 11,310 deaths during the approximately 2-year interval of the outbreak between March 2014 and March 2016.

Two outbreaks were reported in May and August of 2018, both in the Democratic Republic of Congo (where outbreaks also were reported in 2014 and 2017), and while the isolates from the two outbreaks were both the same species, complete genetic homogeneity between the isolates was not present. As of December 11, 2018, 505 probable and confirmed cases (and 296 deaths) were reported from 12 health zones in the two provinces of the Democratic Republic of Congo impacted with EVD, including 51 cases (and 17 deaths) among health care workers. In total, 10 outbreaks of Ebola have occurred in Africa since 1976.

Clinical Findings

A. Symptoms and Signs

At symptom onset, early-stage EVD most typically presents as a nonspecific febrile illness. Along with fever, patients tend to experience headache, weakness, dizziness, malaise, fatigue, myalgia, and arthralgia. After 3–5 days, patients with later stage EVD may develop abdominal pain, severe nausea, vomiting, and diarrhea accompanying the febrile illness. This stage of the illness may continue for a week during which time neurologic symptoms gain prominence. Encephalitis is commonly observed and manifested as confusion, slowed cognition, agitation, and occasional seizures. Shock develops in most patients, but hemorrhagic manifestations develop in only 1–5% of patients. Respiratory symptoms are not typical for EVD, although interstitial pneumonia and respiratory failure are reported.

B. Laboratory Findings

During the first few days of symptoms, diagnosis may be made via several modalities, including antigen-capture ELISA, IgM ELISA, RT-PCR, or virus isolation. Blood samples obtained within the first 3 days of illness and tested by RT-PCR should be repeated if results are negative and clinical symptoms and signs persist. RNA levels peak a median of 7 days after illness onset. Later in the disease course or after recovery, IgM and IgG serologic tests may be sent. After about 10 days, IgM antibodies begin to develop, and, after approximately 2 weeks, an IgG antibody response develops. Postmortem diagnosis may be made by using immunohistochemistry, RT-PCR, or virus isolation.

Given that filoviruses infect dendritic cells and then hepatocytes and renal cortical cells, laboratory findings typically include a low platelet count (and a thrombotic thrombocytopenic purpura syndrome has been postulated with the probable cause multifactorial), leukopenia, and transaminitis (aspartate aminotransferase [AST] greater than alanine aminotransferase [ALT]). Additional observed laboratory abnormalities include hypoalbuminemia, electrolytes imbalance, and increased serum creatinine level. Elevated blood urea nitrogen, AST, and creatinine upon presentation are associated with higher mortality.

Differential Diagnosis

The differential diagnosis varies with the stage of illness. Early-stage EVD is commonly mistaken for malaria, typhoid, and other viral illnesses. As gastrointestinal symptoms develop, health providers should also consider viral hepatitis, toxins, leptospirosis, and rickettsial diseases. In later stage EVD, bacterial, viral, and parasitic illnesses, including cholera and, in children, rotavirus infection can present with severe gastroenteritis and shock. Encephalitis must be differentiated from the confusion associated with uremia. Hemorrhagic manifestations raise suspicion for EVD but could be due to leukemia, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, or disseminated intravascular coagulation. Travel and contact history are crucial when considering the differential diagnosis in areas where Ebola is not endemic.

Complications

Hypovolemic shock and multiorgan failure are the most common complications of EVD. Hemorrhage can occur in late stages. Rhabdomyolysis is reported frequently and may explain many of the associated laboratory abnormalities. Coinfections with malaria or bacteria (or both) are important considerations and can occur before presentation and during treatment of EVD. The virus is known to persist in immunologically privileged sites, such as the CNS, eye, and testes; however, viral relapse is uncommon. Post-EVD musculoskeletal pain, headache, auditory symptoms, and ocular symptoms (uveitis being the most common ocular finding) may develop. EVD survivors exhibit high rates of neuropsychological long-term sequelae including depression, anxiety, and posttraumatic stress disorder.

Treatment

Treatment is supportive. Several studies have shown that intravenous fluids can reduce the mortality rates to less than 50%. Despite the wide availability of oral rehydration salts, mortality approximates 70% in endemic areas. In these studies, the amount of intravenous fluid replacement was relatively less than what would be used in countries with developed health systems. Among patients treated in the United States or Europe, almost all received intravenous fluids, electrolyte supplementation, and empiric antibiotic therapy. Invasive or noninvasive mechanical ventilation and continuous renal replacement therapy are necessary in many cases. This increased level of care likely contributed to the decreased mortality (19%) among these patients. The use of individual air-conditioned biosecure cubicles is preferred to the burdensome protective equipment used during the 2014 West African outbreaks and allows for more time spent with patients.

There are no approved medications for the treatment of EVD, although five agents were available for compassionate use in a Congolese EVD outbreak. Administration of convalescent plasma does not result in improved survival. Several drugs have advanced to clinical trials; however, some trials were terminated due to low enrollment or lack of efficacy. The tested monoclonal antibodies were MAb114 (a first-generation agent isolated from a survivor of the 1995 outbreak in the Congo), ZMapp, and REGN-EB3. ZMapp is an antiviral monoclonal antibody combination developed against Zaire ebolavirus. ZMapp showed some therapeutic benefit, but many of these patients received multiple agents and were not part of randomized controlled trials. The PREVAIL II study evaluated ZMapp for treatment of EVD and found it to be safe and well tolerated but failed to establish efficacy due to low enrollment numbers. REGN-EB3 is given as a single dose, does not require freezing, and shows efficacy in nonhuman primates, including reduction in mortality.

The two antivirals utilized in a recent outbreak were the nucleotide analog remdesivir (GS-5734) and the RNA-dependent RNA polymerase inhibitor favipiravir. Mathematical models show a high likelihood of efficacy for both agents against EVD if given within 3–4 days of infection, and the efficacy of remdesivir is theoretically 100% while that of favipiravir is 60%. Both agents are effective in nonhuman primates and one study in man found favipiravir to be effective in patients with low to moderate viremia.

Aside from supportive treatment and experimental therapeutics, patients typically receive empiric antimalarial agents in endemic areas and broad-spectrum antibiotics.

Prognosis

Children under 5 years of age and adults older than 40 have a high risk of death from

EVD. Pregnancy is a risk factor for severe illness and death. In the 2014–2016 outbreak, the average maternal mortality was 86%. Immunosuppressed patients had shorter incubation time, rapid progression of disease, and poor outcomes. A higher baseline viral load was strong predictor of mortality. In general, poor overall medical care confers a poor prognosis. Among survivors, protective antibodies persist for at least 10 years.

Prevention

Risk reduction should focus on preventing wildlife to human transmission and reducing human to human transmission by surveillance, early detection and isolation of cases, contact tracing, containment measures (disinfection, hygiene, and sanitation), strict droplet and contact precautions in health care setting, and reduction of sexual transmission in Ebola survivors. The WHO recommends that men avoid sexual activity or use barrier protection during intercourse for 12 months from onset of symptoms or until their semen tests negative twice for Ebola virus.

The experimental recombinant vesicular stomatitis virus (rVSV)-based vaccine expressing Zaire ebolavirus (ZEBOV) glycoprotein is found to be highly effective in disease prevention after 10 days from receiving the vaccine. Side effects, such fever, myalgia, chills, fatigue, headaches, and oligo-arthritis, developed in most of the persons who received the vaccine. A phase III clinical trial to evaluate the safety and immunogenicity of rVSV-ZEBOV has shown promising results (most study participants have persistent antibody levels at 1 year; NCT02503202). A chimpanzee type 3 adenovirus vector vaccine is also under evaluation (NCT03140774). More than 12,000 persons were vaccinated with the glycoprotein vaccine in the most recent Congolese outbreak. Final efficacy data for this and the earlier Equateur outbreaks in the Democratic Republic of Congo are pending.

Risk stratification may be useful in deciding when and to whom to administer antiviral postexposure prophylaxis. A high-risk exposure is defined as penetrating sharps injury from used device or through contaminated gloves or clothing, direct contact with an infected patient (alive or deceased) or their bodily fluids with broken skin or mucous membranes such as eyes, nose, or mouth. The ZEBOV vaccine was used in the setting of postexposure prophylaxis among healthcare workers and found to be effective, but the evidence is limited to case series. In addition, the vaccine designed against Zaire ebolavirus might not be effective for infection with other species. The vaccine-mediated immunity requires an average of 10 days to develop and might not be fast enough in certain cases to prevent infection.

Current studies focus on isolation of cross-reactive monoclonal antibodies across Ebola virus species. The use of different preparations of combination monoclonal antibodies (ZMapp and MIL-77E) as postexposure prophylaxis during the West African outbreak failed to show statistical significance, and the conclusion was that the benefit was modest, at best. Newer forms of monoclonal antibodies include virus-like particles (VLP), mucin-deleted glycoproteins, and bispecific binding proteins (which bind Ebola proteins as well as those of related viruses such as the Sudan virus). The use of antiviral agents in postexposure prophylaxis is another alternative that, to date, also shows no clear survival benefit. The agent brincidofovir, for example, was not studied further because of inadequate sample size in Liberia.

When to Admit

Persons living in or returning from a country with high rates of Ebola transmission should be monitored for 21 days and admitted to a health care facility when symptoms meeting the WHO case definition of a suspected EVD case develop, in accordance with the screening protocol designated by the respective country’s governmental health decision-making body.

2. Other Hemorrhagic Fevers

This diverse group of illnesses results from infection with one of several single-stranded RNA viruses (members of the families Arenaviridae, Bunyaviridae, Filoviridae, and Flaviviridae). Flaviviruses, such as the pathogens causing dengue and yellow fever, and Filoviridae, causing EVD, are discussed in separate sections.

Lassa fever is a rodent-associated disease caused by an Old-World arenavirus. Rodents shed the virus in urine and droppings and transmit the virus to humans either by direct contact with these materials, ingestion, or inhalation of aerosolized particles. Lassa fever is mostly endemic in West Africa. Other arenaviruses include the Junin virus (cause of Argentinian hemorrhagic fever) and the Lujo virus. Lujo virus was first described in 2008 in Zambia where it caused a small cluster of nosocomial infections.

The bunyaviruses include hantaviruses (discussed separately). **Crimean Congo hemorrhagic fever** (CCHF) is a disease transmitted from ticks and livestock. Human-to-human transmission can occur in the community or hospital setting by contact with infected body secretions. The geographic distribution is widespread with cases reported from Africa, Asia, the Middle East, and Eastern Europe, with increased incidence recently in the East Mediterranean region. Butchers and slaughterhouse workers in southeastern Iran are at high risk for infection with the CCHF pathogen. Turkey reported the largest outbreak yet in 2002, with nearly 10,000 recorded cases.

Rift Valley fever is transmitted from livestock animals, infected mosquitoes, and flies. To date, there is no human-to-human transmission. Risk factors for acquiring Rift Valley fever include working with abortive animal tissue; slaughtering, skinning, or sheltering animals; and drinking unpasteurized milk. Rift Valley fever causes outbreaks in Africa, Madagascar, and the Arabian Peninsula.

A new bunyavirus, a phlebovirus, was identified in 2010 in central and northeastern China and was named for its symptoms: **severe fever with thrombocytopenia syndrome (SFTS)** virus. STFS is transmitted by tick bite (Ixodidae family, including the newly discovered tick Haemaphysalis longicornis, which is found in Asia as well as among animals [rarely humans] in the eastern United States). It may also be transmitted between humans through direct contact with infected blood or secretions. Another virus (**Heartland virus**), identified in the United States, is similar to the SFTS virus. Transmission occurs via the Lone Star tick (Amblyomma americanum). The virus appears to be amplified in deer and raccoons. In the United States, most cases are reported from the Midwest and southern states.

Clinical Findings

A. Symptoms and Signs

The incubation period varies between species, ranging from 2 to 21 days. The clinical symptoms in the early phase of a viral hemorrhagic fever are indistinguishable from other viral illnesses. Due to lack of specific symptoms on presentation, viral hemorrhagic fevers are an important cause to consider in fever of unknown origin in children in endemic areas. The late phase is more specific and is characterized by organ failure, altered mental status, and hemorrhage. Exanthems and mucosal lesions can occur.

In advanced stages, significant edema, pleural effusion, and fewer hemorrhagic manifestations compared with EVD can develop in patients with Lassa fever and Lujo virus infection. Hearing loss in various degrees is the most common complication of Lassa fever infection. Mortality in pregnant patients during the third trimester and fetal mortality are very high.

CCHF has more prominent hemorrhagic manifestations. Patients have red eyes, flushed face, red throat, and petechiae that progress to severe uncontrollable bleeding. Severe headaches are common in CCHF and correlate with the severity of vascular damage, vasodilatation, and cytokine release.

Rift Valley fever disease can present with three distinct syndromes: (1) ocular disease; retinitis is the most common complication and permanent vision loss develops in 1–10% of patients; (2) meningoencephalitis occurs in less than 1% of cases; these patients have headache, coma, or seizures 1–4 weeks after initial symptoms and a low mortality but a high morbidity with neurologic deficits that can be severe; and (3) a hemorrhagic fever form in which patients present 2–4 days after illness and show evidence of severe liver impairment and later hemorrhages; the hemorrhagic state occurs in less than 1% of patients, but the case-fatality ratio of such patients reaches about 50%.

B. Laboratory Findings

Laboratory features usually include thrombocytopenia, leukopenia (although with Lassa fever leukocytosis is noted), anemia, elevated liver biochemical tests, and abnormalities consistent with disseminated intravascular coagulation.

Special care should be taken for handling clinical specimens of suspected cases. Laboratory personnel should be warned about the diagnostic suspicion, and the CDC must be contacted for guidance. The diagnosis may be made by antigen detection (by ELISA), culture of the virus (the “gold standard” for Lassa virus diagnosis), PCR, or demonstration of a fourfold rise in antibody titer. CCHF is best diagnosed with an IgM serology, although IgG ELISA or immunofluorescence and quantitative RT-PCR are nearly as effective. Isolation of the viruses in culture requires a biosafety level 4 laboratory. Serologic assays are attendant with early false-negative and late false-positive assays.

Differential Diagnosis

The differential diagnosis for hemorrhagic fever includes meningococcemia or other septicemias, Rocky Mountain spotted fever, dengue, typhoid fever, and malaria. SFTS differential diagnosis includes anaplasmosis, hemorrhagic fever with renal syndrome, or leptospirosis. The likelihood of acquiring hemorrhagic fevers among travelers is low.

Treatment & Prevention

Patients should be placed in private rooms with standard contact and droplet precautions. Barrier precautions to prevent contamination of skin or mucous membranes should also be adopted by the caring personnel. Airborne precautions should be considered in patients with significant pulmonary involvement or undergoing procedures that stimulate cough.

Supportive care is the mainstay of therapy. There is no approved antiviral medication, but ribavirin is shown to be effective in vitro and in vivo against certain viruses (Lassa virus, CCHF, and Rift Valley fever pathogens). Early diagnosis and management can reduce mortality.

The efficacy for postexposure ribavirin in the management of Lassa fever, other arenaviruses, or CCHF remains anecdotal. The antitrypanosomal agent suramin may be effective against the Rift Valley fever virus. Sorafenib, a tyrosine kinase inhibitor approved for treatment of renal cell and hepatocellular carcinoma, has antiviral activity against Rift Valley fever virus. A combination of monoclonal antibodies that cross-react with the glycoproteins of Lassa virus have been tested in macaques with promising results.

An inactivated vaccine is available for Rift Valley fever but is not licensed and is not commercially available. There are no vaccines approved for other viruses causing viral hemorrhagic fever. A DNA vaccine against CCHF is developed and shows high humoral immune responses with significant protection in mouse models. A vaccine is also under development in Argentina for Argentinian hemorrhagic fever.

When to Admit

- Persons with symptoms of any hemorrhagic fever and who have been in possible endemic area should be isolated for diagnosis and symptomatic treatment.
- Isolation is particularly important because diseases due to some of these agents, such as Lassa virus, are highly transmissible to health care workers.

3. Dengue

ESSENTIALS OF DIAGNOSIS

- Incubation period 7–10 days.
- Sudden onset of high fever, chills, severe myalgias and arthralgias, headache, and retroorbital pain.
- Severe dengue is defined by the presence of plasma leakage, hemorrhage, or organ involvement.
- Signs of hemorrhage such as ecchymoses, gastrointestinal bleeding, and epistaxis appear later in the disease.

General Considerations

Dengue virus belongs to the genus Flavivirus and has four distinct serotypes that can cause infection. Infection with one serotype does not confer immunity to the other serotypes. Dengue is transmitted primarily from human to human by the bite of the Aedes mosquito. Healthcare-associated transmission (needlestick or mucocutaneous exposure) and vertical transmission occur rarely. WHO reports that dengue is currently endemic in 128 countries, mostly in tropical and subtropical regions with 3.9 billion persons at risk for infection. An estimated 390 million cases of dengue fever occur annually (with 96 million manifesting clinical disease including at least 500,000 with severe disease and up to 20,000 deaths). The surge of cases is associated with climatic factors, travel, and urbanization. Thus, along with malaria, dengue is one of the two most common vector-borne diseases of humans. Dengue is also the second overall cause of a febrile illness (after malaria and excluding common upper respiratory viral infections) in travelers returning from developing countries.

There are several factors that contribute to intermittent outbreaks in these regions, including the season of the year when rainfall is optimal for mosquito breeding, presence of a large population with no previous immunity to the specific serotype, and frequent contact between people and the vector.

In the United States, even though dengue is endemic in Northern Mexico and the Aedes mosquito is common in the southern states, outbreaks are uncommon. Most cases occur in travelers, immigrants, or inhabitants of US territories that are endemic to the dengue virus. Puerto Rico experiences periodic large outbreaks. In 2015 and 2016, an outbreak of locally acquired cases of dengue fever was reported from Hawaii where 264 dengue patients were identified with 46 (17.4%) of the cases among children; all cases were serotype 1.

The incubation period is usually 7–10 days. When the virus is introduced into susceptible populations, usually by viremic travelers from endemic countries, epidemic attack rates range from 50% to 70%.

Clinical Findings

A. Symptoms and Signs

A history of travel to a dengue-endemic area within 14 days of symptom onset is helpful in establishing a diagnosis. Most infected patients are asymptomatic. Only 20% develop symptoms ranging from mild disease (dengue fever) to severe hemorrhagic fever to fatal shock (dengue shock syndrome). In 2009, the WHO classified dengue as the following: dengue without warning signs; dengue with warning signs; and severe dengue.

After the incubation period, the febrile phase begins abruptly with nonspecific symptoms, high fever, chills, facial flushing, malaise, retroorbital eye pain, generalized body pain, and arthralgia. Some patients might have maculopapular rash, sore throat, and conjunctival injection. Not all patients have all symptoms or fever. Mild hemorrhagic manifestations can be seen. Most of the patients will recover, and fever is usually cleared by day 8.

A subset of patients, especially those with suboptimally controlled type 2 diabetes, may progress to severe dengue, which is defined by the presence of plasma leakage, hemorrhage, or organ involvement. Hematocrit drop may be the earliest sign and an indicator of the severity of plasma leakage. Pleural effusion and ascites can develop and may be detected by lateral decubitus chest radiograph or ultrasound before clinical detection. Increasing liver size, persistent vomiting, and severe abdominal pain are indications of plasma leakage. Signs of hemorrhage such as ecchymoses, gastrointestinal bleeding, and epistaxis appear. Severe organ involvement may develop, such as hepatitis, encephalitis, and myocarditis.

Shock develops in patients when a critical volume of plasma is lost through leakage. Decrease in the level of consciousness, hypothermia, hypoperfusion resulting in metabolic acidosis, progressive organ impairment, and disseminated intravascular coagulation leading to severe hemorrhage should raise concern for shock. Acute kidney injury in dengue largely occurs with shock syndrome and shows a high mortality.

B. Laboratory Findings

Leukopenia is characteristic, and elevated transaminases are found frequently in dengue fever. Thrombocytopenia, fibrinolysis, and hemoconcentration occur more often in the hemorrhagic form of the disease. In other forms of disease, especially in children, anemia is more common. The erythrocyte sedimentation rate (ESR) is often normal in most cases.

The nonspecific nature of the illness mandates laboratory verification for diagnosis, usually with IgM and IgG ELISAs after the febrile phase. Virus is recovered from the blood by PCR or detection of the specific viral protein NS1 by ELISA during the first few days of infection. Immunohistochemistry for antigen detection in tissue samples and dried blood spots can also be used. Thrombocytopenia in remote settings can be assessed with a tourniquet cuff test.

Differential Diagnosis

Distinguishing between dengue and other causes of febrile illness in endemic areas is difficult. Fevers due to dengue are more often associated with neutropenia and thrombocytopenia and with myalgias, arthralgias/arthritis, and lethargy among adults. Chikungunya is more apt to develop a chronic arthritis. The arboviral encephalitides require additional epidemiologic information and serologic data to make the diagnosis. Influenza and malaria are easily confused early in disease, although the rhinitis and malaise should help distinguish influenza, and the cyclicity of fevers and presence of splenomegaly should suggest malaria.

Complications

Usual complications include pneumonia, bone marrow failure, hepatitis, iritis, retinal hemorrhages and maculopathy, orchitis, and oophoritis. Neurologic complications (such as encephalitis, Guillain-Barré syndrome, phrenic neuropathy, subdural hematoma, cerebral vasculitis, and transverse myelitis) are less common. Acute disseminated encephalomyelitis has been linked with infection and vaccination. Bacterial superinfection can occur. Oral complications include acute gingivitis, palatal bleeding, tongue plaques, xerostomia, and rarely osteonecrosis of the jaw.

Maternal infection poses a risk of hemorrhage in both the mother and the infant if infection occurs near term. Severe dengue is a risk factor for obstetric complications, cesarean delivery, fetal distress, and maternal morbidity

Treatment

There are no specific therapeutic options for the clinical management of dengue besides supportive care. Treatment entails the appropriate use of volume replacement, blood products, and vasopressors. Acetaminophen is recommended for analgesic and antipyretic treatment. NSAID usage should be minimized and preferably avoided to decrease the risk of gastritis and bleeding, particularly in patients with a predilection for hemorrhage or when there are abnormalities in platelet, liver function, or clotting factors.

Platelet counts do not usefully predict clinically significant bleeding. Platelet transfusions may be considered for severe thrombocytopenia (less than 10,000/mcL) or when there is evidence of bleeding. However, benefit in the absence of bleeding may not be observed, and harm may be caused by delay in count recovery. Monitoring vital signs and blood volume may help in anticipating the complications of dengue hemorrhagic fever or shock syndrome.

Repurposed drugs, such as chloroquine, statins, and balapiravir, are being explored for the treatment of dengue, although none has shown clear therapeutic benefit. New research is focusing on monoclonal antibodies as a therapeutic option as well as drugs including peptide agents that target structural and nonstructural proteins of dengue virus essential to its replication.

Prognosis

Although fatalities occur with severe disease, the estimated mortality (2.5% of severe cases) appears to be diminishing, likely due to improved recognition of the disease and wider availability of supportive treatment. Causes of death include hemorrhagic fever (seen with recurrent disease) and occasionally fulminant hepatitis. Thrombocytopenia and acute hepatitis are predictors of severe dengue and higher mortality. Acute kidney injury in dengue shock syndrome portends poor prognosis. In general, the more advanced forms of disease (hemorrhagic fever and shock) occur more often in Asia than in Americas. Comorbidities of cardiovascular disease, diabetes, stroke, pulmonary disease, kidney disease, and older age are associated with more severe dengue.

Prevention

Preventive measures should be encouraged, such as control of mosquitoes by screening and insect repellents including long-lasting insecticides, particularly during early morning and late afternoon exposures. Screening blood transfusions for dengue is of increasing importance, especially in endemic areas.

Dengvaxia, a recombinant, live, attenuated, tetravalent dengue vaccine (CYD-TDV), is the first vaccine to be approved and is now licensed for use by 19 regulatory authorities. Trials evaluating the efficacy of this vaccine reported overall 60% efficacy; however, efficacy was lower in younger age groups, seronegative individuals at the time of vaccination, and those infected with dengue serotype 2. The vaccine is given as a 0-, 6-, and 12-month series. Serious side effects were no more common than in placebo recipients. Vaccination is indicated for those between ages 9 and 45 years. Some investigators recommend limiting the vaccine to those who have prior exposure because of immune enhancement, and recommend community vaccination only when serosurveys document seropositivity levels of at least 70%. Pregnant women and immunosuppressed persons should not be vaccinated.

4. Hantaviruses

ESSENTIALS OF DIAGNOSIS

- Transmitted by rodents and cause two clinical syndromes.
- **Hemorrhagic fever with renal syndrome (HFRS):** mild to severe illness.
- **Hantavirus pulmonary syndrome (HPS):** 40% mortality rate.

General Considerations

Hantaviruses are enveloped RNA bunyaviruses naturally hosted in rodents, moles, and shrews. Hantavirus infection in humans can cause several disease syndromes. HFRS is primarily caused by Dobrava-Belgrade virus, Puumala virus, Seoul virus, and Hantaan virus in Asia and Europe; these viruses are called Old World hantaviruses. Nephropathia epidemica is a milder form of HFRS. Puumala virus is the most prevalent pathogen and is present throughout Europe. The HPS, also known as hantavirus cardiopulmonary syndrome, is caused mainly by Sin Nombre virus and Andes virus, the New World Hantaviruses in Americas. While they share many clinical features, a specific strain is not associated with a specific syndrome and overlap is seen between the syndromes.

A total of 728 cases of hantavirus infection were reported between 1993 and January 27, 2017. A total of 33 cases were reported in 2017 and 3 cases were reported in 2018.

Aerosols of virus-contaminated rodent urine and feces are thought to be the main vehicle for transmission to humans. Person-to-person transmission is observed only with the Andes virus. Occupation is the main risk factor for transmission of all hantaviruses: animal trappers, forestry workers, laboratory personnel, farmers, and military personnel are at highest risk. Climate change appears to be impacting the incidence of hantavirus infection mainly through effects on reservoir ecology.

Clinical Findings

A. Symptoms and Signs

Vascular leakage is the hallmark of the disease for both syndromes, with kidneys being the main target with variants associated with HFRS and the lungs with variants associated with HPS.

HFRS manifests as mild, moderate, or severe illness depending on the causative strain. A 2- to 3-week incubation period is followed by a protracted clinical course, typically consisting of five distinct phases: febrile period, hypotension, oliguria, diuresis, and convalescence phase. Various degrees of renal involvement are usually seen, occasionally with frank hemorrhage. Disseminated intravascular coagulation and thromboembolic phenomena are recognized complications. Pulmonary edema is not typically seen but when present usually occurs in the final stages of disease (oliguric and diuretic phase). Encephalitis and pituitary involvement are rare findings with hantavirus infection, although a few cases are reported with Puumala virus. Patients may have persistent hematuria, proteinuria, or hypertension up to 35 months after infection. Smoking appears to exacerbate the viremia with the Puumula variant of HFRS.

The clinical course of HPS is divided into a febrile prodrome, a cardiopulmonary stage, oliguric and diuretic phase, followed by convalescence. A 14- to 17-day incubation period is followed by a prodromal phase, typically lasting 3–6 days, that is associated with myalgia; malaise; abdominal pain along with nausea, vomiting, and diarrhea; headache; chills; and fever of abrupt onset. An ensuing cardiopulmonary phase is characterized by the acute onset of pulmonary edema. In this stage, cough is generally present, abdominal pain and symptoms as above may dominate the clinical presentation, and in severe cases, significant myocardial depression occurs. Acute kidney injury and myositis may occur. Sequelae include neuropsychological impairments in some HPS survivors.

B. Laboratory Findings

Laboratory features include hemoconcentration and elevation in lactate dehydrogenase, serum lactate, and hepatocellular enzymes. Early thrombocytopenia and leukocytosis (as high as 90,000 cells/mcL in HPS) are seen in both HFRS and HPS. In HPS, immunoblasts (activated lymphocytes with plasmacytoid features) can be seen in blood, lungs, kidneys, bone marrow, liver, and spleen.

An indirect fluorescent assay and enzyme immunoassay are available for detection of specific IgM or low-avidity IgG virus-specific antibodies. A quantitative RT-PCR is available; however, the viremia of human hantavirus infections is short-term, and therefore, viral RNA cannot be readily detected in the blood or urine of patients unless for the more readily detected early viremia of the Andes variant.

A plaque reduction neutralization test remains a gold standard serologic assay and distinguishes between the different hantavirus species, although cross reaction between Old and New World viruses exist. This test needs to be performed in a laboratory with appropriate biosafety (level 3).

Differential Diagnosis

The differential diagnosis of the acute febrile syndrome seen with HFRS or early HPS includes scrub typhus, leptospirosis, and dengue. HPS requires differentiation from other respiratory infections caused by such pathogens as Legionella, Chlamydia, and Mycoplasma. Coxsackievirus infection should also be considered in the differential diagnosis.

Treatment

Treatment is mainly supportive. Cardiorespiratory support with vasopressors is frequently needed; extracorporeal membrane oxygenation may be required in severe cases of HPS. Intravenous ribavirin is used in HFRS (Hantaan virus) with some success in decreasing the severity of the kidney injury. Its effectiveness in HPS, however, is not established.

Prevention

Because infection is thought to occur by inhalation of rodent waste, prevention is aimed at eradication of rodents in houses and avoidance of exposure to rodent excreta, including forest service facilities. While inactivated vaccines have been used in the past in Korea and China, there is currently no commercially available vaccine and the WHO does not recommend preventive vaccination.

Prognosis

The outcome is highly variable depending on severity of disease. HPS is a more severe disease than HFRS, with a mortality rate of about 40%. In Sin Nombre virus infections, the persistence of elevated IgG titers correlates with a favorable outcome.

de St Maurice A et al. Exposure characteristics of hantavirus pulmonary syndrome patients, United States, 1993–2015. Emerg Infect Dis. 2017 May;23(5):733–9. [PMID: 28418312]

Szabó R. Antiviral therapy and prevention against hantavirus infections. Acta Virol. 2017;61(1):3–12. [PMID: 28105849]

5. Yellow Fever

ESSENTIALS OF DIAGNOSIS

- Endemic area exposure: tropical and subtropical South America and Africa.

- Sudden onset of severe headache, aching in legs, and tachycardia.
- Brief (1 day) remission, followed by bradycardia, hypotension, jaundice, hemorrhagic tendency.
- Albuminuria, leukopenia, bilirubinemia.

General Considerations

Yellow fever is a zoonotic flavivirus infection transmitted by Aedes mosquitoes bite. There are three types of transmission cycles: sylvatic (or jungle; humans working or travelling in the forest are bitten by infected mosquitoes), intermediate (most common type of outbreak in Africa; mosquitoes infect both monkeys and people leading to outbreaks in separate villages), and urban (seen in large epidemics; infected mosquitoes transmit the virus from person to person). Elevated temperatures and increased rainfall are major determinants of transmission.

Yellow fever occurs in 47 endemic countries in Africa and in Central and South America. Around 90% of cases reported every year occur in sub-Saharan Africa. Adults and children are equally susceptible, though attack rates are highest among adult males because of their work habits. Modeling data from Africa in 2013 estimates the annual case load is 84,000 to 170,000 annual cases with 29,000 to 60,000 deaths. The number of susceptible vaccinees worldwide is estimated to be between 394 million and 473 million.

Clinical Findings

A. Symptoms and Signs

Most persons have no illness or only mild illness. The incubation period is 3–6 days in persons in whom symptoms develop.

1. Mild form—Symptoms are malaise, headache, fever, retroorbital pain, nausea, vomiting, and photophobia. Relative bradycardia, conjunctival injection, and facial flushing may be present.

2. Severe form—Severe illness develops in about 15%. Initial symptoms are similar to the mild form, but brief fever remission lasting hours to a few days is followed by a "period of intoxication" manifested by fever and relative bradycardia (Faget sign), hypotension, jaundice, hemorrhage (gastrointestinal, nasal, oral), and delirium that may progress to coma.

B. Laboratory Findings

Leukopenia, elevated liver enzymes, and bilirubin can occur. Proteinuria is present and usually disappears completely with recovery. Bleeding dyscrasias with elevated prothrombin and partial thromboplastin times, decreased platelet count, and presence of fibrin-split products, can also occur.

In the early stages of the disease (up to 10 days), diagnosis is confirmed if yellow fever virus RNA is detected by RT-PCR in blood from a person with no history of recent yellow fever vaccination. PCR determinants are now available that distinguish between wild type virus and vaccine-associated strains.

In later stages, serologic diagnosis can be made by using ELISA to measure IgM 3 days after the onset of symptoms; however, yellow fever vaccine and other flaviviruses, including dengue, West Nile, and Zika viruses, may give a false-positive ELISA test result. Thus, the presence of yellow fever virus–specific IgM antibody and negative ELISA panel for other relevant flaviviruses confirm the diagnosis. If ELISA is positive for other flaviviruses, the more specific plaque reduction neutralization assay should be done in reference laboratories, which measures the titer of the neutralizing antibodies in the serum toward the infecting virus.

Differential Diagnosis

It may be difficult to distinguish yellow fever from other viral hepatidites, malaria, leptospirosis, louse-borne relapsing fever, dengue, and other hemorrhagic fevers on clinical evidence alone. Albuminuria is a constant feature in yellow fever patients, and its presence helps differentiate yellow fever from other viral hepatitides. Serologic confirmation is often needed.

Treatment

No specific antiviral therapy is available. Treatment is directed toward symptomatic relief and management of complications.

Prognosis

The mortality rate of the severe form is 20–50%, with death occurring most commonly between the sixth and the tenth days. Convalescence is prolonged, including 1–2 weeks of asthenia. Infection confers lifelong immunity to those who recover.

Prevention

The yellow fever vaccine, which is derived from the live attenuated 17D strain (with substrains 17D-204 and 17DD similar in efficacy and side effects) and currently given as a single dose for a lifetime, is the most effective way to prevent and control disease. A single dose of vaccine in the past was considered to provide lifelong immunity. While the 10-year booster dose is no longer recommended for most people, persistent seropositivity at 8 years post vaccination is only 85%. Thus, at-risk groups with waning immunity and high probability of exposure may consider receiving a second dose of vaccine after 10 years (these groups are listed at https://www.cdc.gov/yellowfever/healthcareproviders/vaccine-info.html).

Yellow fever vaccine is recommended for persons aged over 9 months who are traveling to or living in areas at risk for yellow fever virus transmission. This vaccine should never be given to children under 6 months old due to their higher risk of developing encephalitis related to the vaccine. WHO recommends that all endemic countries should include yellow fever vaccine in their national immunization programs.

The vaccine is contraindicated in persons with severe egg allergies or who are severely immunocompromised, including patients with primary immunodeficiencies, HIV infection with CD4+ count below 200/mcL, thymus disorder with abnormal immune function, malignant neoplasms, transplantation, or immunosuppressive and immunomodulatory therapies. The vaccine should probably not be given to patients over 60 years of age nor should it be given to breastfeeding women. It should be administered at least 24 hours apart from the measles vaccine. Pregnant women should receive the vaccine only if they cannot defer travel to endemic areas (Chapter 30). Clinicians should be aware of rare but frequently fatal vaccine-induced reactions, including anaphylaxis, yellow fever vaccine–associated viscerotropic disease, and yellow fever vaccine–associated neurologic disease.

A 2017 initiative, the Eliminate Yellow Fever program, is composed of 50 organizations and is designed to increase surveillance and control in 40 countries of Africa and the Americas in an attempt to reach a billion at-risk individuals with seroprotection by 2026.

The best personal protective measures are to avoid mosquito bites. If not in an endemic area, the patient should be isolated from mosquitoes to prevent transmission, since blood in the acute phase is potentially infectious.

OTHER SYSTEMIC VIRAL DISEASES

1. Zika Virus

ESSENTIALS OF DIAGNOSIS

- Most infected persons asymptomatically seroconvert.
- Clinical symptoms are akin to those of chikungunya virus infection but with less arthritis.
- Complications include microcephaly and ocular complications in infants born to mothers infected during pregnancy as well as Guillain-Barré.
- There is no effective antiviral or vaccine.

General Considerations

Zika virus is a flavivirus, akin to the viruses that cause dengue fever, Japanese encephalitis, and West Nile infection.

The virus was noted in Africa and Asia during the 1950s–1980s, but first spread beyond those two continents during 2007 when an outbreak occurred in Yap State, Federated States of Micronesia. A large outbreak occurred in French Polynesia in 2013. A smaller outbreak occurred on Easter Island during 2014. The virus then spread to the Western hemisphere and was first noted in northeastern Brazil in 2015. Zika virus then spread rapidly throughout the Americas, including the United States and worldwide http://www.who.int/csr/disease/zika/en/. Despite distinct lineages, Zika virus exists as only one serotype.

Aedes species mosquitoes, particularly Aedes aegypti, are primarily responsible for transmission of Zika virus. The biodistribution of the species largely determines the area of prevalence for Zika virus. Aedes species mosquitoes are found primarily in the southeastern United States, but one species Aedes albopictus (the Asian tiger mosquito known to sequester in tires) may be seen as far north as Pennsylvania and New Jersey. Rarely, a few other mosquito species including Anopheles and Culex may be competent for the Zika virus. Sexual transmission is reported from males and females to partners via vaginal, anal, or oral sex. Vertical transmission from pregnant woman to fetus is prominent. Transmission via platelet transfusion is also reported.

Since the onset of the first reported cases in the United States in 2015, the number of reported Zika cases is over 43,000, with 37,286 symptomatic cases from US territories (largely Puerto Rico) and 5728 cases from US states. The territorial cases are largely locally acquired and the US state cases are largely travel-acquired (with 231 of the 5728 US cases acquired via local transmission and 55 via sexual, bloodborne, or unknown routes). As of October 31, 2018, the US states reported 45 cases, with California (12) and New York (8) having the highest numbers. The number of annual cases is diminishing markedly in the United States with a peak in 2016 of 4897 travel-associated cases and 224 locally acquired cases (Florida, 218; Texas, 6).

Clinical Findings

A. Symptoms and Signs

The incubation period is about 10 days. Symptoms include acute onset fever, maculopapular rash that is usually pruritic, nonpurulent conjunctivitis, and arthralgias, the latter mimicking the symptoms of the chikungunya virus. Rash may outlast the fever but is not always present. Symptoms last up to 7 days. Most infections are asymptomatic. Viral infections most often confused with Zika include dengue and chikungunya virus infections.

B. Laboratory Findings and Diagnostic Studies

The CDC recommends that persons with symptoms of Zika infection be tested if they live in or have traveled recently to an area with active transmission, as well as all pregnant women who have lived in or visited affected regions.

Diagnosis is made by detecting viral RNA or neutralizing antibody, IgM 4 days or more after symptom onset or IgG after 7 days or more. The Trioplex real-time RT-PCR assay, which detects Zika virus, chikungunya virus, and dengue virus RNA, and the Zika MAC-ELISA, which detects Zika virus IgM antibodies, are available in some laboratories. The real-time RT-PCR detects the virus in blood or urine and should be performed within 2 weeks of illness onset. Matched serum and urine specimens should be tested simultaneously. Although not routinely recommended, RT-PCR can be performed on amniotic fluid, CSF, and placental tissue. A positive real-time RT-PCR test definitively makes the diagnosis of Zika virus infection and does not require additional confirmatory testing. A negative test does not exclude the presence of the virus in other tissues and does not rule out infection. Persons with negative tests should undergo further testing for Zika virus IgM antibody and other arboviral infections.

Persons being tested 14 days or more after symptom onset should be tested for IgM and neutralizing antibodies. Asymptomatic pregnant women should be tested for IgM 2 to 12 weeks, and on occasion longer, after travel to an area with Zika activity or if they have had sexual contact with a man with confirmed Zika virus infection. In areas with active Zika transmission, asymptomatic pregnant women should be tested for IgM antibody as part of routine obstetric care. RT-PCR testing is recommended for pregnant women more than 2 weeks after exposure who test positive for Zika IgM antibody. Persistent Zika virus RNA in serum has been reported in pregnancy. The Zika MAC-ELISA can be performed on serum or CSF. Neutralizing antibodies can cross-react with dengue and other flaviviruses, so samples testing positive should be sent to public health laboratories for confirmation. Pregnant women with confirmed or suspected Zika virus infection (positive IgM antibodies not yet confirmed to be due to Zika infection) may be monitored by serial ultrasounds at 3- to 4-week intervals, assessing fetal anatomy and growth. With a declining prevalence of Zika virus infection, positive antibody tests run the risk of more likely being false-positives and thus the need for the outlined assessments exists.

Complications

Two neurologic complications are of particular concern: (1) congenital microcephaly, often associated with brain calcifications and other abnormalities, first noted during the outbreak in Brazil and subsequently recognized to have occurred in French Polynesia as well; and (2) Guillain-Barré syndrome, first noted during the outbreak in French Polynesia. A Brazilian/European meta-analysis shows the rate of Guillain-Barré syndrome to be about 1.32%. Other congenital anomalies, including arthrogryposis among infected fetuses and infants, and spontaneous abortions are also observed. Rare deaths related to Zika virus infection are reported.

Ocular findings in Zika, reported in those congenitally infected, include focal macular pigment mottling, chorioretinal atrophy (especially in the macular area), congenital glaucoma with optical nerve hypoplasia, and optic disk abnormalities.

As with Ebola virus, the Zika virus can persist in semen for months; in the male reproductive tract the prostate gland and the testes are the presumed reservoirs. Persistence does not appear to occur in the female reproductive tract.

Treatment

There are no antivirals approved for treatment of Zika virus. Sofosbuvir, which is FDA-approved to treat hepatitis C, another flavivirus, shows some ability to inhibit Zika replication and infection in vitro and in mice and appears to also be synergistic with interferon-alpha and with interferon-beta. Sofosbuvir also prevents vertical transmission in a mouse model. Aspirin and NSAIDs are avoided during illness caused by the flavivirus dengue because of its propensity to cause hemorrhage. Zika virus infections, however, do not appear to be associated with major hemorrhagic complications.

Prevention

The most effective means is environmental control of mosquitoes and removal of areas where water is stagnant or builds up. Such measures include screens on houses; removal of old tires and debris from endemic areas of infection; and movement toward better living conditions, including air conditioning in impoverished areas. Because of the association between microcephaly and Zika virus infection during pregnancy, pregnant women are advised to avoid travel to areas where Zika virus is circulating (http://www.who.int/csr/disease/zika/information-for-travelers/en/). Guidelines for testing of pregnant women potentially exposed are available through the CDC. Infected individuals should refrain from blood donations for several months.

No approved vaccine against Zika virus exists. Over 40 vaccines are under study globally and 3 have entered clinical trials, including inactivated virus vaccines, VLP, recombinant viral vaccines, and DNA vaccines. Monoclonal antibodies appear to provide some relief.

2. Chikungunya Fever

Chikungunya ("that which bends up" in the Bantu language Kimakonde) fever is an alphavirus infection transmitted to humans by A aegypti and A albopictus and is considered a classic "arthritogenic" virus. The virus originated with two strains, one in West Africa and the other in East/Central/Southern Africa. In 2013, the first autochthonous case of chikungunya reported in the western hemisphere occurred on Saint Martin in the Caribbean, with isolates derivative of the East/Central/South Africa strains. Despite these differences, only one serotype exists.

For 2018, the CDC reports 75 travel-associated cases in 22 states and Puerto Rico (with the largest number of reports from California, New York, New Jersey, and Texas). The territory of Puerto Rico reports the only current locally acquired cases, with five cases as of October 30, 2018. Chikungunya virus prevalence is ubiquitous in endemic countries in Africa, the Americas, Asia, and Europe.

Among naïve populations, attack rates are often as high as 50%. On Saint Martin, 39% of infections were asymptomatic. Vertical transmission is documented if the mother is viremic during parturition, and transmission does not appear to occur throughout pregnancy as it does with Zika virus. Infectious virus was isolated from saliva, although transmission from oral secretions is not observed among humans. Endemicity of A aegypti in the Americas and the introduction of A albopictus into Europe and the New World raise concern for further extension of the epidemic. Case reports show that chikungunya virus may coinfect patients with yellow fever virus, plasmodia, Zika virus, and dengue virus.

Clinical Findings

A. Symptoms and Signs

After an incubation period of 1–12 days (estimated median 3), there is abrupt onset of fever; headache; intestinal complaints, including diarrhea, vomiting, or abdominal pain; myalgias; and arthralgias/arthritis affecting small, large, and axial joints. The simultaneous involvement of more than 10 joints and the presence of tenosynovitis (especially in the wrist) are characteristic. The stooped posture of patients gives the disease its name. Joint symptoms persist for 4 months in 33% and linger for years in about 10%. A centrally distributed pigmented or pruritic maculopapular rash is reported in 10–40% of patients; it can be bullous with sloughing in children. Mucosal disease occurs in about 15%. Facial edema and localized petechiae are reported. Neurologic complications, including encephalitis, myelopathy, peripheral neuropathy, Guillain-Barré syndrome, myeloneuropathy, and myopathy, are usually found in persons younger than 5 or older than 49 years. Encephalitis occurred in 8.6 per 100,000 persons infected in La Réunion during 2005–2006 with 17% mortality and increased risk of encephalitis among those older than 65 years. Hemorrhagic fever–like presentations are unusual. Coinfection with other respiratory viruses and with dengue is common. Some of the neuropathology may be immune-mediated, and these cases are usually in those over age 20 and associated with longer latencies and better outcomes. Death is rare and usually related to underlying comorbidities.

B. Laboratory Findings

Diagnosis is made epidemiologically and clinically. Mild leukopenia occurs as does thrombocytopenia, which is seldom severe. Elevated inflammatory markers do not correlate well with the severity of arthritis. Radiographs of affected joints are normal during the acute phase. Bone lesions are visible in some patients with chronic symptoms.

Serologic confirmation requires elevated IgM titers or fourfold increase in convalescent IgG levels using an ELISA. RT-PCR and ELISA are commercially available; no ELISA kit is FDA-cleared. Culture techniques (viral isolation in insect or mammalian cell lines or by inoculation of mosquitoes or mice) require BSL-3 containment. Directions on submitting specimens for testing may be obtained from the CDC Arboviral Diseases Branch, 970-221-6400. Suspected cases in the United States should be promptly reported to public health authorities. The differential diagnosis includes other tropical febrile diseases, such as malaria, leishmaniasis, or dengue.

Complications & Prognosis

Common complications of chikungunya fever are long-term weakness, asthenia, myalgia, arthralgia, and arthritis, noted to be present in 25–66.5% of cases at 1 year. Risk factors for long-term arthralgias include the existence of such symptoms at 4 months after onset of disease and age over 35 years. Persons with preexisting arthritis are also at increased risk for prolonged symptoms after chikungunya infection with polyarthralgias occasionally lasting for years. Nasal skin necrosis is rarely reported. The Guillain-Barré syndrome is reported from the French West Indies during an outbreak in 2014, and more recently from New Delhi, India. Comorbid conditions, including hypertension, diabetes, and cardiac diseases, may contribute to severe outcomes; although in some series, patients with significant neurologic complications do not show comorbidities. Severe outcomes and higher mortality are reported among more recent Brazilian cases.

Treatment & Prevention

Treatment is supportive with NSAIDs and corticosteroids. Chloroquine may be useful for managing refractory arthritis. Chronic disease may require disease modifying antirheumatic drugs, such as the reports from La Réunion where methotrexate was associated with a positive response. No licensed vaccine exists, although at least 18 vaccines are in trials including inactivated and live attenuated vaccines. At this time, prevention relies on avoidance of mosquito vectors.

3. Colorado Tick Fever

ESSENTIALS OF DIAGNOSIS

- Onset 1–19 days (average, 4 days) following tick bite.
- Fever, chills, myalgia, headache, prostration.
- Leukopenia, thrombocytopenia.
- Second attack of fever after remission lasting 2–3 days.

General Considerations

Colorado tick fever is a reportable biphasic, febrile illness caused by a reovirus infection transmitted by Dermacentor andersoni tick bite. About five cases occur annually, largely among men over age 40. The disease is limited to the western United States and Canada and is most prevalent during the tick season (March to November). There is a discrete history of tick bite or exposure in 90% of cases. The virus infects the marrow erythrocyte precursors. Blood transfusions can be a vehicle of transmission.

Clinical Findings

A. Symptoms and Signs

The incubation period is 3–6 days, rarely as long as 19 days. The onset is usually abrupt with a high fever. Severe myalgia, headache, photophobia, anorexia, nausea and vomiting, and generalized weakness are prominent. Physical findings are limited to an occasional faint rash. The acute symptoms resolve within a week. Remission is followed in 50% of cases by recurrent fever and a full recrudescence lasting 2–4 days. In an occasional case, there may be three bouts of fever.

The differential diagnosis includes influenza, Rocky Mountain spotted fever, numerous other viral infections, and, in the right setting, relapsing fevers.

B. Laboratory Findings

Leukopenia with a shift to the left and atypical lymphocytes occurs, reaching a nadir 5–6 days after the onset of illness. Thrombocytopenia may occur. An RT-PCR assay may be used to detect early viremia. Detection of IgM by capture ELISA or plaque reduction neutralization is possible after 2 weeks from symptom onset and is the most frequently used diagnostic tool.

Complications

Aseptic meningitis (particularly in children), encephalitis, and hemorrhagic fever occur rarely. Malaise may last weeks to months. Fatalities are very uncommon. Rarely, spontaneous abortion or multiple congenital anomalies may complicate Colorado tick fever infection acquired during pregnancy.

Treatment

No specific treatment is available. Ribavirin has shown efficacy in an animal model. Antipyretics are used, although salicylates should be avoided due to potential bleeding with the thrombocytopenia seen in patients with Colorado tick fever.

Prognosis

The disease is usually self-limited and benign.

Prevention

Tick avoidance is the best prevention. The tick season is primarily from March to November, and the ticks mostly live at high altitudes (over 7000 feet) in sagebrush.

COMMON VIRAL RESPIRATORY INFECTIONS

1. Respiratory Syncytial Virus (RSV) & Other Paramyxoviruses

ESSENTIALS OF DIAGNOSIS

- RSV is a major cause of morbidity and mortality at the extremes of age (younger than 5 and older than 65).
- Treatment is largely supportive.
- No active vaccination for RSV is available.

General Considerations

Respiratory syncytial virus (RSV) is a paramyxovirus that causes annual outbreaks during the wintertime with usual onset of pulmonary symptoms between mid-October and early January in the continental United States (excluding Florida). Outside the United States, RSV usually peaks during wet months in areas with high annual precipitation and during cooler months in hot and dry areas. It occurs earlier in urban areas.

There are two major subtypes, A and B, and it appears that the A subtype is associated with disease severity. RSV is the leading cause of hospitalization in US children, with annual hospitalization rates of 6 per 1000 children younger than 5 years. Globally, the annual RSV hospitalization rates are 4 per 1000 children less than 5 years old, 19 among children less than 1 year old, 20 among children less than 6 months old, and 64 among premature children less than 1 year. Prematurity is a major risk factor for severe disease. Early RSV bronchiolitis in children, along with a family history of asthma, are associated with persistence of airway reactivity later in life.

RSV also causes upper and lower respiratory tract infection in adults, with the virus entering through contact with mucous membranes. RSV occurs with increasing severity in those with comorbid conditions, older adults (accounting for a rate of 4 per 1000 hospitalizations and 14,000 deaths annually), persons with severe combined immunodeficiency, and patients after lung or bone marrow transplantation (because CD8 T cells are not available for viral clearance). An interleukin-1 receptor polymorphism is shown to be associated with more severe bronchiolitis. Recurrences occur throughout life. The average incubation period is 5 days. Up to 10% of disease classified as invasive pneumococcal disease is thought to be RSV or influenza.

In immunocompromised patients, such as bone marrow transplant recipients, serious pneumonia can occur, and outbreaks with a high mortality rate (greater than 70%) are reported.

Other paramyxoviruses important in human disease include human metapneumovirus, parainfluenza virus, and Nipah virus.

Human metapneumovirus is a ubiquitous seasonal virus circulating during late winter to early spring. It is divided into subgroups A and B. Metapneumovirus accounted for 7.3% of childhood (younger than 16 years old) pneumonia in a Norwegian series of 3650 patients in which RSV accounted for 28.7%. Clinical presentations range from mild upper respiratory tract infections to severe lower respiratory tract infections (eg, bronchiolitis, croup, and pneumonia). Lower respiratory tract (sometimes severe) infections have been observed among immunocompromised and elderly adults, especially residents of nursing homes. In lung transplant recipients, human metapneumovirus is a common cause of respiratory illness and is thought to increase the risk of acute and chronic graft rejection. Ribavirin appears to be well tolerated in lung transplant recipients with metapneumovirus infection.

Human parainfluenza viruses (HPIVs) are commonly seen in children and are the most common cause of laryngotracheitis (croup). Four different serotypes are described, and they differ in their clinical presentations as well as epidemiology. HPIV-1 and HPIV-2 are responsible for croup. HPIV-3 is associated with bronchiolitis and pneumonia. HPIV-4 is a less frequently reported pathogen. Reinfections are common throughout life. HPIVs can also cause severe disease in older individuals, immunocompromised persons, and patients with chronic illnesses.

Nipah virus is a highly virulent paramyxovirus first described in 1999. Cases are concentrated mainly in Southeast Asia (Malaysia, Singapore, Bangladesh, and India).

Fruit bats are identified as the natural host of the virus. An outbreak of 14 cases, 8 fatal, occurred in Bangladesh associated with drinking date palm sap between 2010 and 2014. Direct pig-human, cow-human, human-human, and nosocomial transmission are reported. Nipah virus causes acute encephalitis with a high fatality rate (67–92%), although respiratory symptoms are also described. Cranial nerve palsies, encephalopathy, and dystonia are among neurologic sequelae (15–32%) seen in infected individuals. Relapses occurring weeks and months after initial infection are described (3.4–7.5%).

Clinical Findings

A. Symptoms and Signs

In RSV bronchiolitis, proliferation and necrosis of bronchiolar epithelium develop, producing obstruction from sloughed epithelium and increased mucus secretion. Signs of infection include low-grade fever, tachypnea, and wheezes. Apnea is a common presenting symptom. Hyperinflated lungs, decreased gas exchange, and increased work of breathing are present. Pulmonary hemorrhage is reported. In children, RSV is globally the most common cause of acute lower respiratory infection and also a common cause of acute and recurrent otitis media. In patients with Down syndrome, RSV develops at a later age and is associated with more protracted hospitalizations.

B. Laboratory Findings

A rapid diagnosis of RSV infection is made by viral antigen identification of nasal washings using an ELISA or immunofluorescent assay, but PCR-based rapid tests are increasingly used. Multiplex assays in conjunction with influenza A and B tests are available commercially. RSV viral load assay values at day 3 of infection may correlate with requirement of intensive care and respiratory failure in children.

Human metapneumovirus is best diagnosed by PCR. Tests for rapid detection of viral antigens with immunofluorescence or ELISA, and PCR techniques are also widely available for detection of HPIV. Culture may also be used. ELISA (serum and CSF) and PCR (urine and respiratory secretions but not blood) are both used for Nipah virus infection diagnosis.

Treatment & Prevention

Treatment of RSV consists of supportive care, including hydration, humidification of inspired air, antibiotic therapy (to reduce other respiratory morbidity), and ventilatory support as needed. Neither bronchodilating agents nor corticosteroids have demonstrated efficacy in bronchiolitis although individual patients with significant bronchospasm or history of asthma might respond to them. Oral antiviral agents remain under study.

The use of aerosolized ribavirin or RSV-enriched IVIG, or both, can be considered in high-risk patients, such as those with a history of bone marrow transplantation, and appears to lessen mortality. The prophylactic monoclonal antibody palivizumab, while recommended for and effective in high-risk infants (premature infants less than 32 weeks' gestational age, as well as infants with congenital heart and lung diseases and Down syndrome), is not of proven efficacy among adults with RSV.

A 2017 clinical trial studied the administration of palivizumab to preterm infants to prevent long-term sequelae; palivizumab did not suppress the onset of atopic asthma but did result in a significantly lower incidence of recurrent wheezing. Azithromycin therapy during RSV infection has been shown to reduce the probability of recurrent wheezing during the subsequent year by approximately 50%.

No RSV vaccine is currently commercially available.

Prevention in hospitals entails rapid diagnosis, hand washing contact isolation, and perhaps passive immunization. (Passive immunization is costly but is associated with improved antiviral titers in hematologic stem cell transplant recipients). The use of conjugated pneumococcal vaccination appears to decrease the incidence of concomitant pneumonia associated with viral infections in children in some countries. Viral shedding averages 11 days and correlates inversely with age and directly with severity of infection.

Therapeutic modalities for human metapneumovirus and parainfluenza virus infections under investigation include intravenous ribavirin administration.

2. Seasonal Influenza

ESSENTIALS OF DIAGNOSIS

- Cases usually in epidemic pattern.
- Onset with fever, chills, malaise, cough, coryza, and myalgias.
- Aching, fever, and prostration out of proportion to catarrhal symptoms.
- Leukopenia.

General Considerations

Influenza (an orthomyxovirus) is a highly contagious disease transmitted by the respiratory route in humans. Transmission occurs primarily by droplet nuclei rather than fomites or direct contact. There are three types of influenza viruses that infect humans. While type A can infect a variety of mammals (humans, swine, horses, etc) and birds, types B and C almost exclusively infect humans. Type A viruses are further divided into subtypes based on the hemagglutinin (H) and the neuraminidase (N) expressed on their surface. There are 18 subtypes of hemagglutinin and 11 subtypes of neuraminidase.

Annual epidemics usually appear in the fall or winter in temperate climates. Up to 5 million cases of severe influenza are estimated by the WHO to occur annually, with up to 0.5 million annual deaths. Influenza epidemics affect 10–20% of the global population on average each year and are typically the result of minor antigenic variations of the virus, or antigenic drift, which occur often in influenza A virus. On the other hand, pandemics—associated with higher mortality—appear at longer and varying intervals (decades) as a consequence of major genetic reassortment of the virus (antigenic shift) or adaptation of an avian or swine virus to humans (as with the pandemic H1N1 virus of 1918). (https://www.who.int/influenza/surveillance_monitoring/updates/latest_update_GIP_sur

The highly pathogenic avian influenza subtypes are discussed in the next section. The novel swine-origin influenza A (pandemic H1N1) virus emerged in Mexico in 2009 and quickly spread throughout North America and the world causing a pandemic. This virus originated from triple-reassortment of North American swine, human, and avian virus lineages and Eurasian swine virus lineages and replaced the previous H1N1 seasonal virus.

Clinical Findings

A. Symptoms and Signs

Type A and B seasonal influenza viruses produce clinically indistinguishable infections, whereas type C usually causes mild illness. The incubation period is 1–4 days. In unvaccinated persons, uncomplicated influenza often begins abruptly. Symptoms range widely from nearly asymptomatic to a constellation of systemic symptoms (including fever, chills, headache, malaise, and myalgias) and respiratory symptoms (including rhinorrhea, congestion, pharyngitis, hoarseness, nonproductive cough, and substernal soreness). Gastrointestinal symptoms and signs may occur, particularly among young children with influenza B virus infections. Fever lasts 1–7 days (usually 3–5). Elderly patients especially may present with lassitude and confusion, often without fever or respiratory symptoms. Signs include mild pharyngeal injection, flushed face, and conjunctival redness. Moderate enlargement of the cervical lymph nodes and tracheal tenderness may be observed. The presence of fever (higher than 38.2°C) and cough during influenza season is highly predictive of influenza infection in those older than 4 years.

B. Laboratory Findings

Rapid influenza diagnostic tests for detection of influenza antigens from nasal or throat swabs are widely available, highly specific, and produce fast results but have low sensitivity leading to high false-negative results. Not all commercial rapid influenza diagnostic tests can differentiate between influenza A and influenza B, and none of the available rapid influenza diagnostic tests can provide information on influenza A subtypes. Newer digital immunoassays and rapid nucleic acid amplification tests are more sensitive than traditional rapid influenza diagnostic tests; however, the sensitivity of newer PCR techniques is compromised early in the season during low prevalence periods. A nasopharyngeal swab, nasal aspirate, combined nasopharyngeal swab with oropharyngeal swab, or material from a bronchoalveolar lavage can be tested for any influenza strain. When influenza pneumonia is suspected, lower respiratory tract specimens should be collected and tested for influenza viruses by RT-PCR or the above assays.

Differential Diagnosis

The differential diagnoses for influenza-like infections include a variety of viral respiratory infections (parainfluenza, RSV, atypical dengue, adenovirus, enterovirus, coronavirus) or other viral infections (flavivirus, CMV, EBV, acute HIV infection), as well as bacterial infections such as mycobacterial infection (atypical pneumonia), pertussis, and Legionnaire disease. Epidemiologic factors can suggest Legionnaire (elderly smokers). Chronicity of cough may suggest adenovirus, mycobacterial, or pertussis infection. Leukocytosis and lymphadenopathy are more often seen with CMV and EBV. Distinguishing influenza from dengue requires attention to rhinitis (influenza) and thrombocytopenia (dengue).

Complications

Hospitalization or ICU admission for influenza is often a consequence of diffuse viral pneumonitis with severe hypoxemia and sometimes shock. Patients with asthma, residents of nursing homes and long-term care facilities, adults aged 65 years or older, persons who are morbidly obese, and persons with underlying medical conditions (pulmonary, renal, cardiovascular, hepatic, hematologic, neurologic and neurodevelopmental conditions; and immune-deficient conditions, such as HIV, diabetes, and cirrhosis) are at high risk for complications. Infection during pregnancy increases the risk for hospitalization and may be associated with severe illness, sepsis, pneumothorax and respiratory failure, spontaneous abortion, preterm labor, and fetal distress.

Influenza causes necrosis of the respiratory epithelium, increased adherence of bacteria to infected cells, and ciliary dysfunction, which predispose to secondary bacterial infections due to pneumococci, staphylococci, or Haemophilus spp. In turn, bacterial enzymes (eg, proteases, trypsin-like compounds, and streptokinase) activate influenza viruses. Frequent complications are acute sinusitis, otitis media, purulent bronchitis, and pneumonia.

Cardiovascular diseases are a complication of influenza infection, in particular among older adults, and influenza is postulated to be a significant trigger for myocardial infarction, cerebrovascular disease, and sudden death. Several studies suggest that influenza vaccination has protective effect against major adverse cardiovascular events. Neurologic complications, including seizures and encephalopathy, may occur. Encephalopathic complications of influenza are uncommon.

Reye syndrome (fatty liver with encephalopathy) is a rare and severe complication of influenza (usually B type) and other viral diseases (especially varicella), particularly in young children. It consists of rapidly progressive hepatic failure and encephalopathy, and there is a 30% mortality rate. The pathogenesis is unknown, but the syndrome is associated with aspirin use in the management of viral infections.

Treatment

Treatment is supportive. Antiviral therapy should be considered for all persons with acute illness, in particular those at high risk for developing complications who have a suggestive clinical presentation or with laboratory-confirmed influenza. Clinical trials show a reduction in the duration of symptoms, hospital admissions, as well as secondary complications, such as otitis, sinusitis, or pneumonia, but not mortality when using these agents. Maximum benefit is expected with the earliest initiation of therapy. Although the benefit of antiviral therapy after 48 hours of illness is reduced, it should be initiated if the patient is hospitalized or critically ill. Benefit has been noted up to 4–5 days into illness.

The antiviral treatment of choice should be based on the susceptibility of the circulating virus. Currently, since high levels of resistance to the adamantanes (amantadine and rimantadine) persist among seasonal H1N1 and H3N2 influenza A viruses and these agents are not effective against influenza B viruses, amantadine and rimantadine are not recommended for treatment.

Three neuraminidase inhibitors are FDA approved for treatment of influenza A and B: oral oseltamivir, inhaled zanamivir, and intravenous peramivir. The CDC recommends treatment with oral oseltamivir (75 mg twice daily for 5 days) as the drug of choice for patients of any age, pregnant women, and patients who are hospitalized or have complicated infection. Absorption of oral oseltamivir is considered reliable, except in patients with impaired gastric motility or gastrointestinal bleeding.

Inhaled zanamivir (10 mg, 2 inhalations twice daily for 5 days) is indicated for uncomplicated acute influenza in patients 7 years and older, is relatively contraindicated among persons with asthma because of the risk of bronchospasm, and is not formulated for use in mechanically ventilated patients. Inhaled zanamivir lacks efficacy in pneumonia, probably due to poor bioavailability in the peripheral lungs.

Intravenous peramivir (600 mg in single dose) is used for outpatient treatment of uncomplicated infection in patients 18 years and older and is recommended when there is a concern about inadequate oral absorption of oseltamivir. The efficacy of peramivir in patients with severe illness and in patients with influenza B is not well established. Some studies demonstrated that repeated doses for up to 5 days of intravenous peramivir is safe, effective and shorten the duration of influenza illness.

Resistance to neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir) can occur during or after prolonged use in immunocompromised patients, particularly in persons who have undergone hematopoietic stem cell transplant. Intravenous zanamivir is an investigational drug that could be requested for clinical use if there is a concern for oseltamivir-resistant influenza strain. Laninamivir is a long-acting inhaled neuraminidase inhibitor used for the treatment of seasonal influenza, including infection caused by oseltamivir-resistant virus. It is licensed in Japan and South Korea and is currently in phase III clinical trials in the United States.

Baloxavir (a selective inhibitor of influenza cap-dependent endonuclease that is given as a single oral dose) was approved by the FDA in 2018 for treatment of uncomplicated influenza A and B infections. Baloxavir is given as 40 mg or 80 mg orally once daily depending on weight (the higher dose for persons 80 kg or more) and should be given within the first 48 hours of infection. Its side effects include diarrhea and bronchitis, and to date, its effects in patients older than 65 years or younger than 12 years are not established. Baloxavir’s unique mechanism of action will likely make it useful as part of multidrug therapy for resistant disease. For complicated disease, especially in immunosuppressed patients, the combination of oseltamivir, amantadine, and ribavirin appears to produce faster viral clearance but no definite clinical improvement.

The first class of organosilanes have potent antiviral activity against influenza A viruses that are resistant to amantadine and oseltamivir. Dapivirine, an FDA-approved HIV nonnucleoside reverse transcriptase inhibitor, has broad-spectrum antiviral against multiple strains of influenza A and B viruses. Iminosugars are also under study. Updated advice is available at http://www.cdc.gov/flu/index.htm.

Prognosis

The duration of the uncomplicated illness is 1–7 days, and the prognosis is excellent in healthy, nonelderly adults. Hospitalization typically occurs in those with underlying medical disease, at the extremes of age, and in pregnant women. Most fatalities are due to bacterial pneumonia although exacerbations of other disease processes, in particular cardiac diseases, occur. Pneumonia resulting from influenza has a high mortality rate among pregnant women and persons with a history of rheumatic heart disease. Mortality among adults hospitalized with influenza ranges from 4% to 8%, although higher mortality (greater than 10–15%) may be seen during pandemics and among immunocompromised individuals. At least 64% of pneumonia and influenza deaths occurred among elderly persons in the United States, who comprised only 15% of the population.

If the fever recurs or persists for more than 4 days with productive cough and white cell count over 10,000/mcL, secondary bacterial infection should be suspected. Pneumococcal pneumonia is the most common secondary infection, and staphylococcal pneumonia is the most serious. Major complications include viral myocarditis and viral encephalitis.

Prevention

Annual administration of influenza vaccine is the most effective measure for preventing influenza and its complications. Seasonal influenza vaccines can reduce influenza hospitalizations by an estimated 61%. Vaccination of healthcare workers is associated with decreased mortality among hospitalized patients and those in long-term care facilities. Vaccination prevents influenza illness among pregnant women and their infants during the first months of life.

The ACIP and the American College of Obstetricians and Gynecologists’ Committee recommend annual influenza vaccination for all persons over 6 months of age with no contraindications. Vaccination is emphasized for high-risk groups and their contacts and caregivers.

Several Cochrane database analyses have analyzed the efficacy of the influenza vaccines in select populations. The studied groups include patients with COPD (a documented reduction in exacerbations with inactivated vaccine), the elderly (where vaccination shows some efficacy), adults with cancer (weak evidence, some lower mortality and influenza-related outcomes), healthy adults (established efficacy with inactivated vaccine, but only modest effects in pregnant women and newborns), and healthy children (where both live and inactivated vaccines lower the rate of influenza infections).

Other reviews establish the efficacy and safety of influenza vaccination in patients with rheumatoid arthritis, asthma, or myasthenia gravis, and elderly nursing home patients. The obese have an impaired response to the influenza vaccine.

Multiple influenza vaccine products are licensed in the United States and available from different manufacturers. These include inactivated influenza vaccines (standard- or high-dose, trivalent [IIV3] or quadrivalent [IIV4], adjuvanted or unadjuvanted), recombinant vaccines (trivalent [RIV3] or quadrivalent [RIV4]), and live attenuated influenza vaccine (LAIV4). All trivalent vaccines contain antigens from one strain each of influenza A (H1N1), influenza A (H3N2), and influenza B. Quadrivalent vaccines include an additional influenza B strain. The CDC does not endorse one influenza vaccine product over another, although each influenza vaccine product has different age indications and contraindications. The CDC publishes its annual influenza recommendations in the late summer (www.cdc.gov/mmwr).

LAIV4 use, not recommended by the CDC for the last two seasons due to concerns about its effectiveness against influenza viruses in prior years, is currently considered an acceptable option for groups in whom it is indicated. The efficacy of including the fourth A/Slovenian strain is as yet unknown.

Adults over the age of 18 years, including pregnant women, can receive any influenza vaccine, with few exceptions. Patients 65 years or older should receive a high-dose trivalent inactivated influenza vaccine containing four times more hemagglutinin than standard dose, or Fluad, a trivalent inactivated influenza vaccine that contains an adjuvant (MF59), which enhances the immune response to the vaccine. Fluzone intradermal inactivated quadrivalent vaccine is equally immunogenic and safe but more expensive than the intramuscular vaccine and is not recommended for persons older than 65 years. Adults older than 65 years can use any IIV or RIV intramuscular vaccine; in a large randomized trial, high-dose IIV3 showed superior efficacy over standard-dose IIV3 and may provide better protection. Some data suggest intradermal vaccination is more effective than intramuscular vaccination in the elderly. The herpes zoster vaccine can be safely coadministered with the seasonal influenza vaccines in patients over 50 years of age, with similar immunogenicity.

For patients with cancer, chemotherapeutic regimens containing rituximab show persistent perturbations of B-cell and Ig synthesis, and these modifications decrease humoral responses to the influenza vaccine. Adjuvanted vaccine is efficacious but has resulted in brief disease exacerbation in persons with psoriatic arthritis taking TNF-alpha inhibitors.

Vaccination is contraindicated for persons with a history of severe allergic reaction to influenza. Precautions should be taken if patients report a history of Guillain-Barré syndrome 6 weeks following an influenza vaccine and if patients have a moderate to severe acute illness with or without fever until clinical improvement. Persons with a history of egg allergy with hives only may receive any recommended influenza vaccine. Those with more severe allergic reactions to eggs may receive any recommended vaccine under close observation in a health care facility under the supervision of a provider with experience treating severe allergic reactions. Only the recombinant vaccine is completely egg-free.

Additional vaccine information can be found at http://www.cdc.gov/flu/professionals/vaccination/index.htm.

When antiviral chemoprophylaxis is used, it prevents 70–90% of influenza infections. Chemoprophylaxis is not routinely recommended and is not recommended prior to exposure to prevent development of resistance. Chemoprophylaxis may be considered for persons at increased risk for complications from infection who are exposed to an infected patient within 2 weeks of vaccination, for persons unlikely to respond to vaccination because of immunosuppression after exposure to an infected person, for persons for whom vaccination is contraindicated and who are at high risk for complications after exposure to an infected person, and for prevention of infection in residents of institutions during an outbreak. Alternatively, a person can be monitored closely, and antiviral therapy initiated at the first onset of symptoms after exposure. Initiation of chemoprophylaxis is not recommended more than 48 hours after exposure. Patients taking chemoprophylaxis should seek urgent medical care if an influenza-like illness develops.

Chemoprophylaxis against influenza A and B is accomplished with daily administration of the neuraminidase inhibitors oseltamivir (75 mg/day, oral) or zanamivir (10 mg/day, inhaled) to continue through 7 days after last known exposure. For outbreak control in long-term care facilities and hospitals, a minimum of 2 weeks is recommended, including in vaccinated persons if the seasonal vaccine is not well matched to the circulating strain, to continue until 1 week after identification of the last known case. Zanamivir should not be given as chemoprophylaxis to asthmatic persons, nursing home residents, or children younger than 5 years.

Breakthrough infections with influenza occur with neuraminidase inhibitors (in a study with zanamivir) and with vaccination. The efficacy of chemoprophylaxis is proven for individuals and households but not community settings.

Hand hygiene and surgical facemasks appear to prevent household transmission of influenza virus isolates when implemented within 36 hours of recognition of symptoms in an index patient. Such nonpharmaceutical interventions assist in mitigating the spread of pandemic and interpandemic influenza to nonvaccinated persons. In one study, patients with seasonal H1N1 influenza infection were infectious from 1 day before to about 7 days following illness onset. Children and immunosuppressed persons exhibit prolonged viral shedding and may be infectious longer. Winter school breaks during periods of high influenza transmission appear to decrease rates of visits to primary care practitioners for influenza illness among children and adults.

The data are not currently sufficient to modify statin usage for influenza vaccination. There may be, however, some impaired effectiveness against the H3N2 influenza A component of vaccines from the immunomodulatory effects of statins.

Any hospital patient in whom the infection is suspected should be isolated in an individual room with standard and droplet precautions. CDC guidelines recommend the equivalent of N95 masks for aerosol generating procedures (eg, bronchoscopy, elective intubation, suctioning, administering nebulized medications). For such procedures, an airborne infection isolation room can be used, with air exhausted directly outside or recirculated after filtration by a high efficiency particulate air (HEPA) filter. Strict adherence to hand hygiene with soap and water or an alcohol-based hand sanitizer and immediate removal of gloves and other equipment after contact with respiratory secretions is essential. Precautions should be maintained until 7 days from symptom onset or until 24 hours after symptom resolution, whichever is longer. Postexposure prophylaxis or close monitoring and early treatment should be considered for close contacts of patients who are at high risk for complications of influenza and may be considered for health care personnel, public health workers, or first responders who experienced a recognized, unprotected close contact exposure to a person with influenza virus infection during that person’s infectious period.

A regimen of dose sparing vaccination (to 3.5 mcg) is advocated by some providers to address the extreme shortage of influenza vaccine, particularly in developing world countries, with adequate vaccination against all components except H3N2, where there is reduced seroconversion.

When to Admit

- Limited availability of supporting services.
- Pneumonia or decreased oxygen saturation.
- Changes in mental status.
- Consider with pregnancy.

3. Avian Influenza

ESSENTIALS OF DIAGNOSIS

- Most human cases occur after exposure to infected poultry.
- Clinically indistinguishable from seasonal influenza.
- Epidemiologic factors assist in diagnosis.
- Rapid antigen assays confirm diagnosis but do not distinguish avian from seasonal influenza.

General Considerations

Zoonotic influenza viruses are distinct from human seasonal influenza viruses and do not easily transmit between humans. In addition, a number of viral genetic changes are required for adaptation to humans. For avian influenza viruses, birds are the natural hosts. Around the world and in North America, avian influenza A outbreaks occur in poultry from time to time (including a 2016 outbreak in Dubois County, Indiana, with avian but no human cases), and the virus has become endemic in poultry in some countries, mostly in Southeast Asia and Egypt. Occasionally, avian influenza viruses may infect humans or other mammals, including domestic cats and dogs. Illness in humans ranges from mild disease to rapid progressive severe disease and death depending on the subtype.

The primary risk factor for human infection is direct or indirect exposure to infected live or dead poultry or contaminated environments, such as live bird markets. Slaughtering and handling carcasses of infected poultry are also risk factors.

The emergence of H5, H7, and H9 avian influenza virus subtypes in humans raises concern that the virus may undergo genetic reassortment or mutations in some of the genes and develop greater human-to-human transmissibility with the potential to produce a global pandemic. All fatal avian influenza virus infections acquire their internal gene segments from H9N2 viruses, the most widespread avian influenza subtype.

Human infections with H5N1 viruses have been reported to WHO from 16 countries, the first report in the Americas was in Canada in 2014, and approximately 60% of the cases have died. Infection with H7N9 avian influenza virus was first reported in China in 2013. Since then, many cases have been reported around the world with an average case fatality rate of 40%. Infections with other H7 avian influenza viruses (H7N2, H7N3, and H7N7) have occurred sporadically around the world. Rare human cases of influenza H9N2 are also reported.

Clinical Findings

A. Symptoms and Signs

Distinguishing avian influenza from regular influenza is difficult. History of exposure to dead or ill birds or live poultry markets in the prior 10 days, recent travel to Southeast Asia or Egypt, or contact with known cases should be investigated. Patients infected by H5N1 or H7N9 avian influenza A viruses have an aggressive clinical course. The symptoms and signs include fever followed by lower respiratory symptoms (cough, dyspnea). Upper respiratory tract symptoms are less common. Gastrointestinal symptoms are reported more frequently in H5N1 infections. Conjunctivitis is reported in influenza H7 infections. Other systems can also be involved leading to neurologic manifestations (encephalopathy, seizure) and liver impairment. Prolonged febrile states and generalized malaise are common. Respiratory failure, multiorgan dysfunction, and septic shock are the usual cause of death. Bacterial superinfections are reported.

For human infections with H7N7 and N9B2 avian influenza virus infections, most cases have been mild with a few cases hospitalized and very few reports of deaths resulting from infection.

B. Laboratory Findings

Current commercial rapid antigen tests are not optimally sensitive or specific for detection of H5N1 influenza and should not be the definitive test for influenza. More sensitive RT-PCR assays are available through many hospitals and state health departments. Diagnostic yield can be improved by early collection of samples, preferably within 7 days of illness onset. Throat swabs or lower respiratory specimens (such as tracheal aspirate or bronchoalveolar lavage fluid) may provide higher yield of detection than nasal swabs. When highly pathogenic strains, such as H5N1 influenza virus infections, are suspected, extreme care in the handling of these samples must be observed during preliminary testing. Positive samples must then be forwarded to the appropriate public health authorities for further investigation (eg, culture) in laboratories with the adequate level of biosafety (level 3).

Treatment

Persons with severe illness and confirmed and probable cases with mild disease should receive treatment as soon as possible. The current first-line recommendation is to use the neuraminidase inhibitor oseltamivir, 75 mg orally twice daily for 5 days administered within 48 hours from onset of illness. Longer courses of therapy (eg, 10 days) should be considered in hospitalized patients with severe illness and persistent viral shedding. Data are lacking for use of inhaled zanamivir or peramivir for severe avian influenza. Overall oseltamivir, by modeling, is associated with a 49% reduction in mortality from H5N1 avian influenza virus infections. As with seasonal influenza, enteric oseltamivir is well absorbed in critically ill persons without gastric stasis, known malabsorption, or gastrointestinal bleeding. Daily intravenous peramivir (600 mg, reduced to 200 mg for kidney dysfunction) for a minimum of 5 days and a maximum of 10 or more days (depending on severity of illness) or zanamivir (10 mg inhaled daily for 10 days) may be considered in such patients. Combination therapy with amantadine or rimantadine (in countries where H5N1 influenza virus A strains are likely to be susceptible to adamantanes) may be considered in patients with pneumonia or progressive disease. Resistance of avian H5N1 influenza strains to amantadine and rimantadine is present in most geographic areas. Resistance to neuraminidase inhibitors (oseltamivir, zanamivir, and peramivir) can occur with H5NA and H7N9 avian–infected patients. Successful treatment with administration of convalescent plasma is reported.

Prevention

The most effective method of prevention is avoidance of exposure. Persons who work with poultry should practice good hand hygiene and use appropriate personal protective equipment. These workers should also be vaccinated against seasonal influenza, since this can reduce the likelihood of coinfection with avian and seasonal influenza. Persons should avoid visiting live poultry markets when able and should avoid contact with ill birds. No risk exists for acquiring avian influenza through the consumption of well-cooked poultry products. The US government bans the importation of poultry from infected areas. Culling of animals has been effective in ending outbreaks of highly pathogenic avian influenza but is difficult with H7-infected poultry because most are asymptomatic. Policies regarding closure of live poultry markets during avian epidemics are controversial.

Persons with exposure should monitor themselves for 10 days after the last known exposure and should seek prompt medical attention if new fever or respiratory symptoms develop. Postexposure prophylaxis is not recommended in persons working with noninfected birds or who used appropriate personal protective equipment while working with infected birds. For persons with exposure to infected persons, postexposure prophylaxis is recommended for household and family members and may be considered for health care personnel with close unprotected contact. Postexposure prophylaxis regimens include 75 mg of oseltamivir orally or 10 mg inhaled zanamivir twice daily for 5 or 10 days from the last known exposure, depending on the length of the exposure. Careful surveillance for human cases and prudent stockpiling of medications with establishment of an infrastructure for dissemination are essential modalities of control. Nonpharmacologic means of control include masks, social distancing, quarantine, travel limitations, and infrastructure development, particularly for emergency departments.

Current vaccines do not provide cross-protection against strains of the H5, H7, and H9 influenza viruses. The United States government has prepandemic stockpiles of adjuvanted H5N1 vaccines and H7N9 vaccines that are not available to the public. The highly diverse genetic nature and the rapid evolution of the avian influenza viruses has resulted in the emergence of viruses that are distinct from stockpiled vaccines. New vaccine development is ongoing to generate vaccines against H7N9 and H5N1 with broadened protection against unmatched strains. Some of these vaccines are under study in preclinical and clinical trials; however, no vaccines are currently commercially available for humans.

Because the potential for pandemic influenza for many of the new reassortment viruses is not fully known, continued surveillance is essential, and stockpiling of vaccines, adjuvant, and medications (oseltamivir and zanamivir) is warranted at the public health level.

4. Middle East Respiratory Syndrome–Coronavirus (MERS-CoV)

ESSENTIALS OF DIAGNOSIS

- Mild, moderate, or severe respiratory illness.

- Travel to endemic area, including Saudi Arabia, United Arab Emirates, Qatar, and Jordan, within 14 days before symptom onset.
- Contact with camels reported in many cases.
- Fever, cough, and dyspnea.
- CDC can assist with real-time PCR using serum and respiratory samples, or serology.
- Supportive treatment; mortality 36% to 45%.

General Considerations

Middle East respiratory syndrome (MERS) is a syndrome associated with a coronavirus similar to the cause of severe acute respiratory syndrome (SARS). Patients with MERS have had a history of residence or travel in the Middle East, in particular Saudi Arabia, or contact with such patients. The virus is probably transmitted through direct or indirect contact of mucous membranes with infectious respiratory droplets. The virus is shed in stool, but the role of fecal-oral transmission is unknown. The earliest cases were identified in 2012 in the Kingdom of Saudi Arabia, and 75% of all cases have occurred there. Additional cases have occurred throughout the Middle East, Africa, and Europe, with a reported death rate of 36% (http://www.who.int/emergencies/mers-cov/en/). So-called super-spreaders are often responsible for propagating the pathogen in the early stages of an outbreak.

Person-to-person transmission can occur within families; hospital-associated cases comprise 25% of cases. The median incubation period is 5 days (range, 2–14) with the mean age of 50 (range 9 months to 99 years) and 65% occurring among men. Over 90% of patients have an underlying medical condition, including diabetes mellitus (68%), hypertension (34%), or chronic heart or kidney disease. Those with diabetes, kidney disease, chronic lung disease, or other immunocompromising conditions likely are at highest risk for severe disease.

Camels appear to be the principal reservoir, and several studies show that contact with dromedary herds of camels is greater among cases than controls. Raw camel milk is considered a potential source. Persons who work with camels are more likely to have antibody evidence of past infection.

Clinical Findings

A. Symptoms and Signs

MERS is an acute respiratory syndrome, with the most common symptoms being fever

(98%), cough (83%), and dyspnea (72%). Chills and rigors are common (87%). Gastrointestinal symptoms may occur, with diarrhea being most common (26%), followed by nausea and abdominal pain, and may precede respiratory symptoms. Mild and asymptomatic cases are reported.

B. Laboratory Findings and Imaging

Hematologic findings in the largest series to date include thrombocytopenia (36%), lymphopenia (34%), and lymphocytosis (11%). Moderate elevations in lactate dehydrogenase (49%), AST (15%), and ALT (11%) are recognized. Chest radiograph abnormalities are nearly universal and include increased bronchovascular markings, patchy infiltrates or consolidations, interstitial changes, opacities (reticular and nodular) and pleural effusions, and total lung opacification. Ground-glass opacities and consolidation are most commonly seen. The findings mimic those of many other causes of pneumonia.

Serum serologies and RT-PCR are available through CDC (contact information below, on MMWR reference site). Highest viral loads are found in lower respiratory tract specimens, including bronchoalveolar lavage fluid, sputum, and tracheal aspirates. These samples are preferred for diagnosis. The CDC recommends sending lower respiratory tract specimens, nasopharyngeal and oropharyngeal swabs, and serum for testing. In confirmed cases, serial sample collection (perhaps every 2–4 days) from multiple sites is recommended to increase understanding of virus shedding kinetics. In cases in which symptom onset occurred more than 14 days prior and symptoms are ongoing, serum should be sent to the CDC for serologic testing and the above specimens should be sent for RT-PCR.

C. Case Definition

A patient with severe illness shows the following characteristics: fever (38°C, 100.4°F or higher) and pneumonia or ARDS (based on clinical or radiologic evidence); and either history of travel in or near the Arabian Peninsula within 14 days before symptom onset; or close contact with a symptomatic traveler in whom fever and acute respiratory illness (not necessarily pneumonia) developed within 14 days after traveling in or near the Arabian Peninsula (above); or is a member of a cluster of patients with severe acute respiratory illness (eg, fever and pneumonia requiring hospitalization) of unknown etiology in which MERS-CoV is being evaluated, in consultation with state and local health departments.

In milder illness, patients have fever and symptoms of respiratory illness (not necessarily pneumonia; eg, cough, shortness of breath) and history of having close contact with a confirmed MERS case as well as a history of being in a health care facility (as a patient, worker, or visitor) within 14 days of symptom onset in a country or territory within the Arabian Peninsula in which recent health care–associated cases of MERS have been identified.

Of note, fever may not be present in certain patients, including the very young, elderly persons, immunosuppressed individuals, or those taking certain medications.

Complications

Respiratory failure is such a common complication that in a series from Saudi Arabia, 89% of patients required intensive care and mechanical ventilation. Patients with MERS-CoV appear to advance faster to respiratory failure than do those with SARS.

Treatment

Respiratory support is essential. No vaccine or known antiviral therapy exists to combat MERS. Current therapies are adapted from SARS treatments, which include broad-spectrum antibiotics, corticosteroids, interferons, ribavirin, lopinavir-ritonavir, or mycophenolate mofetil. A small retrospective study found improved survival at 14 days with ribavirin and interferon-alpha but not at 28 days.

Prognosis

The overall mortality rate of identified cases is about 36%. Advanced age is associated with a poor prognosis.

Prevention

Isolation and quarantine of cases is authorized by CDC. Strict infection control measures are essential as well as care and management of household contacts and hospital workers engaged in the care of patients. Travelers to Saudi Arabia (including the many pilgrims to the holy sites) should practice frequent hand washing and avoid contact with those who have respiratory symptoms. Evaluation of patients with suspect symptoms within 14 days of return from Saudi Arabia is essential. Because healthcare workers engaged in procedures that involve contact with respiratory droplets are at risk, isolation of high-risk patients is essential, as are simple hygienic measures. Control measures, including quarantining in the home for high-risk exposed persons and the use of facemasks for preventing hospital-acquired infections, are important. Assisting public health authorities with case reporting and surveillance is essential.

Camel workers including slaughterhouse and market workers, veterinarians, and racing personnel should wear facial protection and protective clothing and practice good personal hygiene, including frequent hand washing after touching animals. Family members of such personnel should not be exposed to work paraphernalia including clothing and shoes and workers should shower at the site of employment rather than the home. Avoid direct contact with camels (who may be asymptomatic but who can transmit the virus though nasal or ocular discharge, milk, urine, and feces). All infected animals should be kept off the market, including their meat products, and buried or destroyed.

ADENOVIRUS INFECTIONS

General Considerations

At least 60 serotypes of adenovirus are currently described and these are members of 7 species classified A–G. About half of these subgroups produce a variety of clinical syndromes. Adenoviruses show a worldwide distribution and occur throughout the year. These infections are usually self-limited or clinically inapparent and occur most commonly among infants, young children, and military recruits. However, these infections may cause significant morbidity and mortality in immunocompromised persons, such as HIV-infected persons and COPD patients, as well as in patients who have undergone solid organ and hematopoietic stem cell transplantation or cardiac surgery or in those who have received cancer chemotherapy. A few cases of donor-transmitted adenoviral infection have been reported in past years. An outbreak with adenovirus type 55 was reported in 2017 from a neurosurgical unit in China.

Adenoviruses, although a common cause of human disease, also receive particular recognition through their role as vectors in gene therapy and vaccine development.

Clinical Findings

A. Symptoms and Signs

The incubation period is 4–9 days. Clinical syndromes of adenovirus infection, often overlapping, include the following. The common cold (see Chapter 8) is characterized by rhinitis, pharyngitis, and mild malaise without fever. Conjunctivitis is often present. Nonstreptococcal exudative pharyngitis is characterized by fever lasting 2–12 days and accompanied by malaise and myalgia. Lower respiratory tract infection may occur, including bronchiolitis, suggested by cough and rales, or pneumonia. Types 1, 2, 3, 4, and 7 commonly cause acute respiratory disease and atypical pneumonia; coinfections or serial infections are documented to occur. Infections are especially severe in Native American children. Adenovirus type 14 is increasingly reported as a cause of severe and sometimes fatal pneumonia in those with chronic lung disease but is also seen in healthy young adults and military recruit outbreaks. Viral or bacterial coinfections occur with adenovirus in 15–20% of cases. Pharyngoconjunctival fever is manifested by fever and malaise, conjunctivitis (often unilateral), mild pharyngitis, and cervical adenitis. Epidemic keratoconjunctivitis (transmissible person-to-person, most often types 8, 19, and 37) occurs in adults and is manifested by bilateral conjunctival redness, pain, tearing, and an enlarged preauricular lymph node (multiple types may be involved in a single outbreak). Type 53 (a D adenovirus) was the cause of a 2017 outbreak in a Los Angeles County Eye Clinic. Keratitis may lead to subepithelial opacities (especially with the above types).

Sexually transmitted genitourinary ulcers and urethritis may be caused by types 2, 8, and 37. Adenoviruses also cause acute gastroenteritis (types 40 and 41), mesenteric adenitis, acute appendicitis, rhabdomyolysis, and intussusception. Rarely, they are associated with encephalitis, meningitis, acute respiratory distress syndrome (ARDS), acute flaccid paralysis, and pericarditis. Adenovirus is commonly identified in endomyocardial tissue of patients with myocarditis and dilated cardiomyopathy. Risk factors associated with severity of infection include youth, chronic underlying infections, recent transplantation, and serotypes 5 or 21.

Hepatitis (type 5 adenovirus), pneumonia, and hemorrhagic cystitis (types 11 and 34) tend to develop in infected liver, lung, or kidney transplant recipients, respectively. Disease states that may develop in hematopoietic stem cell transplant patients include hepatitis, pneumonia, diarrhea, hemorrhagic cystitis, tubulointerstitial nephritis, colitis, and encephalitis.

B. Laboratory Findings and Imaging

Antigen detection assays including direct fluorescence assay or enzyme immunoassay are rapid and show sensitivity of 40–60% compared with viral culture (considered the standard). Samples with negative rapid assays require PCR assays or viral cultures for diagnosis. Quantitative real-time rapid-cycle PCR is useful in distinguishing disease from colonization, especially in hematopoietic stem cell transplant patients. Multiplex nucleic acid amplification assays can test for multiple respiratory viruses simultaneously with increased sensitivity. Adenovirus differs from other viral and bacterial respiratory infections seen on chest CT imaging, appearing as a multifocal consolidation or ground-glass opacity without airway inflammatory findings.

Treatment & Prognosis

Treatment is symptomatic. Ribavirin or cidofovir is used in immunocompromised individuals with occasional success, although cidofovir is attendant with significant renal toxicity. Brincidofovir, the lipid-conjugated prodrug of cidofovir, has better oral bioavailability, is better tolerated, and achieves higher intracellular concentrations of active drug than cidofovir but currently is only available through compassionate use policies. A 2017 study of brincidofovir showed efficacy in controlling adenovirus in pediatric hematopoietic cell transplant patients. IVIG is also used in immunocompromised patients and can be used in combination with other therapies, but data are still limited. Reduced immunosuppression is often required. Typing of isolates is useful epidemiologically and in distinguishing transmission from endogenous reactivation. Topical steroids or tacrolimus may be used to treat adenoviral keratoconjunctivitis. Complications of adenovirus pneumonia in children include bronchiolitis obliterans. Deaths are reported on occasion.

The control of epidemic adenoviral conjunctivitis is often difficult and requires meticulous attention to hand hygiene, use of disposable gloves, sterilization of equipment (isopropyl alcohol is insufficient, recommendations of manufacturers are preferred), cohorting of cases, and furloughing of employees. Treatment with a combination of povidone-iodine 1.0% eyedrops and dexamethasone 0.1% eyedrops four times a day can reduce symptoms and expedite recovery.

Vaccines are not available for general use. Use of live oral vaccines containing attenuated type 4 and type 7 was reinstated in military personnel in 2013 and has been associated with significant decrease in adenoviral disease.

OTHER EXANTHEMATOUS VIRAL INFECTIONS

1. Erythroparvovirus Infections

Primate erythroparvovirus 1, more commonly known as parvovirus B19, infects human erythroid precursor cells. It is quite widespread (by age 15 years about 50% of children have detectable IgG), and its transmission occurs through respiratory secretions and saliva, through the placenta (vertical transmission with 30–50% of pregnant women nonimmune), and through administration of blood products. The incubation period is 4–14 days. Chronic forms of the infection can occur. Bocavirus, another erythroparvovirus, is a cause of winter acute respiratory disease in children and adults.

Clinical Findings

A. Symptoms and Signs

Parvovirus B19 causes several syndromes and manifests differently in various populations.

1. Children—In children, an exanthematous illness (“fifth disease,” erythema infectiosum) is characterized by a fiery red “slapped cheek” appearance, circumoral pallor, and a subsequent lacy, maculopapular, evanescent rash on the trunk and limbs. Eosinophilic cellulitis (Well syndrome) is also reported with parvovirus B19, as are microvesicular eruptions and atypical rashes. Parvovirus B19 is also one of the most common causes of myocarditis in childhood.

2. Immunocompromised patients—A transient aplastic crisis and pure red blood cell aplasia may occur. Bone marrow aspirates reveal absence of mature erythroid precursors and characteristic giant pronormoblasts. The parvovirus B19 gene is detected in 16–19% of acute leukemia and chronic myeloid leukemia patients.

3. Adults—A limited nonerosive symmetric polyarthritis that mimics lupus erythematosus and rheumatoid arthritis, which may in some cases be a type II mixed cryoglobulinemia, can develop in middle-aged persons (especially women). Rashes, especially facial, are less common in adults.

Chloroquine and its derivatives exacerbate parvovirus B19–associated anemia and are linked with significantly lower hematocrit in hospital admissions in malaria endemic areas. Rare reported presentations include myocarditis with infarction, constrictive pericarditis, chronic dilated cardiomyopathy (although a 2016 analysis from the Netherlands dispute some cardiac findings), Hashimoto thyroiditis, hepatitis, pneumonitis, neutropenia, thrombocytopenia, a lupus-like syndrome, glomerulonephritis, CNS vasculitis, papular-purpuric "gloves and socks" syndrome, complications of drug hypersensitivity, and a chronic fatigue syndrome. A subclinical infection is documented among patients with sickle cell disease. Other CNS manifestations of parvovirus B19 include encephalitis, meningitis, stroke (usually in sickle cell anemia patients with aplastic crises), and peripheral neuropathy (brachial plexitis and carpal tunnel syndrome) with occasional chronic residua.

The symptoms of parvovirus B19 infection can mimic those of autoimmune states such as lupus, systemic sclerosis, antiphospholipid syndrome, or vasculitis. A more specific entity named relapsing symmetric seronegative synovitis with edema was reported in two cases to be associated serologically with parvovirus B19 infection.

In pregnancy, premature labor, hydrops fetalis, and fetal loss are reported sequelae. Pregnant women with a recent exposure or with suggestive symptoms should be tested for the disease and carefully monitored if results are positive.

A serosurvey from France suggests parvovirus B19 infection may occur more commonly in patients with schizophrenia.

B. Laboratory Findings

The diagnosis is clinical (Table 32–2) but may be confirmed by either an elevated titer of IgM anti-parvovirus B19 antibodies in serum or with PCR in serum or bone marrow. By the time common presenting symptoms manifest, in particular a rash or polyarthropathy in an immunocompetent patient, the viremia may have cleared but IgM antibodies are likely present. In immunocompromised patients, RT-PCR is the optimal test. Autoimmune antibodies (antiphospholipid and antineutrophil cytoplasmic antibodies) can be present and are thought to be a consequence of molecular mimicry. False-positive serologies also occur in the presence of recent IVIG and anti–B-cell therapy. Also, remnant parvovirus B19, from tissue and serum, is thought to explain some false-positive findings. Assays on marrow tissue are indicated only if a marrow is deemed necessary for other hematologic reasons.

Treatment

Treatment in healthy persons is symptomatic (NSAIDs are used to treat arthralgias, and transfusions are used to treat transient aplastic crises). In immunosuppressed patients including those infected with HIV, IVIG is very effective in the short-term reduction of anemia. Relapses tend to occur about 4 months after administration of IVIG. There is no reduction in encephalitic complications with IVIG. Intrauterine blood transfusion can be considered in severe fetal anemia, although such transfusions have been linked to impaired neurologic development.

Prevention & Prognosis

Several nosocomial outbreaks are documented. In these cases, standard containment guidelines, including hand washing after patient exposure and avoiding contact with pregnant women, are paramount.

The prognosis is generally excellent in immunocompetent individuals. In immunosuppressed patients, persistent anemia may require prolonged transfusion dependence. Remission of parvovirus B19 infection in AIDS patients may occur with ART, though the immune reconstitution inflammatory syndrome is also reported.

2. Poxvirus Infections

Among the poxviruses causing disease in humans, the following are the most clinically important: variola/vaccinia, molluscum contagiosum, orf and paravaccinia, and monkeypox.

1. Variola/vaccinia—Smallpox (variola) was a highly contagious disease associated with high mortality and disabling sequelae. Its manifestations include severe headache, acute onset of fever, prostration and a rash characterized by uniform progression from macules to papules to firm, deep-seated vesicles or pustules. The synchronous progression in smallpox readily differentiates lesions from those of varicella (see also Chapter 6).

Complications of smallpox include bacterial superinfections (cellulitis and pneumonia), encephalitis, and keratitis with corneal ulcerations (risk factor for blindness). Effective vaccination led to its global elimination by 1979 and routine vaccination stopped in 1985. Recommendations to destroy remaining samples of this virus have not been acted upon thus far, and significant concern exists for potential misuse of these repositories in military or terrorist activities.

Smallpox should be considered, in concordance with the CDC Smallpox Response Plan (https://www.cdc.gov/smallpox/bioterrorism-response-planning/community/index.html), in any patient with fever and a characteristic rash for which other etiologies—such as herpes infections (eczema herpeticum may be differentiated from suspect smallpox by appropriate serologic stains and clinical appearance), erythema multiforme, drug reactions, or other infections—are unlikely. Patients with suspected infection should be placed in airborne and contact isolation and the official agency contacted (CDC Poxvirus and Rabies Branch help desk may be reached at 404-639-4129 and the Director's Emergency Operation Center at 770-488-7100).

Guidelines regarding smallpox vaccination are available at https://www.cdc.gov/smallpox/vaccine-basics/index.html.

2. Molluscum contagiosum—Molluscum contagiosum is caused by a molluscipox virus that may be transmitted sexually or by other close contact. The disease is manifested by pearly, raised, umbilicated skin nodules sparing the palms and soles. Keratoconjunctivitis can occur. Most ocular lesions are typical umbilicated dome-shaped lesions, but a variety of atypical ocular lesions are reported often in immunocompetent patients, more often in females and young adults (mean age 19).

There may be an association with atopic dermatitis or eczema. Marked and persistent lesions in AIDS patients respond readily to combination ART. Treatment options include destructive therapies (curettage, cryotherapy, cantharidin, 10–15% hydrogen peroxide, and keratolytics, among others), immunomodulators (imiquimod, cimetidine, and Candida antigen), and antiviral agents (topical cidofovir is effective anecdotally in refractory cases; brincidofovir, an agent under investigation for treating other viral infections, has shown some efficacy). No treatment is uniformly effective, and multiple courses of therapy are often needed. One meta-analysis recommends natural resolution of lesions if normal immunity can be restored. Cryptococcal skin lesions can mimic molluscum contagiosum.

3. Orf and paravaccinia—Orf (contagious pustular dermatitis, or ecthyma contagiosa) and paravaccinia (milker's nodules) are occupational diseases acquired by contact with sheep/goats and cattle, respectively. Household meat processing and animal slaughter have been implicated as risk factors. A new poxvirus akin to parapoxviruses was reported in 2015 in two patients from rural Tennessee and Missouri (the latter had also traveled to Tanzania). Orf is a common infection in sheep, goats, and deer. Thus, it is found worldwide, and farmers, veterinarians, and hunters are considered high-risk populations. It progresses through six clinically distinct dermatologic stages and lesions usually heal in 3–6 weeks without scarring. The use of nonporous gloves for persons handling animals is recommended, especially if the persons are immunosuppressed. Molecular tests are used to confirm clinical diagnosis. Although there is no specific treatment, Orf anecdotally responds to imiquimod. A live vaccine is available for animals.

4. Monkeypox—First identified in 1970, monkeypox is enzootic in the rain forests of equatorial Africa and presents in humans as a syndrome similar to smallpox. The incubation period is about 13 days (range, 6–28 in a recent Central African Republic outbreak) and limited person-to-person spread occurs. African mortality rates vary from 3% to 11% depending on the immune status of the patient. Secondary attack rates appear to be about 10%. Since 2016, confirmed cases of monkeypox have occurred in Central African Republic, Democratic Republic of the Congo, Liberia, Nigeria, and Sierra Leone and in captive chimpanzees in Cameroon. Risk factors identified from the Democratic Republic of Congo include being bitten by rodents, working as a hunter, and being male over 18 years of age. Confusion with smallpox and varicella occurs; however, both lymphadenopathy (seen in up to 90% of unvaccinated persons) and a febrile prodrome are prominent features in monkeypox infection. The monkeypox rash is distinguished by its deep-seated and well-circumscribed nature, lesions at the same stage of development (unlike varicella but like smallpox), and its centrifugal progression (including palms and soles). Suspected cases should be placed on standard, contact, and droplet precautions; local and state public health officials and the CDC should be notified for assistance with confirmation of the diagnosis (by electron microscopy, viral culture, ELISA, PCR, and a GeneXpert assay referred to as MPX/OPX [monkeypox/orthopox]). There are no standard or optimized guidelines for the clinical management of monkeypox. Cidofovir is effective in vitro against monkeypox, and its less toxic prodrug brincidofovir may be useful as well. Vaccinia immune globulin can be used in selected cases.

Other general precautions that should be taken are avoidance of contact with rodents from endemic areas (whose illness is manifested by alopecia, rash, and ocular or nasal discharge), appropriate care and isolation of humans exposed to such animals within the prior 3 weeks, and veterinary examination and investigation of suspect animals through health departments. Vaccinia immunization is effective against monkeypox and is recommended for those involved in the investigation of the outbreak and for health care workers caring for those infected with monkeypox if no contraindication exists (outlined above). Postexposure vaccination is also advised for documented contacts of infected persons or animals. US federal agencies prohibit the importation of African rodents.

5. Novel orthopoxviruses—Two cases in the country of Georgia with a novel orthopox virus occurred in 2013 with a third diagnosed serologically from 2010. All cases had animal contact, cattle for two, and serologic data showed possible associations with rodents and shrews as well as cattle. None had been vaccinated for smallpox. Another novel orthopoxvirus was identified in a patient who had undergone kidney transplantation in North America in 2015.

VIRUSES & GASTROENTERITIS

Viruses are responsible for at least 30–40% of cases of infectious diarrhea in the United States. These agents include rotaviruses; caliciviruses, including noroviruses such as Norwalk virus; astroviruses; enteric adenoviruses; and, less often, toroviruses, coronaviruses, picornaviruses (including the Aichi virus), and pestiviruses. Rotaviruses and noroviruses are responsible for most nonbacterial cases of gastroenteritis.

Rotaviruses are reoviruses with eight species and significant animal reservoirs. They are the leading worldwide cause of dehydrating gastroenteritis in very young children and are associated with significant morbidity and mortality. Each year, over 400,000 children die of rotavirus infection worldwide. Children aged 6 months to 2 years are the most affected, although adults are affected occasionally as well. By age 5, virtually every child has been infected with this pathogen. The diverse set of rotaviruses (classified by glycoproteins and protease-sensitive proteins [G-type and P-type antigens], which segregate independently) results in a constellation of phenotypes, although only about four of these are responsible for over 90% of disease. Rotavirus infections follow an endemic pattern, especially in the tropics and low-income countries, but they peak during the winter in temperate regions. The virus is transmitted by fecal-oral route and can be shed in feces for up to 3 weeks in severe infections. In outbreak settings (eg, day care centers), the virus is ubiquitously found in the environment, and secondary attack rates are between 16% and 30% (including household contacts). Nosocomial outbreaks are reported.

The disease is usually mild and self-limiting. A 2- to 3-day prodrome of fever and vomiting is followed by nonbloody diarrhea (up to 10–20 bowel movements per day) lasting for 1–4 days. It is thought that systemic disease occurs rarely, and unusual reported presentations include cerebellitis and pancreatitis. Patients with gastroenteritis are not routinely tested for rotavirus because the results do not alter treatment. Oral and intravenous rehydration solutions are the primary treatment options, but effective adjunctive therapies include specific probiotics (eg, Lactobacillus GG or Saccharomyces boulardii), nitazoxanide, diosmectite, or racecadotril. Adjunctive therapies such as oral odansetron shorten the median duration of diarrhea and hospitalization. Local intestinal immunity gives protection against successive infection.

Vaccines have been highly successful in reducing the global burden of rotavirus. Currently they are recommended for infants older than 6 weeks but younger than 2 years; studies are underway to assess the safety and efficacy of starting vaccination in the newborn period. Several rotavirus vaccines exist, and two are available in the United States: a live, oral, pentavalent human-bovine reassortment rotavirus vaccine (PRV, RotaTeq; to be given at 2, 4, and 6 months of age) and a live, oral attenuated monovalent human rotavirus vaccine (HRV, Rotarix; to be given at 2 and 4 months of age). The vaccines showed 85–98% efficacy against severe rotavirus gastroenteritis in trials based in the Americas and Europe. Reduced efficacy (50–64%) has been noted in studies conducted in Asia and Africa. One advantage of these vaccines is the evidence of heterotypic immunity (prevention against rotavirus strains not included in the vaccine). Accordingly, some data from the Americas suggest that rotavirus vaccination confers herd immunity to children under 1 year of age.

Vaccine coverage is inadequate in the United States for rotavirus (74.6% in the 2016 National Immunization Study), particularly among the poor. National immunization programs of over 80 countries include rotavirus vaccine, and the different rotavirus vaccines are available commercially in 100 countries.

Effectiveness of live oral rotavirus vaccines is reduced in low-resource settings.

With the control of rotavirus, noroviruses, such as Norwalk virus (one of a variety of small round viruses divided into 6 genogroups [3 causing disease in man] and at least 25 genotypes), are now the major cause of diarrhea globally. Noroviruses are a leading cause of food-borne disease in the United States (with food handlers largely responsible and associated foods most often leafy vegetables, fruits/nuts, and mollusks) and are significantly associated with military deployment as well as travel-associated and nosocomial infections.

Norovirus gastroenteritis is responsible for up to 20% of all diarrhea in both children and adults and an estimated 800 deaths annually in the United States and 200,000 deaths globally. The efficacy of the rotavirus vaccination has increased the percentage of gastroenteritis caused by norovirus. The noroviruses appear to evolve by antigenic drift (similar to influenza). While 90% of young adults show serologic evidence of past infection, no long-lasting protective immunity develops, and reinfections are common.

Outbreak environments include long-term care facilities (nursing homes in particular), restaurants, hospitals, schools, day care centers, vacation destinations (including cruise ships), and military bases. Persons at particular risk are younger individuals, older adults, those who are institutionalized, and those who are immunosuppressed. A strain that began in Australia (GII.4 Sydney) is responsible for increasing proportions of US cases. The GII.4 Sydney strain was the main cause of all cruise ship norovirus infections between 2008 and 2014. It was also the predominant cause of acute gastroenteritis in the 2016–2017 season in the United States. Although transmission is usually fecal-oral, airborne, person-to-person, and waterborne transmission are also documented. A short incubation period (24–48 hours), a short symptomatic illness (12–60 hours, but up to 5 days in hospital-associated cases), a high frequency (greater than 50%) of vomiting, and absence of bacterial pathogens in stool samples are highly predictive of norovirus gastroenteritis.

RT-PCR of stool samples is used for diagnostic and epidemiologic purposes. Several licensed multiple pathogen platform assays are available, but they are expensive and interpretation of the cause of illness in a given patient may be difficult. Treatment options are similar to rotavirus (see above) and rely mostly on oral and intravenous rehydration. Deaths are rare in the developed world, and the more common associated diseases are aspiration pneumonia, septicemia, and necrotizing enterocolitis.

Outbreak control for both rotavirus and norovirus infections include strict adherence to general hygienic measures. Despite the promise of alcohol-based sanitizers for the control of pathogen transmission, such cleansers may be relatively ineffective against the noroviruses compared with antibacterial soap and water, reinforcing the need for new hygienic agents against this prevalent group of viruses. Cohorting of sick patients, contact precautions for symptomatic hospitalized patients, exclusion from work of symptomatic staff until symptom resolution (or 48–72 hours after this for norovirus disease), and proper decontamination procedures are crucial.

ENTEROVIRUSES THAT PRODUCE SEVERAL SYNDROMES

The most famous enterovirus, the poliomyelitis virus, is discussed above under Major Vaccine-Preventable Viral Infections. Other clinically relevant enteroviral infections are discussed in this section.

1. Coxsackievirus Infections

Coxsackievirus infections cause several clinical syndromes. As with other enteroviruses, infections are most common during the summer. Two groups, A and B, are defined either serologically or by mouse bioassay. There are more than 50 serotypes.

Clinical Findings

A. Symptoms and Signs

The clinical syndromes associated with coxsackievirus infection are summer grippe; herpangina; epidemic pleurodynia; aseptic meningitis and other neurologic syndromes; acute nonspecific pericarditis; myocarditis; hand, foot, and mouth disease; epidemic conjunctivitis; and other syndromes.

1. Summer grippe (A and B)—A febrile illness, principally of children, summer grippe usually lasts 1–4 days. Minor upper respiratory tract infection symptoms are often present.

2. Herpangina (A2–6, 10; B3)—There is sudden onset of fever, which may be as high as 40.6°C, sometimes with febrile convulsions. Other symptoms are headache, myalgia, and vomiting. The sore throat is characterized early by petechiae or papules on the soft palate that ulcerate in about 3 days and then heal. Treatment is symptomatic.

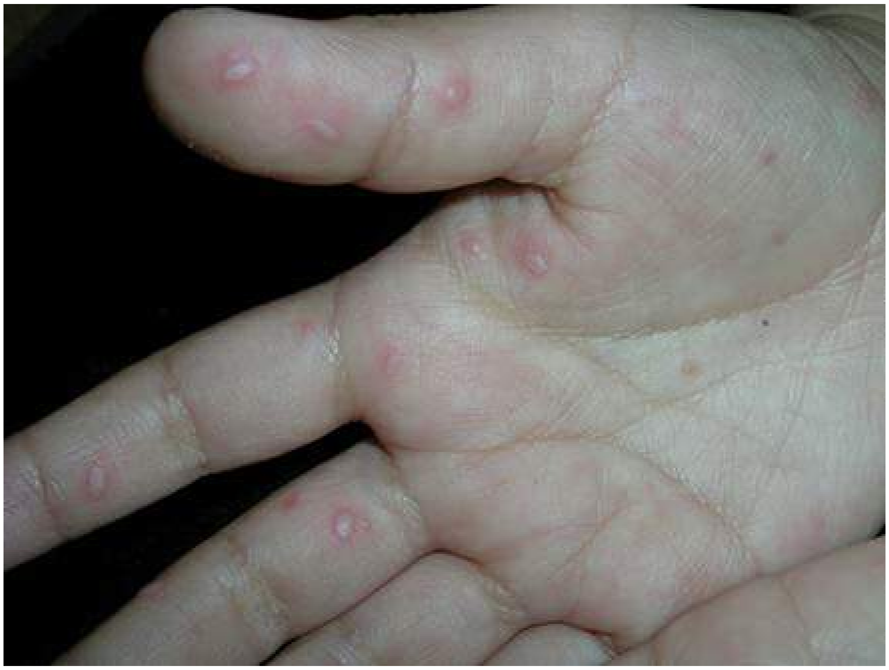
3. Epidemic pleurodynia (Bornholm disease) (B1–5)—Pleuritic pain is prominent. Tenderness, hyperesthesia, and muscle swelling are present over the area of diaphragmatic attachment. Other findings include headache, sore throat, malaise, nausea, and fever. Orchitis and aseptic meningitis occur in less than 10% of patients. Most patients are ill for 4–6 days.

4. Aseptic meningitis (A and B) and other neurologic syndromes—Fever, headache, nausea, vomiting, stiff neck, drowsiness, and CSF lymphocytosis without chemical abnormalities may occur, and pediatric clusters of group B (especially B5) meningitis are reported. Focal encephalitis and transverse myelitis are reported with coxsackievirus group A and acute flaccid paralysis with group B in India. Disseminated encephalitis occurs after group B infection, and acute flaccid paralysis is reported with both coxsackievirus groups A and B.

5. Acute nonspecific pericarditis (B types)—Sudden onset of anterior chest pain, often worse with inspiration and in the supine position, is typical. Fever, myalgia, headache, and pericardial friction rub appear early and these symptoms are often transient. Evidence for pericardial effusion on imaging studies is often present, and the occasional patient has a paradoxical pulse. Electrocardiographic evidence of pericarditis is often present. Relapses may occur.

6. Myocarditis (B1–5)—Heart failure in the neonatal period secondary to in utero myocarditis and over 20% of adult cases of myocarditis and dilated cardiomyopathy are associated with group B (especially B3) infections.

7. Hand, foot, and mouth disease (A5, 6, 10, 12, and 16, B5)—This disease is sometimes epidemic and is characterized by stomatitis, a vesicular rash on hands and feet, nail dystrophies, and onychomadesis (nail shedding) (Figure 32–6). Enterovirus 71 is also a causative agent of usually more severe disease. A16 disease is usually mild. A6 may be atypical but is usually self-limited. Rare fatalities are reported among surveillance programs in China.



▲ **Figure 32–6.** **Typical flat, gray, oval vesicular lesions on the ventral hand and fingers.** (Used, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. The Color Atlas of Family Medicine, 3rd ed. McGraw-Hill, 2019.)

8. Epidemic conjunctivitis—As with enterovirus 70, the A24 variant of coxsackievirus is associated with acute epidemic hemorrhagic conjunctivitis in tropical areas with outbreaks reported in southern China, Pakistan, southern Sudan, the Comoros, Uganda, Cuba, and Thailand. It is also reported as a cause of corneal endothelitis after cataract surgery.

9. Other syndromes associated with coxsackievirus infections—These include rhabdomyolysis, fulminant neonatal hepatitis (occurs rarely), pancreatitis with concomitant hepatitis and myocarditis (A4), glomerulopathy (group B infections), onychomadesis (B1), neonatal hemophagocytic lymphohistocytosis (B1), types 1 and 2 diabetes mellitus (mainly group B infections), and thyroid disease (group B4), although definitive causality is not established. A pathogenic role in primary Sjögren syndrome and acute myocardial infarction has also been proposed for group B coxsackievirus infections. A report of confirmed infective endocarditis due to coxsackievirus B2 in a patient with a prosthetic cardiac device suggests that viral etiologies of culture-negative infective endocarditis should be considered.

B. Laboratory Findings

Routine laboratory studies show no characteristic abnormalities. Neutralizing antibodies appear during convalescence. The virus may be isolated from throat washings or stools inoculated into suckling mice. Viral culture is expensive, labor intensive, and requires several days for results. A PCR test for enterovirus RNA is available and, although it cannot identify the serotype, may be useful, particularly in cases of meningitis.

Treatment & Prognosis

Treatment is symptomatic. Except for meningitis, myocarditis, pericarditis, diabetes, and rare illnesses such as pancreatitis or poliomyelitis-like states, the syndromes caused by coxsackieviruses are benign and self-limited. Two controlled trials showed a potential clinical benefit with pleconaril for patients with enteroviral meningitis although the compassionate use of this medication has stopped (clinicians can contact Schering Plough for updates). There are anecdotal reports of success with IVIG in severe disease. Vaccines against the most common etiologic agents in a given country have been developed, but simultaneous circulation of more than one virus make coxsackievirus vaccines based on a single agent relatively ineffective.

2. Echovirus Infections

Echoviruses are enteroviruses that produce several clinical syndromes, particularly in children. Infection is most common during summer. Among reported specimens, death ensues in about 3%. Males younger than 20 years are more commonly infected than other persons.

Over 30 serotypes of echoviruses are recognized and the most common serotypes for disease are types 6, 9, 11, 19, and 30. Most can cause aseptic meningitis, which may be associated with a rubelliform rash. Transmission is primarily fecal-oral. Hand washing is an effective control measure in outbreaks of aseptic meningitis. Outbreaks related to fecal contamination of water sources, including drinking water and swimming and bathing pools, were reported previously.

Besides meningitis, other conditions associated with echoviruses range from common respiratory diseases and epidemic diarrhea to myocarditis, a hemorrhagic obstetric syndrome, keratoconjunctivitis, severe hepatitis with coagulopathy, leukocytoclastic vasculitis, encephalitis with sepsis, interstitial pneumonitis, pleurodynia, hemophagocytic syndromes (in children with cancer), sudden deafness, encephalitis, acute flaccid paralysis (a leading cause in India), optic neuritis, uveitis, and septic shock. Echoviruses and enteroviruses are also a common cause of nonspecific exanthems.

As with other enterovirus infections, diagnosis is best established by correlation of clinical, epidemiologic, and laboratory evidence. Cytopathic effects are produced in tissue culture after recovery of virus from throat washings, blood, or CSF. An enterovirus PCR of the CSF can assist in the diagnosis and is associated with a shorter duration of hospitalization in febrile neonates. Fourfold or greater rises in antibody titer signify systemic infection.

Treatment is usually symptomatic, and the prognosis is excellent, though there are reports of mild paralysis after CNS infection. In vitro data suggest some role for amantadine or ribavirin, but clinical studies supporting these findings are not available.

From a public health standpoint, clustered illnesses, such as among travelers swimming in sewage-infested seawater, suggest point-source exposure. Prevention of fecal-oral contamination and maintenance of pool hygiene through chlorination and pH control are important public health control measures.

Iwasaki J et al. Lower anti-echovirus antibody responses in children presenting to hospital with asthma exacerbations. Clin Exp Allergy. 2015 Oct;45(10):1523–30. [PMID: 25640320]

3. Enteroviruses 68, 70, 71, & Related Agents

Several distinct clinical syndromes are described in association with enteroviruses.

Enterovirus D68 (EV-D68) is a unique enterovirus that shares epidemiologic characteristics with human rhinovirus and is typically associated with respiratory illness. Several clusters are reported from the Netherlands, Japan, the Philippines, and Thailand. An outbreak throughout the United States was reported during 2014–2015. The outbreak was also associated with cases of acute flaccid myelitis but not definitively linked thus far. The virus is implicated also in aseptic meningitis and encephalitis.

Enterovirus 70 (EV-70), a ubiquitous virus first identified in 1969 and responsible for abrupt bilateral eye discharge and subconjunctival hemorrhage with occasional systemic symptoms, is most commonly associated with acute hemorrhagic conjunctivitis.

Enterovirus 71 (EV-71) almost always occurs in the Asia-Pacific region and is associated with hand, foot, and mouth disease (HFMD), which can be severe or even fatal, herpangina as well as a form of epidemic encephalitis associated on occasion with pulmonary edema, and acute flaccid paralysis often mimicking poliomyelitis. A recombinant virus (between EV-71 and coxsackievirus A16) caused an outbreak of HFMD in Fuyang, China, in 2008. In Taiwan, 29% of EV-71 cases in children are asymptomatic. There is an association reported between gastrointestinal enterovirus infection and type 1 diabetes.

Human enteroviruses are neurotropic. They may have a role in amyotrophic lateral sclerosis. EV-D68 has been reported in a case of fatal meningitis/encephalitis. A number of nonpolio type C enteroviruses are associated with polio-like syndromes, and surveillance for these is most active in China. Enterovirus infection of the pancreas can trigger cell-mediated autoimmune destruction of beta cells resulting in diabetes. Enterovirus myocarditis can be a serious infection in neonates, complicated by cardiac dysfunction and arrhythmias.

Mortality is especially high in EV-71–associated brainstem encephalitis, which is often complicated by pulmonary edema, particularly when it occurs in children younger than 5 years. A complication is autonomic nervous system dysregulation, which may precede the pulmonary edema. Because of lower herd immunity, HFMD tends to infect the very young (under age 5) in nonendemic areas. Clinical and epidemiologic findings aided by isolation of the suspect agent from conjunctival scraping for EV-70; vesicle swabs, body secretions, or CSF for EV-71; and respiratory secretions for D68 facilitate diagnosis of these enteroviral entities. Enzyme immunoassays and complement fixation tests show good specificity but poor sensitivity (less than 80%). RT-PCR may increase the detection rate in enterovirus infections and is useful in the analysis of CSF samples among patients with meningitis and of blood samples among infants with a sepsis-like illness.

Treatment of these entities remains largely symptomatic. A study in China showed that recombinant human interferon-alpha1b in EV-71–associated hand, foot, and mouth disease was associated with decreased fever duration, healing time of typical skin or oral mucosal lesions, and EV-71 viral load. There is anecdotal success in managing myocarditis with immunoglobulins.

The major complication associated with EV-70 is the rare development of an acute neurologic illness with motor paralysis akin to poliomyelitis. Treatment of acute flaccid paralysis related to EV-71 with IVIG does not appear to improve neurologic outcomes. Attention-deficit with hyperactivity occurs in about 20% with confirmed infection.

EV-D68 requires supportive care with particular attention to respiratory support. The CDC’s National Enterovirus Surveillance System should receive reports of disease at wnix@cdc.gov.

Household contacts, especially children under 6 months of age, are at particular risk for EV-71 acquisition. A commercial disinfectant, Virkon S at 1–2% application, appears to reduce infectivity of fomites. A stage-based supportive treatment for EV-71 infections, recognizing the potential for late-onset CNS disease and cardiopulmonary failure is important. There is no commercially available EV-71 vaccine in the United States, although vaccines produced in China appear to be successful against EV-71–associated hand, foot, and mouth disease and herpangina. Decreases in antibody titers suggest booster doses of these vaccines may be needed.

Enterovirus 72 (EV-72) is another term for hepatitis A virus (see Chapter 16). Enterovirus EV-104A is related to rhinoviruses and associated with respiratory illness in reports from Italy and Switzerland.

4. Human Parechovirus Infection (HPeV)

HPeV is 1 of 19 genotypes among a distinct genus of picornaviruses and causes a wide variety of disease in humans, especially in infants. The pathogen mainly affects small children during the summer and early fall, although disease can also occur in older adults. Cases are reported worldwide. HPeV3 is the most commonly reported isolate in the United States. Clinical presentation is mainly driven by gastrointestinal and respiratory illness, although otitis, neonatal sepsis, fever without a detectable source, gastroenteritis, flaccid paralysis, myalgias (which may be epidemic), diffuse maculopapular and palmar-plantar rashes, aseptic meningitis, intracranial hemorrhage, seizures, pericarditis, and an acute disseminated encephalitis are described in the literature.

HPeV6 typically affects individuals older than 20 years. HPeV3 is responsible for meningitis/encephalitis, neonatal sepsis (13% of late-onset neonatal sepsis [between 4 and 120 days of life] in one series was due to parechovirus) and was reported in association with necrotizing enterocolitis and hepatitis. It is the most common cause of neonatal meningitis and is the picornavirus most often found in CSF samples of CNS-related infections in very young children. CSF parameters include a normal count in over 90% and an abnormal protein in less than 50%. CNS infection may be seen with HPeV4 as well. Respiratory and gastrointestinal illnesses are seen with types HPeV4–HPeV6, HPeV10, and HPeV13-HPeV15.

Treatment is largely supportive and rapid identification of the viral antigen by PCR in stools, respiratory samples, and CSF may decrease use of unnecessary antibiotics and shorten hospital stay, although current PCR assays are not always sufficiently sensitive to exclude parechoviruses. Intravenous immunoglobulin was anecdotally successful in one case of parechovirus dilated cardiomyopathy and maternal antibodies to parechovirus type 3 are protective. Reported complications of neonatal cerebral infections include learning disabilities, epilepsy, and cerebral palsy. Because intrafamilial transmission is well documented, it may help isolate the affected children.

RICKETTSIAL DISEASES

TYPHUS GROUP

1. Epidemic (Louse-Borne) Typhus

ESSENTIALS OF DIAGNOSIS

- Prodrome of headache, then chills and fever.
- Severe, intractable headaches, prostration, persisting high fever.
- Macular rash appearing on days 4–7 on the trunk and in the axillae, spreading to the

rest of the body but sparing the face, palms, and soles.

- Diagnosis confirmed by complement fixation, microagglutination, or immunofluorescence.

General Considerations

Epidemic louse-borne typhus is caused by Rickettsia prowazekii, an obligate parasite of the body louse Pediculus humanus (other lice were thought not to contribute although a 2018 report from Turkey suggests P humanus capitus may transmit R prowazekii) (Table 32–3). Transmission is favored by crowded, unsanitary living conditions, famine, war, or any circumstances that predispose to heavy infestation with lice. After biting a person infected with R prowazekii, the louse becomes infected by the organism, which persists in the louse gut and is excreted in its feces. When the same louse bites an uninfected individual, the feces enter the bloodstream when the person scratches the itching wound. Dry, infectious louse feces may also enter via the respiratory tract. Cases can be acquired by travel to pockets of infection (eg, central and northeastern Africa, Central and South America). Outbreaks have been reported from Peru, Burundi, Ethiopia, Turkey, and Russia and are associated with migration of peoples as well as with refugee camps where crowding and poor hygiene may occur. Because of aerosol transmissibility, R prowazekii is considered a possible bioterrorism agent. In the United States, cases occur among the homeless, refugees, and the unhygienic, most often in the winter.

Table 32–3. Rickettsial diseases.

Disease	Rickettsial Pathogen	Geographic Areas of Prevalence	Insect Vector	Mammalian Reservoir	Travel Association
Typhus Group					
Epidemic (louse-borne) typhus	*Rickettsia prowazekii*	South America, Northeastern and Central Africa	Louse	Humans, flying squirrels	Rare
Endemic (murine) typhus	*Rickettsia typhi*	Worldwide; small foci (United States: southeastern Gulf Coast)	Flea	Rodents, opossums	Often
Scrub Typhus Group					
Scrub typhus	*Orientia tsutsugamushi*	Southeast Asia, Japan, Australia, Western Siberia	Mite[1]	Rodents	Often
Spotted Fever Group					
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Western hemisphere; United States (especially mid-Atlantic coast region)	Tick[1]	Rodents, dogs, porcupines	Rare
California flea rickettsiosis	*Rickettsia felis*	Worldwide	Flea	Cats, opossums	
Mediterranean spotted fever, Boutonneuse fever, Kenya tick typhus, South African tick fever, Indian tick typhus	*Rickettsia conorii*	Africa, India, Mediterranean regions	Tick[1]	Rodents, dogs	Often
Queensland tick typhus	*Rickettsia australis*	Eastern Australia	Tick[1]	Rodents, marsupials	Rare
Siberian Asian tick typhus	*Rickettsia sibirica*	Siberia, Mongolia	Tick[1]	Rodents	Rare
African tick bite fever	*Rickettsia africae*	Rural sub-Saharan Africa, Eastern Caribbean	Tick[1]	Cattle	Often
Lymphangitis-associated rickettsiosis	*R sibirica mongolitimonae*	Europe, Africa, Mongolia	Tick[1]	Unknown	Unknown
Tick-borne lymphadenopathy/ Dermacentor-borne necrosis erythema lymphadenopathy/scalp eschar neck lymphadenopathy	*R slovaca, R raoultii, Candidatus R rioja*	Europe	Tick	Unknown	Occasional
Transitional Group					
Rickettsialpox	*Rickettsia akari*	United States, Korea, former USSR	Mite[1]	Mice	Occasional
Other					
Ehrlichiosis and anaplasmosis, human Monocytic	*Ehrlichia chaffeensis, Anaplasma equi, Ehrlichia canis*	Southeastern United States	Tick[1]	Dogs	Occasional
Granulocytic	*Anaplasma phagocytophilum, Ehrlichia ewingii, Ehrlichia muris eauclairensis*[2] *Neorickettsia sennetsu*[2]	Northeastern United States and upper Midwest (*E muris eauclairensis*) Southeast Asia (*N sennetsu*)	Tick[1]	Rodents, deer, sheep	Occasional
Q fever	*Coxiella burnetii*	Worldwide	None[3]	Cattle, sheep, goats	Occasional

---

[1] Also serve as arthropod reservoirs by maintaining rickettsiae through transovarian transmission.

[2] Limited data available on exact cell involved in pathogenesis.

[3] Human infection results from inhalation of dust.

R prowazekii can survive in lymphoid and adipose (in endothelial reservoirs) tissues after primary infection, and years later, produce recrudescence of disease (Brill-Zinsser disease) without exposure to infected lice. This phenomenon can serve as a point source for future outbreaks.

An extrahuman reservoir of R prowazekii in the United States is flying squirrels, Glaucomys volans. Transmission to humans can occur through their ectoparasites, known as sylvatic typhus, usually causing atypical mild disease. A case of recrudescent (Brill-Zinsser) disease 11 years after disease acquired by contact with flying squirrels is reported. Foci of sylvatic typhus are found in the eastern United States and are reported to occur in Brazil, Ethiopia, and Mexico.

Clinical Findings

A. Symptoms and Signs

Prodromal malaise, cough, headache, backache, arthralgia, myalgia, and chest pain begin after an incubation period of 10–14 days, followed by an abrupt onset of chills, high fever, and prostration, with flu-like symptoms progressing to delirium and stupor. The headache is severe, and the fever is prolonged (Table 32–2).

Other findings consist of conjunctivitis, mild vitritis, retinal lesions, optic neuritis, and hearing loss from neuropathy of the eighth cranial nerve, abdominal pain, and often splenomegaly. Flushed faces and macular rash (that may become confluent) appear; the rash appears first in the axillae and then over the trunk, spreading to the extremities on the fifth or sixth day of illness but sparing the palms of hands and soles of feet. In severely ill patients, the rash becomes hemorrhagic, and hypotension becomes marked. Pneumonia, thromboses, vasculitis with major vessel obstruction and gangrene, circulatory collapse, myocarditis, uremia, and seizure may occur. Improvement begins 13–16 days after onset with a rapid drop of fever and typically a spontaneous recovery.

Brill-Zinsser disease has a more gradual onset than primary R prowazekii infection; fever and rash are of shorter duration, and the disease is milder.

B. Laboratory Findings

The white blood cell count is variable. Thrombocytopenia, elevated liver enzymes, proteinuria, and hematuria commonly occur. Serum obtained 5–12 days after onset of symptoms usually shows specific antibodies for R prowazekii antigens as demonstrated by complement fixation, microagglutination, or immunofluorescence. In primary rickettsial infection, early antibodies are IgM; in recrudescence (Brill-Zinsser disease), early antibodies are predominantly IgG. A PCR test exists, but its availability is limited.

C. Imaging

Radiographs of the chest may show patchy consolidation.

Differential Diagnosis

The prodromal symptoms and the early febrile stage lack enough specificity to permit diagnosis in nonepidemic situations. The rash is sufficiently distinctive for diagnosis, but it may be absent in up to 50% of cases or may be difficult to observe in dark-skinned persons. A variety of other acute febrile diseases should be considered, including typhoid fever, meningococcemia, and measles.

Treatment

Treatment consists of doxycycline 100 mg orally twice daily for 7–10 days or for at least 3 days after the fever subsides. A single dose of 200 mg of doxycycline may be effective; however, some patients may relapse. Chloramphenicol is considered less effective than doxycycline, but it is still the drug of choice in pregnancy.

Prognosis

The prognosis depends greatly on the patient’s age and immune status. The mortality rate is 10% in the second and third decades but in the past, it reached 60% in the sixth decade. Brill-Zinsser disease is rarely fatal.

Prevention

Prevention consists of louse control with insecticides, particularly by applying chemicals to clothing or treating it with heat, and frequent bathing.

A deloused and bathed typhus patient is not infectious. The disease is not transmitted from person to person. Patients are infectious from the lice during the febrile period and perhaps 2–3 days after the fever returns to normal.

No vaccine is available for the prevention of R prowazekii infection.

Ulutasdemir N et al. The epidemic typhus and trench fever are risk for public health due to increased migration in southeast of Turkey. Acta Trop. 2018 Feb;178:115–

8. [PMID: 29126839]

2. Endemic (Murine) Typhus

Rickettsia typhi, a ubiquitous pathogen recognized on all continents, is transmitted from rat to rat through the rat flea (Table 32–3). Serosurveys of animals show high prevalence of antibodies to R typhi in opossums, followed by dogs and cats. Humans usually acquire the infection in an urban or suburban setting when bitten by an infected flea. Rare human cases in the developed world occur in travelers, usually to Southeast Asia, Africa, or the Mediterranean area, although other pockets of infection are also known to occur in the Andes and the Yucatán. In the United States, the related Rickettsia felis cases (now a spotted fever rickettsia, discussed below) are mainly reported from Texas and southern California.

Clinical Findings

A. Symptoms and Signs

The presentation is nonspecific, including fever, headache, myalgia, and chills. Relative bradycardia is reported. Maculopapular rash occurs in around 50% of cases; it is concentrated on the trunk, mostly sparing the palms and soles, and fades rapidly.

The illness may be associated with maternal death, miscarriage, preterm birth, and low birth weight if acquired early during pregnancy.

B. Laboratory Findings

Serologic confirmation may be necessary for differentiation, with complement-fixing or immunofluorescent antibodies detectable within 15 days after onset, with specific R typhi antigens. A fourfold rise in serum antibody titers between the acute and the convalescent phase is diagnostic. It is important to note that R typhi antigens frequently cross-react with those of R prowazekii. The PCR can distinguish between these two infections depending on the sample type, the timing of sample collection, bacterial load, and severity of disease. During the first week of illness, PCR is the most sensitive test if samples are taken before doxycycline administration.

Differential Diagnosis

The most common entity in the differential diagnosis is Rocky Mountain spotted fever, usually occurring after rural exposure and with a different rash (centripetal versus centrifugal for epidemic or endemic typhus).

Complications

The most common complication is pulmonary, in the form of pneumonia, followed by pleural effusion and respiratory failure. Other complications include neurologic (peripheral facial paralysis, meningismus, ataxia, seizures), acute kidney injury, and multiorgan failure. Rare complications include ocular findings, disseminated intravascular coagulation, and hemophagocytosis syndrome. Anemia, thrombocytopenia, leukopenia, hyponatremia, and elevated levels of liver enzymes commonly occur.

Treatment

Doxycycline 100 mg orally twice daily for 7–10 days (or until the patient is afebrile for 48 hours) is the drug of choice, except during pregnancy. Ciprofloxacin (500–750 mg orally twice a day) and ampicillin (500 mg orally three times a day) are reportedly successful in pregnant women. Azithromycin is frequently used but is not associated with improved fetal outcomes.

Prevention

Preventive measures are directed at control of rats and ectoparasites (rat fleas) with insecticides, rat poisons, and rat-proofing of buildings.

Prognosis

Endemic typhus is usually a self-limited disease. A large case series from Texas reported a fatality rate of 0.4%.

3. Scrub Typhus (Tsutsugamushi Fever)

ESSENTIALS OF DIAGNOSIS

- Exposure to mites in endemic South and East Asia, the western Pacific (including Korea), and Australia.
- Black eschar at site of the bite, with regional and generalized lymphadenopathy.
- High fever, relative bradycardia, headache, myalgia, and a short-lived macular rash.
- Frequent pneumonitis, encephalitis, and myocarditis.

General Considerations

Scrub typhus is caused by Orientia tsutsugamushi, which is a parasite of rodents and is transmitted by larval trombiculid mites (chiggers). Multiple strains exist and are associated with geographic areas. The disease is endemic in Korea; China; Taiwan; Japan; Pakistan; India (where it is reported to be the leading cause of acute febrile illness in central India); Thailand (where scrub typhus is also the leading cause of acute undifferentiated fever); Malaysia; Vietnam; Laos; and Queensland, Australia (Table 32–3), which form an area known as the “tsutsugamushi triangle.” Scrub typhus is a cause of acute febrile illness in India and China and is a recognized cause of fever of unknown origin. Cases are also reported in the Middle East, Kenya, and South America. Transmission is often more common at higher altitudes. The mites live on vegetation (grass and brush) but complete their maturation cycle by biting humans who encounter infested vegetation. Risk factors in China include female sex, age between 60 and 69 years, and farming. Therefore, the disease is more common in rural areas, but urban cases have also been described. Vertical transmission occurs, and blood transfusions may transmit the pathogen as well. Rare occupational transmission via inhalation is documented among laboratory workers. Cases among travelers to endemic areas are increasingly recognized.

Clinical Findings

A. Symptoms and Signs

After a 1- to 3-week incubation period, malaise, chills, severe headache, and backache develop. At the site of the bite, a papule evolves into a flat black eschar (the groin and the abdomen being the most common sites followed by the chest and axilla), which is a helpful finding for diagnosis but was only described in 19% of patients in a South Korean series of scrub typhus. The regional lymph nodes are commonly enlarged and tender, and sometimes a more generalized adenopathy occurs. Fever rises gradually during the first week of infection, and the rash is usually macular and primarily on the trunk area. The rash can be fleeting or more severe, peaking at 8 days but lasting up to 21 days after onset of infection. Relative bradycardia, defined as an increase in heart rate of fewer than 10 beats/min for a 1-degree Celsius increase in temperature, frequently accompanies scrub typhus infection. The occurrence of relative bradycardia has no effect on clinical outcome. Gastrointestinal symptoms, including nausea, vomiting, and diarrhea, occur in nearly two-thirds of patients and correspond to the presence of superficial mucosal hemorrhage, multiple erosions, or ulcers in the gastrointestinal tract. Acute kidney injury and other renal abnormalities are frequently present.

Severe complications, such as pneumonitis, myocarditis, encephalitis or aseptic meningitis, peritonitis, granulomatous hepatitis, hemophagocytic syndrome, immune thrombocytopenia, disseminated intravascular coagulation, cerebrovascular hemorrhage or infarction, cranial nerve palsies, parkinsonian symptoms, ARDS, or hemophagocytosis, may develop during the second or third week. An attack confers prolonged immunity against homologous strains and transient immunity against heterologous strains. Heterologous strains produce mild disease if infection occurs within a year after the first episode.

B. Laboratory Findings

Thrombocytopenia and elevation of liver enzymes, bilirubin, and creatinine are common. Indirect immunofluorescent assay and indirect immunoperoxidase assays are the gold standard for scrub typhus diagnosis. These tests are expensive and have limited availability. An ELISA detecting Orientia specific antibodies in serum is available. PCR (from the eschar or blood) is the most sensitive diagnostic test but remains positive even after initiation of treatment. Culture of the organism from blood obtained in the first few days of illness is another diagnostic modality but requires a specialized biological safety level 3 laboratory. It is suggested to combine IgM detection by ELISA and conventional PCR to improve the diagnosis of scrub typhus.

Differential Diagnosis

Leptospirosis, typhoid, dengue, malaria, Q fever, hemorrhagic fevers, tuberculous meningitis, and other rickettsial infections should be considered. The headache may mimic trigeminal neuralgia. Scrub typhus is a recognized cause of obscure tropical fevers, especially in children. The presence of an eschar, lymphocytosis, and elevated C-reactive protein (CRP) helped distinguish scrub typhus from dengue in a Northern Thai study.

Treatment & Prognosis

Without treatment, fever subsides spontaneously after 2 weeks, but the mortality rate may be 10–30%. The treatment of choice is doxycycline (100 mg orally twice daily) or minocycline (100 mg intravenously twice daily) until there is evidence of clinical improvement for at least 3 days after the fever subsides. Shorter duration of therapy is associated with relapse. Alternative therapy for pregnant women and patients with doxycycline allergy include chloramphenicol, although chloramphenicol- and tetracycline-resistant strains have been reported from Southeast Asia. Azithromycin is shown to be as effective as doxycycline with fewer side effects, but it is more expensive. Azithromycin may not prevent poor fetal outcomes in infected pregnant women.

Poor prognostic factors include hypotension requiring vasopressors, ICU care, age over 60 years, absence of an eschar (making the diagnosis difficult), pregnancy, and laboratory findings such as leukocytosis or hypoalbuminemia. Most patients recover without neurologic sequelae.

Prevention

Mite control with repeated application of long-acting miticides and, less so, rodent control can make endemic areas safe. Insect repellents on clothing and skin as well as protective clothing are effective preventive measures. Although chemoprophylaxis with doxycycline has been used, the CDC does not recommend prophylaxis with antibiotics for asymptomatic travelers. No effective vaccines are available.

SPOTTED FEVERS

1. Rocky Mountain Spotted Fever

ESSENTIALS OF DIAGNOSIS

- Exposure to tick bite in an endemic area.
- Influenza-like prodrome followed by fever, severe headache, and myalgias; occasionally, delirium and coma.
- Red macular rash appears between days 2 and 6 of fever, first on the wrists and ankles and then spreading centrally; it may become petechial.
- Mortality over 70% in untreated patients.
- Serial serologic examinations by indirect fluorescent antibody confirm the diagnosis retrospectively.

General Considerations

Despite its name, most cases of Rocky Mountain spotted fever (RMSF) occur outside the Rocky Mountain area. More than half of the cases are from five states: North Carolina, Tennessee, Oklahoma, Missouri, and Arkansas. RMSF is endemic in Central and South America with a small fatal familial cluster reported from Panama (Table 32–3). Native Americans are at high risk for infection. The causative agent, R rickettsii, is transmitted to humans by the bite of ticks, including the Rocky Mountain wood tick, Dermacentor andersoni, in the western United States, and the American dog tick, D variabilis, in the eastern United States. Several hours of contact between the tick and the human host are required for transmission. The brown dog tick, Rhipicephalus sanguineus, is a vector in eastern Arizona and responsible for many Native American cases. Epidemic RMSF, as described in Arizona and Mexico, is associated with massive local infestations of the brown dog tick in domestic dogs, which may explain why the incidence of RMSF in the three most highly affected communities in an Arizona epidemic from 2003 to 2012 was 150 times the US national average. Other hard-bodied ticks transmit the organism in the southern United States and in Central and South America and are responsible for transmitting it among rodents, dogs, porcupines, and other animals. Human cases reemerged in Mexico in 2008 after decades of quiescence (since the 1940s). In 2015, northern Mexico reported a total of 1129 RMSF cases including 188 deaths, mostly in Sonora, Mexico.

There are 25 genotypes of R rickettsii in four different groups, and potential genomic-clinical correlations are underway. Several other rickettsial species cause mild, nonlethal infections in the United States, including R parkeri, R phillipi, and R massiliae. These are discussed in the “tick typhus” section.

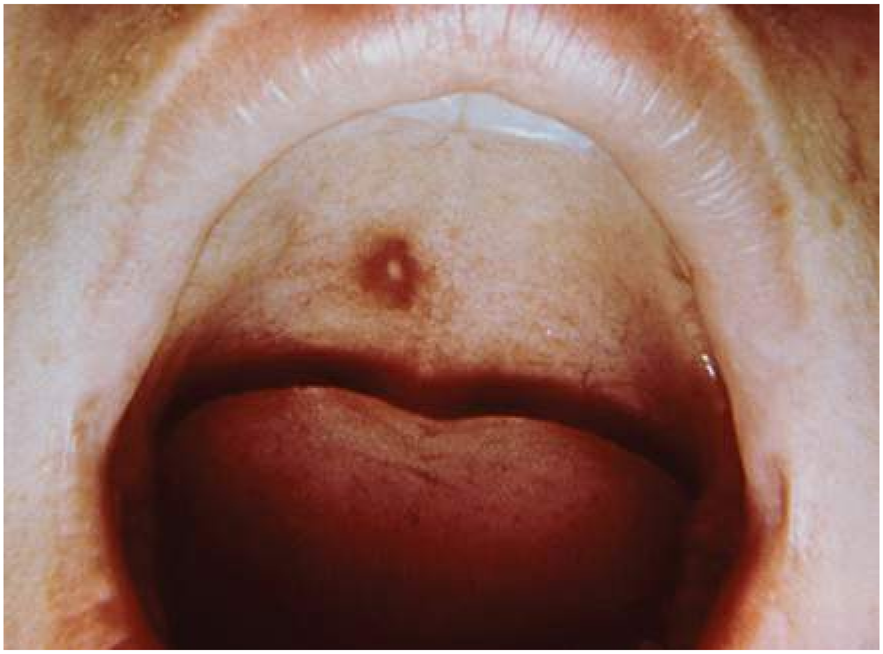
In the United States, the estimated annual incidence of RMSF is as high as seven cases per million persons (primarily occurring from April through September), with a higher incidence among children and men. Better diagnostic capacity and improved surveillance are thought responsible for the changing epidemiology.

A Brazilian spotted fever with higher mortality than RMSF is thought to be due to a virulent strain of R rickettsii. A host of spotted fever species have been identified from human patients over the last 20 years throughout the world including species from China (Rickettsia sp. XY99), Slovakia (R slovaca), Morocco (R aeschlimannii), Sicily (R massiiliae), China, and Egypt (R sibirica monolitimonae).

Clinical Findings

A. Symptoms and Signs

RMSF can cause severe multiorgan dysfunction and fatality rates of up to 73% if left untreated, making it the most serious rickettsial disease. Two to 14 days (mean, 7 days) after the bite of an infectious tick, symptoms begin with the abrupt onset of high fever, chills, headache, nausea and vomiting, myalgias, restlessness, insomnia, and irritability. The characteristic rash (faint macules that progress to maculopapules and then petechiae) appears between days 2 and 6 of fever. It initially involves the wrists and ankles, spreading centrally to the arms, legs, and trunk over the next 2–3 days. Involvement of the palms and soles is characteristic. Facial flushing, conjunctival injection, and hard palate lesions (Figure 32–7) may occur. In about 10% of cases, however, no rash or only a minimal rash is seen. Cough and pneumonitis may develop, and delirium, lethargy, seizures, stupor, and coma may also appear in more severe cases. Splenomegaly, hepatomegaly, jaundice, myocarditis (which may mimic an acute coronary syndrome), adrenal hemorrhage, polyarticular arthritis, or uremia is occasionally present. ARDS and necrotizing vasculitis, when present, are of greatest concern.



▲ **Figure 32–7. Hard palate lesion caused by Rocky Mountain spotted fever**. (Public Health Image Library, CDC.)

A group of four cases of RMSF in pregnant women from Sonora, Mexico, in 2015–2016, three of whom sustained spontaneous abortions, is a reminder of the grave risk of this infection for pregnant women and their fetuses.

B. Laboratory Findings

Thrombocytopenia, hyponatremia, elevated aminotransferases, and hyperbilirubinemia are common. CSF may show hypoglycorrhachia and mild pleocytosis. Disseminated intravascular coagulation is observed in severe cases. Diagnosis during the acute phase of the illness can be made by immunohistologic or PCR demonstration of R rickettsii in skin biopsy specimens (or cutaneous swabs of eschars or skin lesions). Performing such studies as soon as skin lesions become apparent and before antibiotics commence maximizes sensitivity.

Serologic studies confirm the diagnosis, but most patients do not mount an antibody response until the second week of illness. The indirect fluorescent antibody test is most commonly used.

Differential Diagnosis

The diagnosis is challenging because early symptoms resemble those of many other infections. The classic triad of fever, rash, and tick bite is rarely recognized, with up to 40% of patients not recalling a tick bite. Moreover, the rash may be confused with that of measles, typhoid, and ehrlichiosis, or—most importantly—meningococcemia. Blood cultures and examination of CSF establish the latter. Coinfections may mask the diagnosis. Some spotted fever rickettsioses may also mimic RMSF but will not be detected by routine serologic testing for RMSF.

Treatment & Prognosis

Treatment with doxycycline at similar doses and duration as for epidemic typhus (100 mg orally twice daily for 4–10 days) is recommended. Similarly, chloramphenicol (50–100 mg/kg/day in four divided doses, orally or intravenously for 4–10 days) is the preferred alternative during pregnancy. Patients usually defervesce within 48–72 hours, and therapy should be continued for at least 3 days after defervescence occurs.

The reported mortality rate for treated patients in the United States is about 3–5%. The following features are associated with increased mortality: (1) infection in older adults or Native Americans; (2) the presence of atypical clinical features (absence of headache, no history of tick attachment, gastrointestinal symptoms) and underlying chronic diseases; and (3) a delay in initiation of appropriate antibiotic therapy. The usual cause of death is pneumonitis with respiratory or cardiac failure. A fulminant form of RMSF can be seen in patients with glucose-6-phosphate dehydrogenase deficiency. Sequelae may include seizures, encephalopathy, peripheral neuropathy, paraparesis, bowel and bladder incontinence, cerebellar and vestibular dysfunction, hearing loss, and motor deficits.

Unfavorable prognostic factors for mortality from a 2017 Brazilian series of spotted fever cases included male sex, shock, seizures, and hypotension, and favorable prognostic factors were urban exposure, recognition of a tick, and lymphadenopathy. Recent Mexican cases were more severe among children under 10 years of age and among the very poor.

Prevention

Protective clothing, tick-repellent chemicals, and the removal of ticks at frequent intervals are helpful measures. The effectiveness of aggressive campaigns to decrease ticks in the community is under investigation in Native American communities with high RMSF attack rates. Prophylactic therapy after a tick bite is not recommended.

2. Tick Typhus (Rickettsial Fever)

The term "tick typhus" denotes a variety of spotted rickettsial fevers, often named by their geographic location (eg, Mediterranean spotted fever, Queensland tick typhus, Oriental spotted fever, African tick bite fever, Siberian tick typhus, North Asian tick typhus) or by morphology (eg, boutonneuse fever). These illnesses are caused by various rickettsial organisms (eg, R africae, R australis, R conorii, R japonica, R massiliae, R parkeri, R sibirica, and R 364D) and are transmitted by various tick species. Lymphangitis-associated rickettsiosis (LAR), caused by R sibirica mongolitimonae, was first described in 1996 and has been reported in Europe only thus far, including a small outbreak in Spain (Table 32–3). Dogs and wild animals, usually rodents and even reptiles, may serve as reservoirs for rickettsial fevers. Travel is a risk factor for disease, particularly among elderly ecotourists. In a series of 280 international travelers with rickettsial disease, the most common cause was spotted fever rickettsiosis (231 cases, 82.5% of the total) followed by scrub typhus (16, 5.7%).

Tick-borne rickettsioses are the main source of rickettsia infections in Europe and cause a syndrome similar to that seen in Mediterranean spotted fever. Newer recognized species include R helvetica, R monacensis, R massiliae, and R aeschlimannii. Another described syndrome is tick-borne lymphadenopathy/Dermacentor-borne-necrosis-erythema-lymphadenopathy/scalp eschar neck lymphadenopathy associated with R slovaca, Candidatus R rioja, and R raoultii and characterized by tick bite, eschar on the scalp, and cervical lymphadenopathy.

The pathogens usually produce an eschar or black spot (tâche noire) at the site of the tick bite that may be useful in diagnosis, though spotless boutonneuse fever occurs. Symptoms include fever, headache, myalgias, and rash. Painful lymphadenopathy or lymphangitis may also occur. Rarely, papulovesicular lesions may resemble rickettsialpox. Endothelial injury produces perivascular edema and dermal necrosis. Regional adenopathy, disseminated lesions, kidney disease, splenic rupture, and focal hepatic necrosis are observed. Neurologic manifestations, including encephalitis, internuclear ophthalmoplegia, coronary involvement, and the hemophagocytic syndrome, are rare.

The diagnosis is clinical, with serologic or PCR (culture can be used but is less sensitive than either) of the buffy coat of blood, or an eschar if one is available, used for confirmation. Treatment should be started upon clinical suspicion since delayed therapy is the usual cause of increased morbidity. Oral treatment with doxycycline (100 mg twice daily) or chloramphenicol (50–75 mg/kg/day in four divided doses) for 7–10 days is indicated. Caution is advised with the use of ciprofloxacin because it is associated with a poor outcome and increases the severity of disease in Mediterranean spotted fever. The combination of azithromycin and rifampin is effective and safe in pregnancy. Prevention entails protective clothing, repellents, and inspection for and removal of ticks.

Formerly classified as an endemic or murine typhus, the cat-flea typhus, caused by R felis is more properly classified as a spotted fever. The causative agent has been linked to the cat flea and opossum exposure. While the diseases appear to be ubiquitous, most cases in the United States (southern Texas and California, and possibly Hawaii) occur in the spring and summer. Treatment is the same as for other rickettsial fevers.

Cases of non-rickettsiae–associated spotted fever tend to have a better prognosis than due those due to R rickettsiae infection. Treatment for non-rickettsiae–associated spotted fever as well as R rickettsiae infection is with tetracycline, and there is some laboratory evidence that these organisms may be less responsive to macrolides.

RICKETTSIALPOX

Rickettsialpox is an acute, self-limiting, febrile illness caused by Rickettsia akari, a parasite of mice, transmitted by the mite Liponyssoides sanguineus (Table 32–3). Because rickettsialpox has features of both the typhus group and of the spotted fever group of rickettsia, it falls into its own “transitional” category. R akari infections are reported globally. Seroprevalence studies among injection drug users in Baltimore show seropositivity as high as 16%. In New York, its association with poverty is very strong. The illness has also been found in farming communities. Crowded conditions and mouse-infested housing allow transmission of the pathogen to humans. The classic triad of fever, rash, and eschar is found in 99% of cases. The primary lesion is a painless red papule that appears at variable times but on the average a week after a mite bite. The lesion often vesiculates and forms a black eschar.

The onset of symptoms—chills, fever, headache, photophobia, and disseminated aches and pains—is sudden. The fever may be followed by a widespread papular eruption 2–4 days later, with an average of 30–40 lesions that spare the palms and soles. The interval from vesiculation to crust formation is about 10 days. Early lesions may resemble those of chickenpox (typically vesicular versus papulovesicular in rickettsialpox). Pathologic findings include dermal edema, subepidermal vesicles, and at times a lymphocytic vasculitis.

Transient leukopenia and thrombocytopenia and acute hepatitis can occur. A fourfold rise in serum antibody titers to rickettsial antigen, detected by complement fixation or indirect fluorescent assays, is diagnostic and available through the CDC. Conjugated anti-rickettsial globulin can identify antigen in punch biopsies of skin lesions. PCR detection of rickettsial DNA in fresh tissue also appears of value. R akari can also be isolated from eschar biopsy specimens.

Treatment consists of oral doxycycline (100 mg twice daily) for 2–5 days or until defervescence. The disease is usually mild and self-limited without treatment, but occasionally, severe symptoms may require hospitalization. Control requires the elimination of mice from human habitations and insecticide applications.

OTHER RICKETTSIAL & RICKETTSIAL-LIKE DISEASES

1. Ehrlichiosis & Anaplasmosis

ESSENTIALS OF DIAGNOSIS

- Infection of monocyte or granulocyte by tick-borne gram-negative bacteria.
- Nine-day incubation period; clinical disease ranges from asymptomatic to life-threatening.
- Malaise, nausea, fever, and headaches.
- US cases of ehrlichiosis typically occur in men aged 60–69 years; US cases of anaplasmosis typically occur in men aged over 40 years; both occur in the summer, with different geographic areas of prevalence.
- Excellent response to therapy with tetracyclines.

General Considerations

Human ehrlichiosis and anaplasmosis are endemic in the United States.

Ehrlichia chaffeensis (Table 32–3), the most common species infecting humans, is seen primarily in the south-central United States (especially Arkansas, Missouri, Oklahoma, and New York). Ehrlichia ewingii causes human granulocytic ehrlichiosis similar to anaplasmosis and constitutes almost 10% of ehrlichiosis cases; most cases in the United States are reported from the Midwest and Southeast. A new species of Ehrlichia isolated in 2009 is referred to as Ehrlichia muris eauclairensis and is seen in the upper Midwestern United States. Human granulocytic anaplasmosis is caused by Anaplasma phagocytophilum; most cases in the United States are reported from New England, New York, Minnesota, and Wisconsin. Increasingly, anaplasmosis is being reported from Asia, South Korea, Mongolia, China (where a new species is identified, Anaplasma capra), and Northern Europe.

In North America, the major tick-borne rickettsial disease vectors for these pathogens are (1) the Lone Star tick (Amblyomma americanus), which is the vector for E chaffeensis and E ewingii; (2) the black-legged tick (Ixodes scapularis), which is a vector for B burgdorferi (Lyme disease), Babesia microti (babesiosis), and A phagocytophilum (anaplasmosis), and a possible vector for E muris eauclairensis; and (3) the western black-legged tick (Ixodes pacificus), which is a vector for A phagocytophilum along the Pacific coast of the United States. Vectors for European and Asian cases are not reported to date. The principal reservoirs for human monocytic ehrlichiosis and human granulocytic anaplasmosis are the white tail deer and the white-footed mouse, respectively. Other mammals are implicated as well. Transfusion-transmitted anaplasmosis has been reported.

CDC reports indicate that the incidences of human monocytic ehrlichiosis, granulocytic ehrlichiosis and, in particular, anaplasmosis are increasing; cases are reportable to local and state health departments. Because more than one agent may coexist in the same area, cases of human ehrlichiosis and anaplasmosis may be reported as “human ehrlichiosis/anaplasmosis undetermined” in the absence of species identification.

Neorickettsia sennetsu is a related rickettsial pathogen that causes rare infection in Southeast Asia among populations who consume raw fish.

The case fatality rate is 1% with E chaffeensis infections and 0.3% among cases of human anaplasmosis. Contrary to earlier reports, most recent cases of E ewingii infection have occurred among immunocompetent patients. No deaths have been reported from either E ewingii or E muris eauclairensis.

Clinical Findings

A. Symptoms and Signs

Clinical disease of human monocytic ehrlichiosis ranges from mild to life-threatening.

Typically, after a 1- to 2-week incubation period and a prodrome consisting of malaise, rigors, and nausea, high fever and headache develop. A pleomorphic rash may occur. Presentation in immunosuppressed patients (including transplant patients) and older patients tends to be more severe. Rare serious sequelae include acute respiratory failure and ARDS; neurologic complications, the most common being meningoencephalitis and aseptic meningitis; acute kidney disease (which may mimic thrombotic thrombocytopenic purpura); hemophagocytic syndrome; and multiorgan failure.

The clinical manifestations of human granulocytic ehrlichiosis and anaplasmosis are similar to those seen with human monocytic ehrlichiosis. Rash, however, is infrequent. If a rash is present, coinfection with other tick-borne diseases or an alternative diagnosis should be suspected. Persistent fever and malaise are reported to occur for 2 or more years. Reported complications of anaplasmosis include leukopenia, thrombocytopenia, and cerebral infarction.

Coinfection with anaplasmosis and Lyme disease or babesiosis may occur, but the clinical manifestations (including fever and cytopenias) are more severe with anaplasmosis than with Lyme disease. A spirochete, Borrelia miyamotoi, may mimic anaplasmosis in its clinical manifestations.

B. Laboratory Findings

Diagnosis can be made by the history of tick exposure followed by a characteristic clinical presentation. Leukopenia, absolute lymphopenia, thrombocytopenia, and transaminitis occur often. Thrombocytopenia occurs more often than leukopenia in human granulocytic ehrlichiosis. Examination of peripheral blood with Giemsa stain may reveal characteristic intraleukocytic vacuoles (morulae) in up to 20% of patients. An indirect fluorescent antibody assay is available through the CDC and requires acute and convalescent sera. A PCR assay can be helpful for making the diagnosis early in the disease course. PCR assay is most sensitive in the first week of illness and can be used as a confirmatory test.

Treatment & Prevention

Treatment for human ehrlichiosis and anaplasmosis is with doxycycline, 100 mg twice daily (orally or intravenously) for 10–14 days or until 3 days of defervescence. Rifampin is an alternative in pregnant women. Treatment should not be withheld while awaiting confirmatory serology when suspicion is high. Lack of clinical improvement and defervescence 48 hours after doxycycline initiation suggests an alternate diagnosis. Some patients may continue to have headache, weakness, and malaise for weeks despite adequate treatment. Tick control is the essence of prevention.

Centers for Disease Control and Prevention (CDC). Ehrlichiosis: epidemiology and statistics. Last reviewed 2019 Feb 11. https://www.cdc.gov/ehrlichiosis/stats/index.html

Centers for Disease Control and Prevention (CDC). Anaplasmosis: epidemiology and statistics. Last reviewed 2019 Feb 19. https://www.cdc.gov/anaplasmosis/stats/index.html

2. Q Fever (Coxiella burnetti Infection)

ESSENTIALS OF DIAGNOSIS

- Exposure to sheep, goats, cattle, or their products; some infections are laboratory acquired.
- Acute or chronic febrile illness: headache, cough, prostration, and abdominal pain.
- Pneumonitis, hepatitis, or encephalopathy; less often, endocarditis, vascular infections, or chronic fatigue syndrome.
- A common cause of culture-negative endocarditis.

General Considerations

Q fever, a reportable and significantly underestimated disease in the United States, is caused by the gram-negative intracellular coccobacillus C burnetii. Coxiella infections occur globally, mostly in cattle, sheep, and goats, in which they cause mild or subclinical disease (Table 32–3). In these animals, reactivation of the infection occurs during pregnancy and causes abortions or low birth weight offspring. Coxiella is resistant to heat and drying and remains infective in the environment for months.

Human infection occurs via inhalation of aerosolized bacteria (in dust or droplets) from feces, urine, milk, or products of conception of infected animals. Ingestion and skin penetration are other recognized routes of transmission. A major outbreak in the Netherlands during 2007–2010 was thought to be due inhalation of aborted cattle products of conception associated with changes in breeding practices. There is a known occupational risk for animal handlers, slaughterhouse workers, veterinarians, laboratory workers, and other workers exposed to animal products. In the United States, over 60% of cases do not report an exposure to potentially infectious animals, but cases are more than twice as likely as non-cases to report drinking raw milk.

Human-to-human transmission does not seem to occur, but maternal-fetal infection can occur and infection after liver transplant is reported.

Clinical Findings

A. Symptoms and Signs

Asymptomatic infection is common. For the remaining cases, a febrile illness develops after an incubation period of 2–3 weeks, usually accompanied by headache, relative bradycardia, prostration, and muscle pains. The clinical course may be acute, chronic (duration 6 months or longer), or relapsing. Pneumonia and granulomatous hepatitis are the predominant manifestations in the acute form (and these may vary in incidence geographically), whereas other less common manifestations include skin rashes (maculopapular or purpuric), fever of unknown origin, myocarditis, pericarditis, aortic aneurysms, aseptic meningitis, encephalitis, orchitis, iliopsoas abscess, spondylodiscitis, tenosynovitis, granulomatous osteomyelitis (more often seen in children), and regional (mediastinal) or diffuse lymphadenopathies.

It has been recommended that the term "chronic Q fever" be abandoned to avoid confusion and be replaced with "persistent focalized infections." The most common presentation in patients with persistent focalized infections is culture-negative endocarditis. Risk factors for endocarditis are the immunocompromised state, presence of preexisting valvular conditions, male sex, and age above 40 years. Valvular prosthesis (mechanical or bioprosthesis) represents the most important risk factor. In series of post-cardiac surgery patients with culture-negative endocarditis, Q fever is often the most common cause (about 40% of cases).

The clinical manifestations of endocarditis are nonspecific with fever, night sweats, and weight loss. Rarely, urticaria, edema, erythema nodosum, and arthralgias are reported. Sudden cardiac insufficiency, stroke, or other embolic and mycotic aneurysms can also develop. Vascular infections, particularly of the aorta (causing mycotic aneurysms) and of graft prostheses, are the second most common presentation and are associated with a high mortality (25%). A post–Q fever chronic fatigue syndrome (1 year after acute infection with chronic symptoms) is controversial and of unknown pathophysiology. Cognitive behavioral therapy is effective in reducing fatigue severity in patients with Q fever fatigue syndrome; long-term treatment with doxycycline has not been shown to be effective.

New infection or reactivation of Q fever can occur in pregnant women and is associated with spontaneous abortions, intrauterine growth retardation, intrauterine fetal death, and premature delivery. C burnetii infection during the first trimester can cause oligohydramnios.

B. Laboratory Findings

Laboratory examination during the acute phase may show elevated liver biochemical tests and occasional leukocytosis. Patients with acute Q fever usually produce antibodies to C burnetii phase II antigen (phase II antigens are formed in vitro from deleted avirulent mutants and are empirically more commonly seen in acute disease, whereas phase I antigens, seen in nature and laboratory infections, are found in the IgG form in chronic disease). A fourfold rise between acute and convalescent sera by indirect immunofluorescence is diagnostic of the infection. Real-time PCR for C burnetii DNA is helpful only in early diagnosis of Q fever. C burnetii DNA becomes undetectable in serum as serologic responses develop. The positive predictive value of antibodies to phase II antigens in acute disease is at most 65%, and considerable intertest variability exists with phase 2 antigens. Diagnostic tests combining PCR with ELISA (Immuno-PCR) improve the sensitivity and specificity during the first 2 weeks after the onset of symptoms.

While persistent infection can be diagnosed based on serologic tests done at 3- and 6-month intervals (with an IgG titer against phase I antigen of 1:1600 or greater), the sensitivity of such serologies is often low, and the diagnosis of Q fever is often made clinically. An automated epifluorescence assay has greater than 95% sensitivity for the detection of phase I antigens in persistent infection. C burnetii–specific interferon-gamma, interferon-gamma/IL-2 ratio has a sensitivity of 79% and a specificity and 97% for the diagnosis of persistent infection.

Diagnosis of Q fever endocarditis is often made at the time of valve replacement with PCR of tissue samples. C burnetii may also be isolated from affected valves using the shell-vial technique.

C. Imaging

Radiographs of the chest can show patchy pulmonary infiltrates. All patients with acute Q fever should be screened for underlying valvular disease with echocardiography. Initial imaging and follow-up with serial 18-FDG PET/CT scan may be helpful in identifying chronic infection and monitoring treatment response.

Differential Diagnosis

Viral, mycoplasma, and bacterial pneumonias; viral hepatitis; brucellosis; Legionnaire disease; murine or scrub typhus; Kawasaki disease; tuberculosis; psittacosis; and other animal-borne diseases can have similar clinical presentations to Q fever. Q fever should be considered in cases of unexplained fevers with negative blood cultures in association with embolic or cardiac disease. Cases of Q fever can mimic autoimmune disease. Coinfection with typhus and leptospirosis is reported.

Treatment & Prognosis

Doxycycline is the most effective drug against C burnetii; there are rare reports of doxycycline resistance. Isolates remain susceptible to levofloxacin, moxifloxacin, and to a lesser extent ciprofloxacin. No resistance to sulfamethoxazole-trimethoprim is reported to date.

For acute infection, treatment with doxycycline (100 mg orally twice daily) for 14 days or at least 3 full days after defervescence is recommended. Even in untreated patients, the mortality rate is usually low, except when endocarditis develops.

There are no clear guidelines on the treatment of persistent C burnetii infections. To date, there is no antibiotic that has bactericidal effect against C burnetii. Most experts recommend a combination oral therapy with doxycycline (100 mg twice a day) plus a quinolone, rifampin, or hydroxychloroquine for approximately 18 months for native valve endocarditis and 24 months for prosthetic valve endocarditis.

Serologic responses can be monitored during and after completion of therapy and treatment can be extended in the absence of favorable serologic response. The general variability of serologic data, however, limits their usefulness and providers usually rely on clinical criteria. Patients should be monitored for at least 5 years due to risk of relapse.

For patients with endocarditis, clinical cure is possible without valve replacement. Heart valve replacement is not associated with better survival, except in the group of patients with a valvular prosthesis. Given the difficulty in treating endocarditis, transthoracic echocardiography is recommended to screen for predisposing valvulopathy in all patients with acute Q fever, and the same therapy for 1 year should be offered in the presence of valvulopathy. In addition, patients undergoing routine valve surgery should have routine Q fever serologies in endemic countries and appropriate treatment if tests are positive for Q fever.

All infected pregnant women should be given long-term trimethoprim-sulfamethoxazole (320/1600 mg orally for the duration of pregnancy, but not beyond 32 weeks' gestation) to prevent the obstetric complications.

In retrospective studies, an increased risk of diffuse B-cell lymphoma and follicular lymphoma was found in patients with Q fever compared with the general population. Patients with persistent focalized infections were at higher risk for lymphadenitis and progression to lymphoma.

Prevention

Prevention is based on detection of the infection in livestock, with reduction of contact with infected and parturient animals or contaminated dust; special care when working with animal tissues; and effective pasteurization of milk. A whole-cell Q fever vaccine is available in Australia for persons with high-risk exposures, although there are reports of vaccine failure more than 15 days after vaccination.

The organism is highly transmissible to laboratory workers and culture techniques require a biosafety level 3 setting. C burnetii is a category B bioterrorism agent. In the setting of a bioterrorist attack, postexposure prophylaxis with doxycycline 100 mg orally twice a day for 5–7 days should be administered within 8–12 days of exposure. Pregnant women may take trimethoprim-sulfamethoxazole as an alternative.

KAWASAKI DISEASE

ESSENTIALS OF DIAGNOSIS

- Fever, conjunctivitis, oral mucosal changes, rash, cervical lymphadenopathy, peripheral extremity changes.
- Elevated ESR and CRP levels.
- Risk for coronary arteritis and aneurysms.

General Considerations

Kawasaki disease is a worldwide multisystem disease. It is also known as the “mucocutaneous lymph node syndrome.” It occurs mainly in children between the ages of 3 months and 5 years but can occur occasionally in adults as well. Kawasaki disease occurs most often in Asians or native Pacific Islanders. Its incidence in Japan is twice that of the United States, and it occurs among siblings at twice the incidence of cases and at higher rates among parents of cases. These findings plus the known seasonality (higher incidence in winter and early spring) and occasional epidemic pattern of cases point to the inadequate current understanding of the etiology of this disease.

It is an acute, self-limiting, mucocutaneous vasculitis characterized by the infiltration of vessel walls with mononuclear cells and later by IgA secreting plasma cells that can result in the destruction of the tunica media and aneurysm formation. The cause of Kawasaki disease remains unknown. Epidemiologic studies show an increased risk with advanced maternal age, mother of foreign birth, maternal group B Streptococcus colonization, and early infancy hospitalization for a bacterial illness. Genetic factors are considered to play an important role in the pathogenesis of the disease. Ongoing analyses identify many gene polymorphisms, which significantly correlate with Kawasaki disease susceptibility (at least 23 to disease, and 10 to the presence of coronary aneurysms).

Clinical Findings

A clinical diagnosis of classic or "complete" Kawasaki disease requires the presence of at least 5 days of fever, usually high-grade (over 39°C to 40°C) and four of the following five criteria: (1) bilateral nonexudative conjunctivitis (begins shortly after the onset of fever), (2) oral changes (erythema and cracking of lips, strawberry tongue, and erythema of oral and pharyngeal mucosa; ulcers and pharyngeal exudates are not consistent with Kawasaki disease), (3) peripheral extremity changes (erythema and edema of the hands and feet in the acute phase, and/or periungual desquamation within 2 to 3 weeks after the onset of fever), (4) polymorphous rash, and (5) cervical lymphadenopathy (larger than 1.5 cm diameter, usually unilateral; least common of the clinical features). The revised case definition allows the diagnosis on day 4 in the presence of more than four principal clinical criteria, particularly when redness and swelling of the hands and feet are present.

A diagnosis of atypical or "incomplete" Kawasaki disease could be diagnosed in patients with unexplained fever and fewer than four principal criteria if accompanied by compatible laboratory or findings of aneurysms detected by echocardiography or angiography.

Laboratory findings in the acute phase typically include leukocytosis with neutrophilic predominance, anemia, and an elevated ESR and CRP. High platelet counts are characteristic but occur in the second week. N-terminal moiety of B-type natriuretic peptide (NT-proBNP), likely indicative of myocardial involvement, may be elevated in some patients with Kawasaki disease.

Major complications include arteritis and aneurysms of the coronary vessels. The arteritis begins 6–8 days after the onset of disease, occurs in about 25% of untreated patients, and occasionally causes myocardial infarction. Coronary complications are more common among patients older than 6 years or younger than 1 year of age; males;

and those unresponsive to IVIG, who received a smaller dose of IVIG, or did not receive treatment within 10 days of symptom onset. While myocarditis can be found in all patients with Kawasaki disease on histologic specimens and is prominent during the acute stage, only a small percentage of patients are clinically symptomatic.

Cardiac complications include left ventricular dysfunction, which usually normalizes promptly with IVIG therapy, and mitral regurgitation, which occurs early and does not appear to persist. Noninvasive diagnosis of coronary complications can be made with CT coronary angiography (the most sensitive test), magnetic resonance angiography, or transthoracic echocardiography (advocated for early screening). Kawasaki shock syndrome is a complication, with an estimated incidence of 7%, possibly caused by decrease in peripheral vascular resistance, myocarditis with or without myocardial ischemia, and capillary leakage.

The multisystemic findings of Kawasaki disease show it to be a systemic disease that affects medium-sized arteries of multiple organs, causing elevations in serum transaminases, interstitial pneumonitis, abdominal pain, vomiting, diarrhea, gallbladder hydrops, pancreatitis, lymphadenopathy, hypoalbuminemia, arrhythmias, aseptic meningitis, acute encephalopathy with biphasic seizures and late reduced diffusion, retinal and choroidal detachment, pulmonary complications (effusions, empyema, pneumothorax), hemophagocytic lymphohistiocytosis syndrome, and pyuria. CSF pleocytosis with a mononuclear cell predominance, normal glucose levels, and protein levels is seen in one-third of children who undergo lumbar puncture.

Other diseases with similar presentation that should be considered include measles in unimmunized children as well as other viral infections, such as adenovirus, scarlet fever, and toxic shock syndrome; rickettsial infections; or leptospirosis and drug hypersensitivity reactions.

Treatment & Prevention

All patients meeting the diagnostic criteria for Kawasaki disease (complete and incomplete), including patients with recurrent Kawasaki disease, should be treated as soon as the diagnosis is suspected to reduce inflammation and arterial damage.

A single dose of IVIG should be given in the first 10 days of the illness. Patients in whom the diagnosis was made later than the tenth day may still benefit from IVIG treatment if they have elevated inflammatory markers (ESR or CRP), with persistent fever or have coronary artery aneurysms. When IVIG treatment is not given, coronary artery aneurysms occur in 20% of children. Even when treated with IVIG within the first 10 days of illness, coronary artery aneurysms still develop in 5% of patients. Rare cases of aseptic meningitis are reported with IVIG. Coombs-positive hemolytic anemia, especially in individuals with AB blood type and anaphylactic reactions to immunoglobulins with selective IgA deficiency are other complications associated with

IVIG administration.

Although aspirin does not lower the frequency of development of coronary abnormalities, it has important anti-inflammatory activity and antiplatelet activity. Concomitant aspirin with IVIG should be started at 80–100 mg/kg/day orally (divided into four doses and not exceeding 4 g/day) until the patient is afebrile for 48 hours and then reduced to 3–5 mg/kg/day until markers of acute inflammation normalize. Since ibuprofen antagonizes the irreversible platelet inhibition induced by aspirin, it should be avoided when aspirin is given.

The use of corticosteroids for children with Kawasaki disease is controversial. According to the most recent published guidelines by the American Heart Association, single-dose pulse methylprednisolone should not be used routinely for patients with Kawasaki disease. A course of corticosteroid therapy with tapering over 2–3 weeks could be considered in addition to IVIG and aspirin for patients at high-risk for not responding to IVIG.

Resistant Kawasaki disease, defined as having recrudescent or persistent fever at least 36 hours after the end of the first IVIG infusion when no other source of fever is found, develops in about 10–20% of patients. The Egami score is a predictor used in Japan to help determine who will respond to IVIG, although the scoring system has been shown to have lower utility in US cases. The presence of coronary artery abnormalities on the initial echocardiogram and their presence before day 5 of fever predict nonresponse to IVIG in one Israeli study.

Options for refractory cases include a second dose of IVIG, high-dose pulse corticosteroids over 3 days with or without a subsequent oral taper course, longer oral tapering course of corticosteroids over 2–3 weeks together with IVIG and aspirin, infliximab, the anti-inflammatory interleukin 1 receptor antagonist anakinra, low-dose methotrexate, and cyclosporine. Immunomodulatory monoclonal antibody therapy and cytotoxic agents, or (rarely) plasma exchange should be considered only in highly refractory cases in which other therapy has failed.

The most common serious complication in the acute phase is thrombotic occlusion of a coronary artery aneurysm leading to myocardial infarction or sudden death. An echocardiogram is recommended within 1–2 weeks and 4–6 weeks after treatment for uncomplicated patients. More frequent imaging is recommended for patients with significant and evolving coronary artery abnormalities. Anticoagulation with warfarin or low-molecular-weight heparin is indicated, along with aspirin, in patients with rapidly expanding coronary artery aneurysms. Aspirin, a second antiplatelet agent, and anticoagulation with warfarin, low-molecular-weight heparin, or direct-acting oral anticoagulants (which need further study in this population) may be considered for patients with large or giant aneurysms (at least 8 mm) (which correlate with delay in diagnosis) and a recent history of coronary artery thrombosis. If myocardial infarction occurs, therapy with thrombolytics, percutaneous coronary intervention, coronary artery bypass grafts, and even cardiac transplantation should be considered. Manifestations of coronary artery aneurysms can occur as late as in the third or fourth decade of life with a study showing a prevalence of 5% coronary sequelae from Kawasaki disease among young adults evaluated with angiography. Calcified coronary aneurysms on CT scans are less likely to regress.

Prognosis

The reported recurrence rate is 3% in one study from Japan. The highest risk of recurrence occurs in the first 2 years after the first episode. The mortality peaks between 15 and 45 days after the onset of fever, at the time of coronary artery vasculitis, thrombocytosis, and a hypercoagulable state.

Over the long-term, the risk for clinical cardiac events in patients with no coronary artery abnormalities is similar to the general population. For patients in whom coronary artery abnormalities developed, the risk for cardiac complications, such as thrombosis, stenosis, myocardial infarction, and death, ranges between 1% and 48%. Follow-up is especially needed among the subset of patients with neutropenia who have been treated with IVIG. The administration of IVIG is shown to improve left ventricular function. The AHA recommends risk stratification based on the assessment of coronary luminal dimensions by echocardiogram, under cardiologic supervision. The frequency of clinical follow-up, diagnostic testing, reproductive counseling, indications for medical therapy (beta-blockers, statins), and thromboprophylaxis (aspirin and anticoagulation) depends on the individual's risk assessment.

When to Refer

All cases of Kawasaki disease merit referral to specialists.

Bacterial & Chlamydial Infections

Bryn A. Boslett, MD
Brian S. Schwartz, MD

INFECTIONS CAUSED BY GRAM-POSITIVE BACTERIA

STREPTOCOCCAL INFECTIONS

1. Pharyngitis

ESSENTIALS OF DIAGNOSIS

- Abrupt onset of sore throat, fever, malaise, nausea.
- Throat red and edematous, with or without exudate; cervical nodes tender.
- Diagnosis confirmed by culture of throat.

General Considerations

Group A beta-hemolytic streptococci (Streptococcus pyogenes) are the most common bacterial cause of pharyngitis. Transmission occurs by droplets of infected secretions. Group A streptococci producing erythrogenic toxin may cause scarlet fever in susceptible persons.

Clinical Findings

A. Symptoms and Signs

"Strep throat" is characterized by a sudden onset of fever, sore throat, pain on swallowing, tender cervical adenopathy, malaise, and nausea. The pharynx, soft palate, and tonsils are red and edematous. There may be a purulent exudate. The **Centor clinical criteria** for the diagnosis of streptococcal pharyngitis are temperature greater than 38°C, tender anterior cervical adenopathy, lack of a cough, and pharyngotonsillar exudate.

The rash of **scarlet fever** (also called scarletina) is diffusely erythematous and resembles a sunburn, and superimposed fine red papules give the skin a sandpaper consistency; it is most intense in the groin and axillas. It blanches on pressure, may become petechial, and fades in 2–5 days, leaving a fine desquamation. The face is flushed, with circumoral pallor, and the tongue is coated with enlarged red papillae (strawberry tongue).

B. Laboratory Findings

Leukocytosis with neutrophil predominance is common. Throat culture onto a single blood agar plate has a sensitivity of 80–90%. Rapid diagnostic tests based on detection of streptococcal antigen are slightly less sensitive than culture. Clinical criteria, such as the Centor criteria, are useful for identifying patients in whom a rapid antigen test or throat culture is indicated. Patients who meet two or more of these criteria merit further testing. When three of the four are present, laboratory sensitivity of rapid antigen testing exceeds 90%. When only one criterion is present, streptococcal pharyngitis is unlikely. In high-prevalence settings or if clinical suspicion for streptococcal pharyngitis is high, a negative antigen test or culture should be confirmed by a follow-up culture.

Complications

Suppurative complications include sinusitis, otitis media, mastoiditis, peritonsillar abscess, and cervical lymphadenitis.

Nonsuppurative complications are rheumatic fever and glomerulonephritis. Rheumatic fever may follow recurrent episodes of pharyngitis beginning 1–4 weeks after the onset of symptoms. Glomerulonephritis follows a single infection with a nephritogenic strain of streptococcus group A (eg, types 4, 12, 2, 49, and 60), more commonly on the skin than in the throat, and begins 1–3 weeks after the onset of the infection. These complications are more common in children.

Differential Diagnosis

Streptococcal sore throat resembles (and cannot be reliably distinguished clinically from) pharyngitis caused by viruses such as adenoviruses, Epstein-Barr virus, or other bacteria such as Fusobacterium necrophorum and Arcanobacterium haemolyticum (which also may cause a rash). Pharyngitis and lymphadenopathy are common findings in acute HIV infection. Generalized lymphadenopathy, splenomegaly, atypical lymphocytosis, and a positive serologic test distinguish mononucleosis from streptococcal pharyngitis. Diphtheria is characterized by a pseudomembrane; oropharyngeal candidiasis shows white patches of exudate and less erythema; and necrotizing ulcerative gingivostomatitis (Vincent fusospirochetal gingivitis or stomatitis) presents with shallow ulcers in the mouth. Neisseria gonorrhoeae, Chlamydia trachomatis, and primary herpes simplex virus should be considered in those with risk factors. Retropharyngeal abscess or bacterial epiglottitis should be considered when odynophagia and difficulty in handling secretions are present and when the severity of symptoms is disproportionate to findings on examination of the pharynx. F necrophorum causes pharyngitis at a similar rate as group A beta-hemolytic streptococci in adolescents and young adults. F necrophorum pharyngitis is associated with Lemierre syndrome, suppurative thrombophlebitis of the internal jugular vein, bacteremia, and metastatic infections. Early recognition and treatment of this syndrome is important.

Treatment

Antimicrobial therapy has a modest effect on resolution of symptoms and primarily is administered for prevention of complications. Antibiotic therapy can be safely delayed until the diagnosis is established on the basis of a positive antigen test or culture. Empiric therapy usually is not a cost-effective approach to the management of most adults with pharyngitis because the prevalence of streptococcal pharyngitis is likely to be no more than 10–20% in typical clinical settings. The positive predictive value of clinical criteria is low. Since macrolides are not reliable against F necrophorum infection, adolescents or young adults with pharyngitis and unconfirmed streptococcal infection should be given penicillin or amoxicillin preferentially at the doses listed below. If the pharyngitis does not resolve quickly, symptoms worsen, or unilateral neck swelling develops, clinicians should consider suppurative complications such as peritonsillar abscess and Lemierre syndrome.

A. Benzathine Penicillin G

Benzathine penicillin G, 1.2 million units intramuscularly as a single dose, is optimal therapy.

B. Penicillin VK

Penicillin VK, 250 mg orally four times daily or 500 mg orally twice daily for 10 days, is effective.

C. Amoxicillin

Amoxicillin, 1000 mg orally once daily or 500 mg orally twice daily for 10 days, is another option.

D. Cephalosporins

Cephalexin, 500 mg orally twice daily for 10 days, cefdinir, 300 mg orally twice daily for 5–10 days or 600 mg orally once daily for 10 days, cefadroxil, 1000 mg orally once daily for 10 days, and cefpodoxime, 100 mg orally twice daily for 5–10 days, should be reserved for penicillin-allergic patients who do not have immediate-type hypersensitivity.

E. Macrolides

Erythromycin, 500 mg orally four times a day, or azithromycin, 500 mg orally once daily for 5 days, is an alternative for the penicillin-allergic patient. Macrolides are less effective than penicillins and are considered second-line agents. Macrolide-resistant strains almost always are susceptible to clindamycin, a suitable alternative to penicillins; a 10-day course of 300 mg orally three times daily is effective.

Prevention of Recurrent Rheumatic Fever

Effectively controlling rheumatic fever depends on identification and treatment of primary streptococcal infection and secondary prevention of recurrences. Patients who have had rheumatic fever should be treated with a continuous course of antimicrobial prophylaxis for at least 5 years. Effective regimens are erythromycin, 250 mg orally twice daily, or penicillin G, 500 mg orally daily.

When to Refer

Patients with peritonsillar or retropharyngeal abscess should be referred to an otolaryngologist.

When to Admit

- Odynophagia resulting in dehydration.
- Suspected or known epiglottitis.

van Driel ML et al. Different antibiotic treatments for group A streptococcal pharyngitis. Cochrane Database Syst Rev. 2016 Sep 11;9:CD004406. [PMID:

27614728]

2. Streptococcal Skin Infections

Group A beta-hemolytic streptococci are not normal skin flora. Streptococcal skin infections result from colonization of normal skin by contact with other infected individuals or by preceding streptococcal respiratory infection.

Clinical Findings

A. Symptoms and Signs

Erysipelas is a painful superficial cellulitis that frequently involves the face. It is well demarcated from the surrounding normal skin. It affects skin with impaired lymphatic drainage, such as edematous lower extremities or wounds (Figure 33–1).

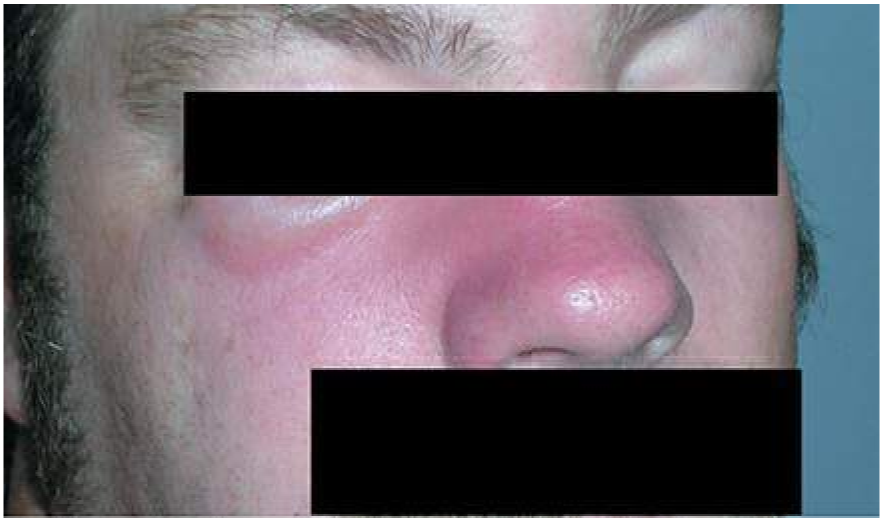

Figure 33–1. **Erysipelas of the central face that responded well to oral antibiotic therapy.** (Used, with permission, from Ernesto Samano Ayon, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. The Color Atlas of Family Medicine, 2nd ed. McGraw-Hill, 2013.)

Impetigo is a focal, vesicular, pustular lesion with a thick, amber-colored crust with a “stuck-on” appearance (see Chapter 6).

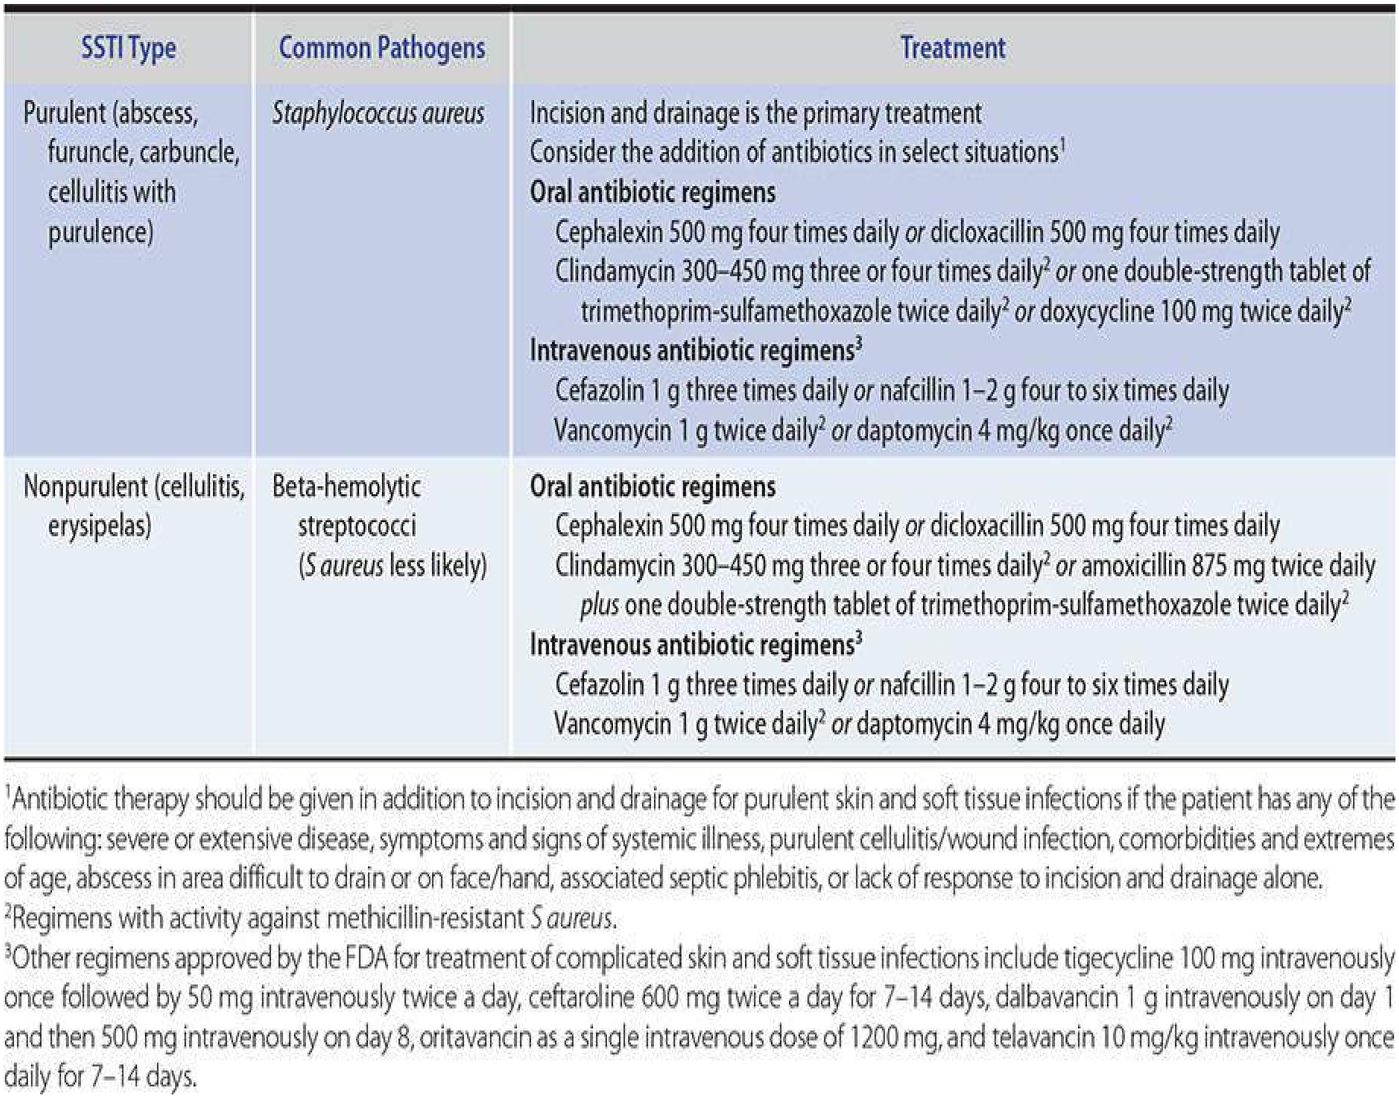
B. Laboratory Findings

Cultures obtained from a wound or pustule are likely to grow group A streptococci. Blood cultures are occasionally positive.

Treatment

Parenteral antibiotics are indicated for patients with facial erysipelas or evidence of systemic infection. Penicillin, 2 million units intravenously every 4 hours, is the drug of choice. However, staphylococcal infections may at times be difficult to differentiate from streptococcal infections. In practice, initial therapy for patients with risk factors for Staphylococcus aureus (eg, injection drug use, diabetes mellitus, wound infection) should cover this organism. Either nafcillin, 1–2 g every 4–6 hours intravenously, or cefazolin, 1 g intravenously or intramuscularly every 8 hours, is a reasonable choice. In the patient at risk for methicillin-resistant S aureus infection or with a serious penicillin allergy (ie, anaphylaxis), vancomycin, 1 g intravenously every 12 hours, or daptomycin, 4 mg/kg intravenously daily, should be used (Table 33–1).

Table 33–1. Empiric treatment of common skin and soft tissue infections (SSTIs).



SSTI Type	Common Pathogens	Treatment
Purulent (abscess, furuncle, carbuncle, cellulitis with purulence)	*Staphylococcus aureus*	Incision and drainage is the primary treatment Consider the addition of antibiotics in select situations[1] **Oral antibiotic regimens** Cephalexin 500 mg four times daily *or* dicloxacillin 500 mg four times daily Clindamycin 300–450 mg three or four times daily[2] *or* one double-strength tablet of trimethoprim-sulfamethoxazole twice daily[2] *or* doxycycline 100 mg twice daily[2] **Intravenous antibiotic regimens**[3] Cefazolin 1 g three times daily *or* nafcillin 1–2 g four to six times daily Vancomycin 1 g twice daily[2] *or* daptomycin 4 mg/kg once daily[2]
Nonpurulent (cellulitis, erysipelas)	Beta-hemolytic streptococci (*S aureus* less likely)	**Oral antibiotic regimens** Cephalexin 500 mg four times daily *or* dicloxacillin 500 mg four times daily Clindamycin 300–450 mg three or four times daily[2] *or* amoxicillin 875 mg twice daily *plus* one double-strength tablet of trimethoprim-sulfamethoxazole twice daily[2] **Intravenous antibiotic regimens**[3] Cefazolin 1 g three times daily *or* nafcillin 1–2 g four to six times daily Vancomycin 1 g twice daily[2] *or* daptomycin 4 mg/kg once daily

[1] Antibiotic therapy should be given in addition to incision and drainage for purulent skin and soft tissue infections if the patient has any of the following: severe or extensive disease, symptoms and signs of systemic illness, purulent cellulitis/wound infection, comorbidities and extremes of age, abscess in area difficult to drain or on face/hand, associated septic phlebitis, or lack of response to incision and drainage alone.

[2] Regimens with activity against methicillin-resistant *S aureus*.

[3] Other regimens approved by the FDA for treatment of complicated skin and soft tissue infections include tigecycline 100 mg intravenously once followed by 50 mg intravenously twice a day, ceftaroline 600 mg twice a day for 7–14 days, dalbavancin 1 g intravenously on day 1 and then 500 mg intravenously on day 8, oritavancin as a single intravenous dose of 1200 mg, and telavancin 10 mg/kg intravenously once daily for 7–14 days.

Patients who do not require parenteral therapy may be treated with amoxicillin, 500 mg three times daily or 875 mg twice daily for 7–10 days. A first-generation oral cephalosporin, eg, cephalexin, 500 mg four times daily, or clindamycin, 300 mg orally three times daily, is an alternative to amoxicillin. In patients with recurrent cellulitis of the leg, maintenance therapy (for at least 1 year) with penicillin, 250 mg orally twice daily, may reduce relapses.

3. Other Group A Streptococcal Infections

Arthritis, pneumonia, empyema, endocarditis, and necrotizing fasciitis are relatively uncommon infections that may be caused by group A streptococci. Toxic shock–like syndrome also occurs.

Arthritis generally occurs in association with cellulitis. In addition to intravenous therapy with penicillin G, 2 million units every 4 hours (or cefazolin or vancomycin in doses recommended above for penicillin-allergic patients), frequent percutaneous needle aspiration should be performed to remove joint effusions. Open surgical drainage may be necessary in many cases.

Pneumonia and **empyema** often are characterized by extensive tissue destruction and an aggressive, rapidly progressive clinical course associated with significant morbidity and mortality. High-dose penicillin and chest tube drainage are indicated for treatment of empyema. Vancomycin is an acceptable substitute in penicillin-allergic patients.

Group A streptococci can cause **endocarditis** in rare instances. Endocarditis should be treated with 4 million units of penicillin G intravenously every 4 hours for 4–6 weeks. Vancomycin, 1 g intravenously every 12 hours, is recommended for persons allergic to penicillin.

Necrotizing fasciitis is a rapidly spreading infection involving the fascia of deep muscle. The clinical findings at presentation may be those of severe cellulitis, but the presence of systemic toxicity and severe pain, which may be followed by anesthesia of the involved area due to destruction of nerves as infection advances through the fascial planes, is a clue to the diagnosis. Surgical exploration is mandatory when the diagnosis is suspected. Early and extensive debridement is essential for survival.

Any streptococcal infection—and necrotizing fasciitis in particular—can be associated with **streptococcal toxic shock syndrome**, typified by invasion of skin or soft tissues, acute respiratory distress syndrome, and kidney failure. Persons who are very young, older adults, and those with underlying medical conditions are at particularly high risk for invasive disease. Bacteremia occurs in most cases. Skin rash and desquamation may not be present. Mortality rates can be up to 80%. The syndrome is due to elaboration of pyrogenic erythrotoxin (which also causes **scarlet fever**), a superantigen that stimulates massive release of inflammatory cytokines believed to mediate the shock. A beta-lactam, such as penicillin, remains the drug of choice for treatment of serious streptococcal infections, but clindamycin, which is a potent inhibitor of toxin production, should also be administered at a dose of 600 mg every 8 hours intravenously for invasive disease, especially in the presence of shock. Intravenous immune globulin can be considered for streptococcal toxic shock syndrome for possible therapeutic benefit from specific antibody to streptococcal exotoxins in immune globulin preparations. Many dosing regimens have been used, including 0.5 g/kg once daily for 5–6 days or a single dose of 2 g/kg with a repeat dose at 48 hours if the patient remains unstable.

Outbreaks of invasive disease have been associated with colonization by invasive clones that can be transmitted to close contacts who, though asymptomatic, may be a reservoir for disease. Tracing contacts of patients with invasive disease is controversial.

Gunderson CG et al. Do patients with cellulitis need to be hospitalized? A systematic review and meta-analysis of mortality rates of inpatients with cellulitis. J Gen Intern Med. 2018 Sep;33(9):1553–60. [PMID: 30022408]

Stevens DL et al. Necrotizing soft-tissue infections. N Engl J Med. 2017 Dec 7;377(23):2253–65. [PMID: 29211672]

4. Non–Group A Streptococcal Infections

Non–group A hemolytic streptococci (eg, groups B, C, and G) produce a spectrum of disease similar to that of group A streptococci. The treatment of infections caused by these strains is similar to group A streptococci.

Group B streptococci are an important cause of sepsis, bacteremia, and meningitis in the neonate. Antepartum screening to identify carriers and peripartum antimicrobial prophylaxis are recommended in pregnancy. This organism, part of the normal vaginal flora, may cause septic abortion, endometritis, or peripartum infections and, less commonly, cellulitis, bacteremia, and endocarditis in adults. Treatment of infections caused by group B streptococci is with either penicillin or vancomycin in doses recommended for group A streptococci. Because of in vitro synergism, some experts recommend the addition of low-dose gentamicin, 1 mg/kg every 8 hours.

Viridans streptococci, which are nonhemolytic or alpha-hemolytic (ie, producing a green zone of hemolysis on blood agar), are part of the normal oral flora. Although these strains may produce focal pyogenic infection, they are most notable as the leading cause of native valve endocarditis.

Group D streptococci include Streptococcus gallolyticus (bovis) and the enterococci. S gallolyticus (bovis) is a cause of endocarditis in association with bowel neoplasia or cirrhosis and is treated like viridans streptococci.

Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications: a scientific statement for healthcare professionals from the American Heart Association. Circulation. 2015 Oct 13; 132(15):1435–86. Erratum in: Circulation. 2015 Oct 27; 132(17):e215. [PMID: 26373316]

Kim SL et al. Distribution of streptococcal groups causing infective endocarditis: a descriptive study. Diagn Microbiol Infect Dis. 2018 Jul;91(3):269–72. [PMID: 29567126]

ENTEROCOCCAL INFECTIONS

Two species, Enterococcus faecalis and Enterococcus faecium, are responsible for most human enterococcal infections. Enterococci cause wound infections, urinary tract infections, bacteremia, and endocarditis. Infections caused by penicillin-susceptible strains should be treated with ampicillin 2 g every 4 hours or penicillin 3–4 million units every 4 hours; if the patient is penicillin-allergic, vancomycin 15 mg/kg every 12 hours intravenously can be given. If the patient has endocarditis or meningitis, gentamicin 1 mg/kg every 8 hours intravenously should be added to the regimen for a duration of 2–3 weeks in order to achieve the bactericidal activity that is required to cure these infections. In cases of endocarditis, ceftriaxone 2 g every 12 hours may be given instead of gentamicin in combination with the ampicillin.

Resistance to vancomycin, penicillin, and gentamicin is common among enterococcal isolates, especially E faecium; it is essential to determine antimicrobial susceptibility of isolates. Infection control measures that may be indicated to limit their spread include isolation, barrier precautions, and avoidance of overuse of vancomycin and gentamicin. Consultation with an infectious diseases specialist is strongly advised when treating infections caused by resistant strains of enterococci. Quinupristin/dalfopristin and linezolid are approved by the FDA for treatment of infections caused by vancomycin-resistant strains of enterococci. Daptomycin, tigecycline, tedizolid, and oritavancin are not approved by the FDA for the treatment for vancomycin-resistant strains of enterococci, although they are frequently active in vitro.

Quinupristin/dalfopristin is not active against strains of E faecalis and should be used only for infections caused by E faecium. The dose is 7.5 mg/kg intravenously every 8–12 hours. Phlebitis and irritation at the infusion site (often requiring a central line) and an arthralgia-myalgia syndrome are relatively common side effects. Linezolid, an oxazolidinone, is active against both E faecalis and E faecium. The dose is 600 mg twice daily, and both intravenous and oral preparations are available. Its two principal side effects are thrombocytopenia and bone marrow suppression; however, peripheral neuropathy, optic neuritis, and lactic acidosis have been observed with prolonged use (typically greater than 6 weeks) due to mitochondrial toxicity. Emergence of resistance has occurred during therapy with both quinupristin/dalfopristin and linezolid.

PNEUMOCOCCAL INFECTIONS

1. Pneumococcal Pneumonia

ESSENTIALS OF DIAGNOSIS

- Productive cough, fever, rigors, dyspnea, early pleuritic chest pain.
- Consolidating lobar pneumonia on chest radiograph.
- Gram-positive diplococci on Gram stain of sputum.

General Considerations

Pneumococcus is the most common cause of community-acquired pyogenic bacterial pneumonia. Alcoholism, asthma, HIV infection, sickle cell disease, splenectomy, and hematologic disorders are predisposing factors. Mortality rates remain high in cases of advanced age, multilobar disease, hypoxemia, extrapulmonary complications, and bacteremia.

Clinical Findings

A. Symptoms and Signs

Presenting symptoms and signs include high fever, productive cough, occasional hemoptysis, and pleuritic chest pain. Rigors may occur initially but are uncommon later in the course. Bronchial breath sounds are an early sign.

B. Laboratory Findings

Pneumococcal pneumonia classically is a lobar pneumonia with radiographic findings of consolidation and occasionally effusion. However, differentiating it from other pneumonias is not possible radiographically or clinically because of significant overlap in presentations. Diagnosis requires isolation of the organism in culture, although the Gram stain appearance of sputum can be suggestive. Sputum and blood cultures, positive in 60% and 25% of cases of pneumococcal pneumonia, respectively, should be obtained prior to initiation of antimicrobial therapy in patients who are admitted to the hospital. A good-quality sputum sample (less than 10 epithelial cells and greater than 25 polymorphonuclear leukocytes per high-power field) shows gram-positive diplococci in 80–90% of cases. A rapid urinary antigen test for Streptococcus pneumoniae, with sensitivity of 70–80% and specificity greater than 95%, can assist with early diagnosis.

Complications

Parapneumonic (sympathetic) effusion is common and may cause recurrence or persistence of fever. These sterile fluid accumulations need no specific therapy. Empyema occurs in 5% or less of cases and is differentiated from sympathetic effusion by the presence of organisms on Gram-stained fluid or positive pleural fluid cultures.

Pneumococcal pericarditis is a rare complication that can cause tamponade. Pneumococcal arthritis also is uncommon. Pneumococcal endocarditis usually involves the aortic valve and often occurs in association with meningitis and pneumonia (sometimes referred to as Austrian or Osler triad). Early heart failure and multiple embolic events are typical.

Treatment

A. Specific Measures

Initial antimicrobial therapy for pneumonia is empiric (see Table 9–9) pending isolation and identification of the causative agent. Once S pneumoniae is identified as the infecting pathogen, any of several antimicrobial agents may be used depending on the clinical setting, community patterns of penicillin resistance, and susceptibility of the particular isolate. Uncomplicated pneumococcal pneumonia (ie, arterial PO_2 greater than 60 mm Hg, no coexisting medical problems, and single-lobe disease without signs of extrapulmonary infection) caused by penicillin-susceptible strains of pneumococcus may be treated on an outpatient basis with amoxicillin, 750 mg orally twice daily for 7–10 days. Cephalosporins including cefpodoxime, 200 mg orally twice daily, and cefdinir, 300 mg twice daily, may also be used. For penicillin-allergic patients, alternatives are azithromycin, one 500-mg dose orally on the first day and 250 mg for the next 4 days; clarithromycin, 500 mg orally twice daily for 10 days; doxycycline, 100 mg orally twice daily for 10 days; levofloxacin, 750 mg orally for 5 days; or moxifloxacin, 400 mg orally for 7–14 days. Patients should be monitored for clinical response (eg, less cough, defervescence within 2–3 days) because pneumococci have become increasingly resistant to penicillin and the second-line agents.

Parenteral therapy is generally recommended for the hospitalized patient at least until there has been clinical improvement. Aqueous penicillin G, 2 million units intravenously every 4 hours, or ceftriaxone, 1 g intravenously every 24 hours, is effective for strains that are penicillin-susceptible (ie, strains for which the minimum inhibitory concentration [MIC] of penicillin is 2 mcg/mL or less for non-CNS specimens). For serious penicillin allergy or infection caused by a highly penicillin-resistant strain, vancomycin, 1 g intravenously every 12 hours, is effective. Alternatively, a respiratory fluoroquinolone (eg, levofloxacin, 750 mg) can be used. The total duration of therapy is not well defined but 5 days is appropriate for patients who have an uncomplicated infection and demonstrate a good clinical response. Corticosteroid use remains controversial in community-acquired pneumonia and should not be administered routinely.

B. Treatment of Complications

Pleural effusions developing after initiation of antimicrobial therapy usually are sterile, and thoracentesis need not be performed if the patient is otherwise improving. Thoracentesis is indicated for an effusion present prior to initiation of therapy and in the patient who has not responded to antibiotics after 3–4 days. Chest tube drainage may be required if pneumococci are identified by culture or Gram stain, especially if aspiration of the fluid is difficult.

Echocardiography should be done if pericardial effusion is suspected. Patients with pericardial effusion who are responding to antibiotic therapy and have no signs of tamponade may be monitored and treated with indomethacin, 50 mg orally three times daily, for pain. In patients with increasing effusion, unsatisfactory clinical response, or evidence of tamponade, pericardiocentesis will determine whether the pericardial space is infected. Infected fluid must be drained either percutaneously (by tube placement or needle aspiration), by placement of a pericardial window, or by pericardiectomy. Pericardiectomy eventually may be required to prevent or treat constrictive pericarditis.

Endocarditis should be treated for 4 weeks with 3–4 million units of penicillin G every 4 hours intravenously; ceftriaxone, 2 g once daily intravenously; or vancomycin, 15 mg/kg every 12 hours intravenously. Mild heart failure due to valvular regurgitation may respond to medical therapy, but moderate to severe heart failure is an indication for prosthetic valve implantation, as are systemic emboli or large friable vegetations as determined by echocardiography.

C. Penicillin-Resistant Pneumococci

Resistance breakpoints for parenterally administered penicillin and high-dose oral amoxicillin (2 g twice daily) are as follows: susceptible, penicillin MIC of 2 mcg/mL or less; intermediate, MIC of 4 mcg/mL; resistant, MIC of 8 mcg/mL or more. Note, however, that these breakpoints do not apply to orally administered penicillin, which are the same as for use of penicillin in treatment of meningitis. In cases of pneumococcal pneumonia where the isolate has a penicillin MIC greater than 2 mcg/mL, cephalosporin cross-resistance is common, and a non–beta-lactam antimicrobial, such as vancomycin, 1 g intravenously every 12 hours, or a fluoroquinolone with enhanced gram-positive activity (eg, levofloxacin, 750 mg intravenously or orally once daily, or moxifloxacin, 400 mg intravenously or orally once daily), is recommended. Penicillin-resistant strains of pneumococci may be resistant to macrolides, trimethoprim-sulfamethoxazole, and chloramphenicol, and susceptibility must be documented prior to their use. All blood and cerebrospinal fluid isolates should still be tested for resistance to penicillin. There has been no change to the penicillin susceptibility breakpoint for pneumococcal isolates causing meningitis, nor any change in treatment recommendations.

Prevention

See Chapter 30 for discussion of pneumococcal vaccines. All patients should have screening for smoking cessation.

When to Refer

- All patients with suspected pneumococcal endocarditis or meningitis to an infectious disease specialist.
- Extensive disease.
- Seriously ill patient with pneumonia, particularly in the setting of comorbid conditions (eg, liver disease).
- Progression of pneumonia or failure to improve on antibiotics.

When to Admit

- All patients in whom pneumococcal endocarditis or meningitis is suspected or documented should be admitted for observation and empiric therapy.
- All patients with pneumococcal pneumonia that is multilobar or associated with significant hypoxemia.
- Failure of outpatient pneumonia therapy, including inability to maintain oral intake and medications.
- Exacerbations of underlying disease (eg, heart failure) by pneumonia that would benefit from hospitalization.

2. Pneumococcal Meningitis

ESSENTIALS OF DIAGNOSIS

- Fever, headache, altered mental status.

- Meningismus.
- Gram-positive diplococci on Gram stain of cerebrospinal fluid.

General Considerations

S pneumoniae is the most common cause of meningitis in adults. Head trauma with cerebrospinal fluid leaks, sinusitis, and pneumonia may precede it.

Clinical Findings

A. Symptoms and Signs

The onset is rapid, with fever, headache, meningismus, and altered mentation. Pneumonia may be present. Compared with meningitis caused by the meningococcus, pneumococcal meningitis lacks a rash. Obtundation, focal neurologic deficits, and cranial nerve palsies are more prominent features and may lead to long-term sequelae.

B. Laboratory Findings

The cerebrospinal fluid typically has greater than 1000 white blood cells per microliter, over 60% of which are polymorphonuclear leukocytes; the glucose concentration is less than 40 mg/dL (2.22 mmol/L), or less than 50% of the simultaneous serum concentration; and the protein usually exceeds 150 mg/dL (1500 mg/L) (see Chapter 30). Not all cases of meningitis will have these typical findings, and alterations in cerebrospinal fluid cell counts and chemistries may be surprisingly minimal, overlapping with those of aseptic meningitis.

Gram stain of cerebrospinal fluid shows gram-positive cocci in 80–90% of cases, and in untreated cases, blood or cerebrospinal fluid cultures are almost always positive.

Treatment

Antibiotics should be given as soon as the diagnosis is suspected. If lumbar puncture must be delayed (eg, while awaiting results of an imaging study to exclude a mass lesion), the patient should be treated empirically for presumed meningitis with intravenous ceftriaxone, 2 g, plus vancomycin, 15 mg/kg, plus dexamethasone, 0.15 mg/kg administered concomitantly after blood cultures (positive in 50% of cases) have been obtained. Once susceptibility to penicillin has been confirmed, penicillin, 24 million units intravenously daily in six divided doses, or ceftriaxone, 2 g every 12 hours intravenously, is continued for 10–14 days in documented cases.

The best therapy for penicillin-resistant strains is not known. Penicillin-resistant strains (MIC greater than 0.06 mcg/mL) are often cross-resistant to the third-generation cephalosporins as well as other antibiotics. Susceptibility testing is essential to proper management of this infection. If the MIC of ceftriaxone or cefotaxime is 0.5 mcg/mL or less, single-drug therapy with either of these cephalosporins is likely to be effective; when the MIC is 1 mcg/mL or more, treatment with a combination of ceftriaxone, 2 g intravenously every 12 hours, plus vancomycin, 30 mg/kg/day intravenously in two or three divided doses, is recommended. If a patient with a penicillin-resistant organism is slow to respond clinically, repeat lumbar puncture may be indicated to assess bacteriologic response.

Dexamethasone administered with antibiotic to adults has been associated with a 60% reduction in mortality and a 50% reduction in unfavorable outcomes. It is recommended that dexamethasone be given immediately prior to or concomitantly with the first dose of appropriate antibiotic and continued in those with pneumococcal disease every 6 hours thereafter for a total of 4 days. The effect of dexamethasone on outcome of meningitis caused by penicillin-resistant organisms is not known.

STAPHYLOCOCCUS AUREUS INFECTIONS

1. Skin & Soft Tissue Infections

ESSENTIALS OF DIAGNOSIS

- Localized erythema with induration and purulent drainage.
- Abscess formation.
- Folliculitis commonly observed.
- Gram stain of pus shows gram-positive cocci in clusters; cultures usually positive.

General Considerations

Approximately one-quarter of people are asymptomatic nasal carriers of S aureus, which is spread by direct contact. Carriage often precedes infection, which occurs as a consequence of disruption of the cutaneous barrier or impairment of host defenses. S aureus tends to cause more purulent skin infections than streptococci, and abscess formation is common. The prevalence of methicillin-resistant strains in many communities is high and should influence antibiotic choices when antimicrobial therapy is needed.

Clinical Findings

A. Symptoms and Signs

S aureus skin infections may begin around one or more hair follicles, causing folliculitis; may become localized to form boils (or furuncles); or may spread to adjacent skin and deeper subcutaneous tissue (ie, a carbuncle) (Figure 33–2). Deep abscesses involving muscle or fascia may occur, often in association with a deep wound or other inoculation or injection. Necrotizing fasciitis, a rare form of S aureus skin and soft tissues infection, has been reported with community strains of methicillin-resistant S aureus.

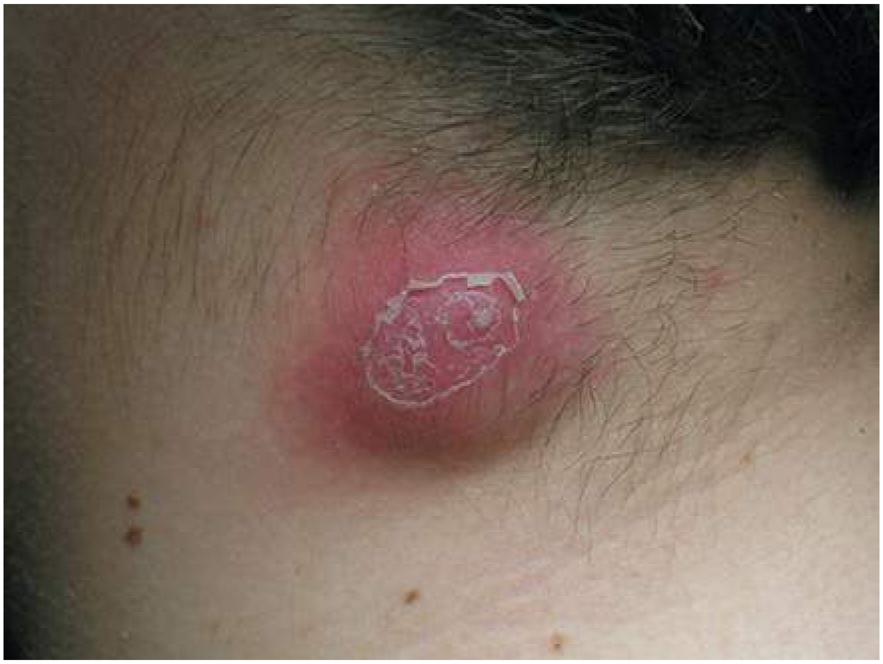

Figure 33–2. **Methicillin-resistant Staphylococcus aureus (MRSA) abscess of the neck.** (From Edward Wright, MD; reproduced, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. The Color Atlas of Family Medicine. McGraw-Hill, 2009.)

B. Laboratory Findings

Cultures of the wound or abscess material will almost always yield the organism. In patients with systemic signs of infection, blood cultures should be obtained because of potential bacteremia, endocarditis, osteomyelitis, or metastatic seeding of other sites. Patients who are bacteremic should have blood cultures taken early during therapy to exclude persistent bacteremia, an indicator of severe or complicated infection.

Treatment

Proper drainage of abscess fluid or other focal infections is the mainstay of therapy. Incision and drainage alone is highly effective for the treatment of most uncomplicated cutaneous abscesses. A small benefit can be obtained from the addition of antimicrobials following incision and drainage. In areas where methicillin resistance among community S aureus isolates is high, recommended oral antimicrobials agents include clindamycin, 300 mg three times daily; trimethoprim-sulfamethoxazole, given in two divided doses based on 5–10 mg/kg/day of the trimethoprim component; or doxycycline or minocycline, 100 mg twice daily. When the risk of methicillin resistance is low or methicillin susceptibility has been confirmed by testing of the isolate, consider dicloxacillin or cephalexin, 500 mg four times a day (see Table 33–1). Seven days of treatment are sufficient in most cases.

For complicated infections with extensive cutaneous or deep tissue involvement or fever, initial parenteral therapy is often indicated. When methicillin resistance rates are high (above 10%), empiric therapy with vancomycin, 1 g intravenously every 12 hours, is a drug of choice. Cefazolin 1 g intravenously or intramuscularly or a penicillinase-resistant penicillin such as nafcillin or oxacillin in a dosage of 1.5 g every 6 hours intravenously is preferred for infections caused by methicillin-susceptible isolates. Total duration of therapy for soft tissue infections depends on clinical response and effectiveness of drainage/debridement. Courses of 7 days with early transition to oral therapy are effective in many cases.

Linezolid is FDA approved for treatment of skin and skin-structure infections as well as hospital-acquired pneumonia caused by methicillin-resistant strains of S aureus and clinically is as effective as vancomycin for these indications. The dose is 600 mg orally or intravenously twice a day for 10–14 days. Its considerable cost makes it an unattractive choice for most routine outpatient infections, and its safety in treatment courses lasting longer than 2–3 weeks is not well characterized. Tedizolid (an oxazolidinone, like linezolid) is also approved for treating skin and soft tissue infection at a dose of 200 mg orally once daily for 6 days. Other drugs FDA approved for treating skin and soft tissue infections include daptomycin, 4 mg/kg intravenously once daily for 7–14 days; tigecycline (a glycylcycline class antimicrobial), 100 mg intravenously once followed by 50 mg intravenously twice a day for 5–14 days; ceftaroline (a novel cephalosporin with activity against methicillin-resistant S aureus), 600 mg twice a day for 7–14 days; dalbavancin (a lipoglycopeptide), a single intravenous dose of 1500 mg; oritavancin (a lipoglycopeptide), a single intravenous dose of 1200 mg; telavancin (a lipoglycopeptide), 10 mg/kg intravenously once daily for 7–14 days; and delafloxacin, 450 mg orally or 300 intravenously twice daily for 5–14 days. Telavancin is also approved for the treatment of hospital-acquired S aureus pneumonia but has been associated with nephrotoxicity.

2. Osteomyelitis

S aureus causes approximately 60% of all cases of osteomyelitis. Osteomyelitis may be caused by direct inoculation, eg, from an open fracture or as a result of surgery; by extension from a contiguous focus of infection or open wound; or by hematogenous spread. Long bones and vertebrae are the usual sites. Epidural abscess is a common complication of vertebral osteomyelitis and should be suspected if fever and severe back or neck pain are accompanied by radicular pain or symptoms or signs indicative of spinal cord compression (eg, incontinence, extremity weakness, pathologic extremity reflexes).

Clinical Findings

A. Symptoms and Signs

The infection may be acute, with abrupt development of local symptoms and systemic toxicity, or indolent, with insidious onset of vague pain over the site of infection, progressing to local tenderness and constitutional symptoms (fever, malaise, anorexia, night sweats). Fever is absent in one-third or more of cases. Back pain is often the only symptom in vertebral osteomyelitis and may be associated with an epidural abscess and spinal cord compression. Draining sinus tracts occur in chronic infections or infections of foreign body implants.

B. Laboratory Findings

The diagnosis is established by isolation of S aureus from the blood, bone, or a contiguous focus of a patient with symptoms and signs of focal bone infection. Blood culture will be positive in approximately 60% of untreated cases. Bone biopsy and culture are indicated if blood cultures are sterile. Inflammatory markers (C-reactive protein, erythrocyte sedimentation rate) are typically elevated.

C. Imaging

Bone scan and gallium scan, each with a sensitivity of approximately 95% and a specificity of 60–70%, are useful in identifying or confirming the site of bone infection. Plain bone films early in the course of infection are often normal but will become abnormal in most cases even with effective therapy. Spinal infection (unlike malignancy) traverses the disk space to involve the contiguous vertebral body. CT is more sensitive than plain films and helps localize associated abscesses. MRI is slightly less sensitive than bone scan, but has a specificity of 90%. It is indicated when epidural abscess is suspected in association with vertebral osteomyelitis. ^{18}F-FDG-PET/CT may be useful in diagnosis of vertebral osteomyelitis as well as the detection of other metastatic sites of infection.

Treatment

Prolonged therapy is required to cure staphylococcal osteomyelitis. Durations of 4–6 weeks or longer are recommended. Intravenous therapy is preferred, particularly during the acute phase of the infection for patients with systemic toxicity. Cefazolin, 2 g every 8 hours, or alternatively, nafcillin or oxacillin, 9–12 g/day in six divided doses, are the drugs of choice for infection with methicillin-sensitive isolates. Patients with infections due to methicillin-resistant strains of S aureus or who have severe penicillin allergies should be treated with vancomycin, 30 mg/kg/day intravenously divided in two or three doses. Doses should be adjusted to achieve a vancomycin trough level of 15–20 mcg/mL. In patients with S aureus isolates susceptible to a fluoroquinolone and rifampin, that combination has been shown to be effective if given for 4 weeks following 2 weeks of induction therapy with an intravenous agent as above. Consultation with an infectious diseases specialist is recommended. The role of newer agents, such as daptomycin or linezolid, remains to be defined.

Surgical treatment is often indicated under the following circumstances: (1)

staphylococcal osteomyelitis with associated epidural abscess and spinal cord compression, (2) other abscesses (psoas, paraspinal), (3) extensive disease, or (4) recurrent or persistent infection despite standard medical therapy. Follow-up imaging may not be needed in patients who demonstrate improvement in symptoms and normalization of inflammatory markers.

3. Staphylococcal Bacteremia

S aureus readily invades the bloodstream and infects sites distant from the primary site of infection. Whenever S aureus is recovered from blood cultures, the possibility of endocarditis, osteomyelitis, or other metastatic deep infection must be considered. Bacteremia that persists for more than 48–96 hours after initiation of therapy is strongly predictive of worse outcome and complicated infection. Given the relatively high risk of infective endocarditis in patients with S aureus bacteremia, transesophageal echocardiography is recommended for most patients as a sensitive and cost-effective method for excluding underlying endocarditis. However, transthoracic echocardiography may be sufficient in select patients considered to be at low risk for endocarditis, namely those who meet all the following criteria: (1) no permanent intracardiac device, (2) sterile follow-up blood cultures within 4 days after the initial set, (3) no hemodialysis dependence, (4) nosocomial acquisition of S aureus bacteremia, and (5) no clinical signs of infective endocarditis or secondary foci of infection.

Empiric therapy of staphylococcal bacteremia should be with vancomycin, 15–20 mg/kg/dose intravenously every 8–12 hours, or daptomycin 6 mg/kg/day intravenously until results of susceptibility tests are known. If the S aureus isolate is methicillin-susceptible, treatment should be narrowed to cefazolin, 2 g every 8 hours, or nafcillin or oxacillin, 2 g intravenously every 4 hours. Cefazolin is as effective as nafcillin or oxacillin and has been associated with fewer adverse events during treatment. In patients with methicillin-resistant S aureus, treatment should be with vancomycin, 15–20 mg/kg/dose intravenously every 8–12 hours. Maintaining a vancomycin trough concentration of 15–20 mcg/mL may improve outcomes and is recommended. Daptomycin 6 mg/kg/day is also an FDA-approved option as long as the patient does not require treatment for concomitant S aureus pneumonia. The addition of rifamycins to standard antimicrobial therapy has not been shown to be beneficial in the absence of indwelling prosthetic material and is associated with more adverse events. Duration of therapy for S aureus bacteremia is 4–6 weeks of antibiotic therapy but a subset of patients with uncomplicated infection may be able to be treated for 14 days. A patient with uncomplicated bacteremia must meet all the following criteria: (1) infective endocarditis has been excluded, (2) no implanted prostheses are present, (3) follow-up blood cultures drawn 2–4 days after the initial set are sterile, (4) the patient defervesces within 72 hours of initiation of effective antibiotic therapy, and (5) no evidence of metastatic infection is present on examination. When present at the time of diagnosis, central venous catheters should be removed. Vancomycin treatment failures are relatively common, particularly for complicated bacteremia and among infections involving foreign bodies. Improved outcomes have been demonstrated when consultation is obtained with an infectious diseases specialist and should be considered in all cases of S aureus bacteremia.

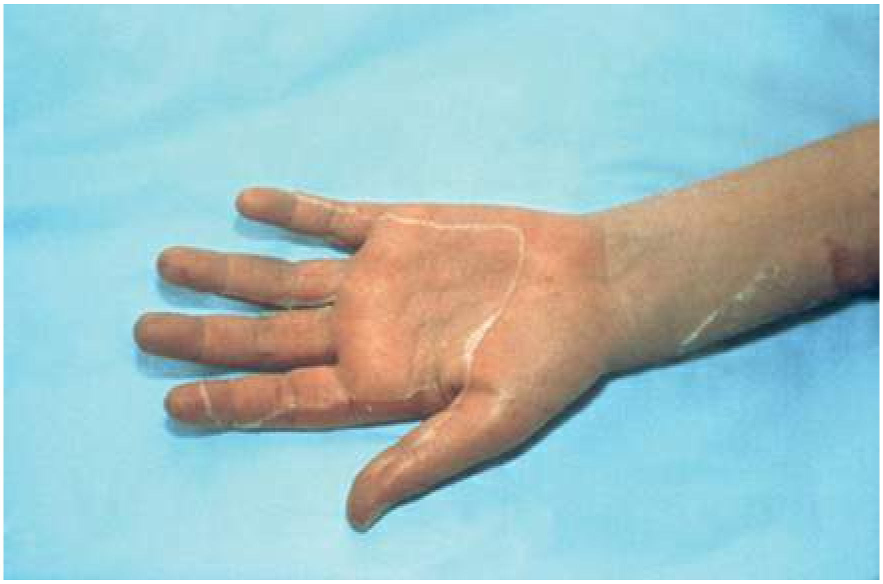
Rao SN et al. Treatment outcomes with cefazolin versus oxacillin for deep-seated methicillin-susceptible Staphylococcus aureus bloodstream infections. Antimicrob Agents Chemother. 2015 Sep;59(9):5232–8. Erratum in: Antimicrob Agents Chemother. 2015 Nov;59(11):7159. [PMID: 26077253]

4. Toxic Shock Syndrome

S aureus produces toxins that cause three important entities: “scalded skin syndrome” in children, toxic shock syndrome in adults, and enterotoxin food poisoning. Toxic shock syndrome is characterized by abrupt onset of high fever, vomiting, and watery diarrhea. Sore throat, myalgias, and headache are common. Hypotension with kidney and heart failure is associated with a poor outcome. A diffuse macular erythematous rash and nonpurulent conjunctivitis are common, and desquamation, especially of palms and soles, is typical during recovery (Figure 33–3). Fatality rates may be as high as 15%. Although originally associated with tampon use, any focus (eg, nasopharynx, bone, vagina, rectum, abscess, or wound) harboring a toxin-producing S aureus strain can cause toxic shock syndrome. Classically, blood cultures are negative because symptoms are due to the effects of the toxin and not systemic infection. Other entities associated with toxic shock include invasive group A streptococcal infection and certain Clostridium species (C perfringens, C sordellii).



▲ Figure 33–3. **Marked desquamation due to toxic shock syndrome, which develops late in the disease.** (Public Health Image Library, CDC.)

Important aspects of treatment include rapid rehydration, targeted antimicrobials (antistaphylococcal therapy when S aureus is implicated), management of kidney or heart failure, and addressing sources of toxin, eg, removal of tampon or drainage of abscess. Intravenous clindamycin, 900 mg every 8 hours, is often added to inhibit toxin production. Intravenous immune globulin may be considered, although there are limited data compared with streptococcus toxic shock syndrome.

5. Infections Caused by Coagulase-Negative Staphylococci

Coagulase-negative staphylococci are an important cause of infections of intravascular and prosthetic devices and of wound infection following cardiothoracic surgery. These organisms infrequently cause infections such as osteomyelitis and endocarditis in the absence of a prosthesis. Most human infections are caused by Staphylococcus epidermidis, S haemolyticus, S hominis, S warnerii, S saprophyticus, S saccharolyticus, and S cohnii. These common hospital-acquired pathogens are less virulent than S aureus, and infections caused by them tend to be more indolent.

Because coagulase-negative staphylococci are normal inhabitants of human skin, it is difficult to distinguish infection from contamination, the latter perhaps accounting for three-fourths of blood culture isolates. Infection is more likely if the patient has a foreign body (eg, sternal wires, prosthetic joint, prosthetic cardiac valve, pacemaker, intracranial pressure monitor, cerebrospinal fluid shunt, peritoneal dialysis catheter) or an intravascular device in place. Purulent or serosanguineous drainage, erythema, pain, or tenderness at the site of the foreign body or device suggests infection. Joint instability and pain are signs of prosthetic joint infection. Fever, a new murmur, instability of the prosthesis, or signs of systemic embolization are evidence of prosthetic valve endocarditis.

Infection is also more likely if the same strain is consistently isolated from two or more blood cultures (particularly if samples were obtained at different times) and from the foreign body site. Contamination is more likely when a single blood culture is positive or if more than one strain is isolated from blood cultures. The antimicrobial susceptibility pattern and speciation are used to determine whether one or more strains have been isolated.

Whenever possible, the intravascular device or foreign body suspected of being infected should be removed. However, removal and replacement of some devices (eg, prosthetic joint, prosthetic valve, cerebrospinal fluid shunt) can be a difficult or risky procedure, and it may sometimes be preferable to treat with antibiotics alone with the understanding that the probability of cure is reduced and that surgical management may eventually be necessary.

Coagulase-negative staphylococci are commonly resistant to beta-lactams and multiple other antibiotics. For patients with normal kidney function, vancomycin, 1 g intravenously every 12 hours, is the treatment of choice until susceptibility to penicillinase-resistant penicillins or other agents has been confirmed. Duration of therapy has not been established for relatively uncomplicated infections, such as those secondary to intravenous devices, which may be eliminated by simply removing the device. Infection involving bone or a prosthetic valve should be treated for 6 weeks. A combination regimen of vancomycin plus rifampin, 300 mg orally twice daily, plus gentamicin, 1 mg/kg intravenously every 8 hours, is recommended for treatment of prosthetic valve endocarditis caused by methicillin-resistant strains.

CLOSTRIDIAL DISEASES

1. Clostridial Myonecrosis (Gas Gangrene)

ESSENTIALS OF DIAGNOSIS

- Sudden onset of pain and edema in an area of wound contamination.
- Prostration and systemic toxicity.
- Brown to blood-tinged watery exudate, with skin discoloration of surrounding area.
- Gas in the tissue by palpation or radiograph.
- Gram-positive rods in culture or smear of exudate.

General Considerations

Gas gangrene or clostridial myonecrosis is produced by any one of several clostridia (Clostridium perfringens, C ramosum, C bifermentans, C histolyticum, C novyi, etc). Trauma and injection drug use are common predisposing conditions. Toxins produced in devitalized tissues under anaerobic conditions result in shock, hemolysis, and myonecrosis.

Clinical Findings

A. Symptoms and Signs

The onset is usually sudden, with rapidly increasing pain in the affected area, hypotension, and tachycardia. Fever is present, but is not proportionate to the severity of the infection. In the last stages of the disease, severe prostration, stupor, delirium, and coma occur.

The wound becomes swollen, and the surrounding skin is pale. There is a foul-smelling brown, blood-tinged serous discharge. As the disease advances, the surrounding tissue changes from pale to dusky and finally becomes deeply discolored, with coalescent, red, fluid-filled vesicles. Gas may be palpable in the tissues.

B. Laboratory Findings

Gas gangrene is a clinical diagnosis, and empiric therapy is indicated if the diagnosis is suspected. Radiographic studies may show gas within the soft tissues, but this finding is not sensitive nor specific. The smear shows absence of neutrophils and the presence of gram-positive rods. Anaerobic culture confirms the diagnosis.

Differential Diagnosis

Other bacteria can produce gas in infected tissue, eg, enteric gram-negative organisms, or anaerobes.

Treatment

Adequate surgical debridement and exposure of infected areas are essential, with radical surgical excision often necessary. Penicillin, 2 million units every 3 hours intravenously, is an effective adjunct. Clindamycin may decrease the production of bacterial toxin, and some experts recommend the addition of clindamycin, 600–900 mg every 8 hours intravenously, to penicillin. Hyperbaric oxygen therapy has been used empirically, but must be used in conjunction with administration of an appropriate antibiotic and surgical debridement.

Stevens DL et al. Practice guidelines for the diagnosis and management of skin and soft tissue infections: 2014 update by the Infectious Diseases Society of America. Clin Infect Dis. 2014 Jul 15;59(2):147–59. [PMID: 24947530]

Yang Z et al. Interventions for treating gas gangrene. Cochrane Database Syst Rev. 2015 Dec 3;12:CD010577. [PMID: 26631369]

2. Tetanus

ESSENTIALS OF DIAGNOSIS

- History of wound and possible contamination.
- Jaw muscle stiffness (“lock jaw”), then spasms (trismus).
- Stiffness of the neck and other muscles, dysphagia, irritability, hyperreflexia.

- Finally, painful convulsions precipitated by minimal stimuli.

General Considerations

Tetanus is caused by the neurotoxin tetanospasmin, elaborated by C tetani. Spores of this organism are ubiquitous in soil and may germinate when introduced into a wound. Tetanospasmin interferes with neurotransmission at spinal synapses of inhibitory neurons. As a result, minor stimuli result in uncontrolled spasms, and reflexes are exaggerated. The incubation period is 5 days to 15 weeks, with the average being 8–12 days.

Most cases occur in unvaccinated individuals. Persons at risk are older adults, migrant workers, newborns, and injection drug users. While puncture wounds are particularly prone to causing tetanus, any wound, including bites or decubiti, may become colonized and infected by C tetani.

Clinical Findings

A. Symptoms and Signs

The first symptom may be pain and tingling at the site of inoculation, followed by spasticity of the muscles nearby. Stiffness of the jaw, neck stiffness, dysphagia, and irritability are other early signs. Hyperreflexia develops later, with spasms of the jaw muscles (trismus) or facial muscles and rigidity and spasm of the muscles of the abdomen, neck, and back. Painful tonic convulsions precipitated by minor stimuli are common. Spasms of the glottis and respiratory muscles may cause acute asphyxia. The patient is awake and alert throughout the illness. The sensory examination is normal. The temperature is normal or only slightly elevated.

B. Laboratory Findings

The diagnosis of tetanus is made clinically.

Differential Diagnosis

Tetanus must be differentiated from various acute central nervous system (CNS) infections such as meningitis. Trismus may occasionally develop with the use of phenothiazines. Strychnine poisoning should also be considered.

Complications

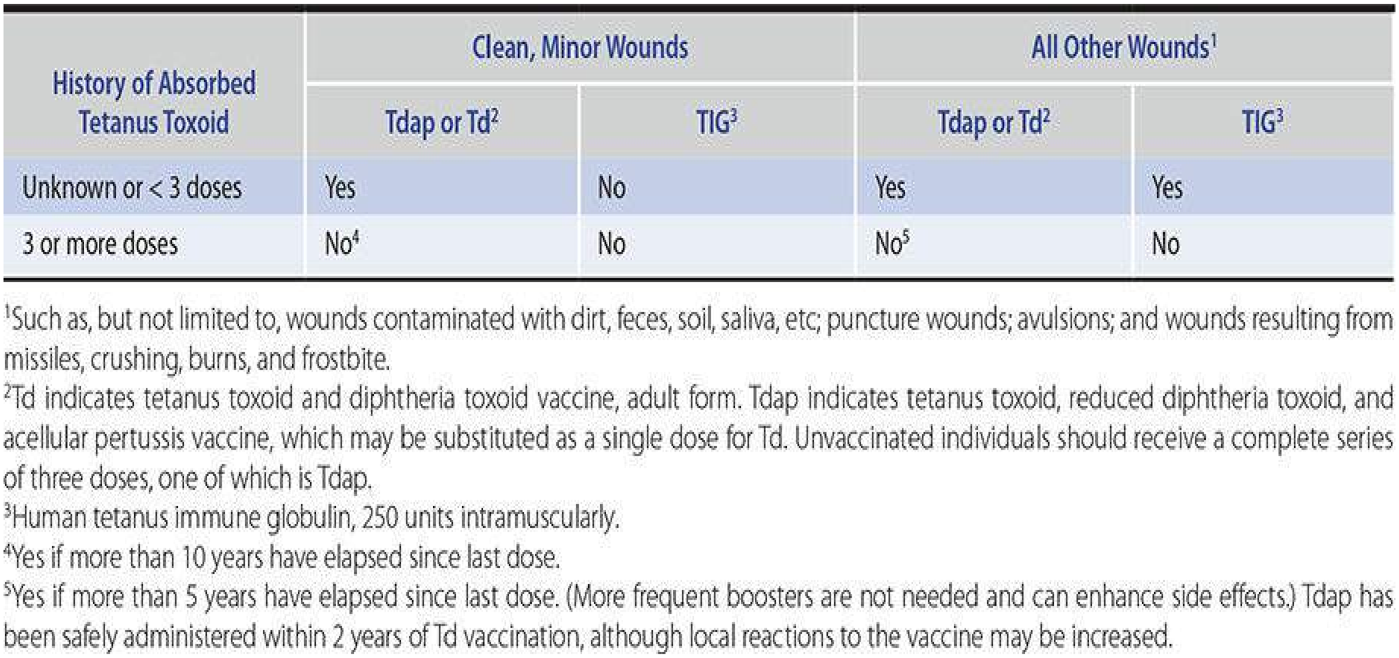
Airway obstruction is common. Urinary retention and constipation may result from spasm of the sphincters. Respiratory arrest and cardiac failure are late, life-threatening events.

Prevention

Tetanus is preventable by active immunization (see Table 30–7). For primary immunization of adults, Td (tetanus and diphtheria toxoids vaccine) is administered as two doses 4–6 weeks apart, with a third dose 6–12 months later. For one of the three doses, Tdap (tetanus toxoid, reduced-dose diphtheria toxoid, acellular pertussis vaccine) should be substituted for Td. Booster Td doses are given every 10 years or at the time of major injury if it occurs more than 5 years after a dose; a single dose of Tdap is preferred to Td for wound management if the patient has not been previously vaccinated with Tdap. Women should receive Tdap with each pregnancy, preferably between 27 and 36 weeks, with immunization at 27–30 weeks associated with the highest antibody concentrations.

Passive immunization should be used in nonimmunized individuals and those whose immunization status is uncertain whenever a wound is contaminated or likely to have devitalized tissue; tetanus immune globulin, 250 units, is given intramuscularly. Active immunization with tetanus toxoid vaccine is started concurrently. Table 33–2 provides a guide to prophylactic management.

Table 33–2. Guide to tetanus prophylaxis in wound management.



History of Absorbed Tetanus Toxoid	Clean, Minor Wounds		All Other Wounds[1]	
	Tdap or Td[2]	TIG[3]	Tdap or Td[2]	TIG[3]
Unknown or < 3 doses	Yes	No	Yes	Yes
3 or more doses	No[4]	No	No[5]	No

[1] Such as, but not limited to, wounds contaminated with dirt, feces, soil, saliva, etc; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

[2] Td indicates tetanus toxoid and diphtheria toxoid vaccine, adult form. Tdap indicates tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, which may be substituted as a single dose for Td. Unvaccinated individuals should receive a complete series of three doses, one of which is Tdap.

[3] Human tetanus immune globulin, 250 units intramuscularly.

[4] Yes if more than 10 years have elapsed since last dose.

[5] Yes if more than 5 years have elapsed since last dose. (More frequent boosters are not needed and can enhance side effects.) Tdap has been safely administered within 2 years of Td vaccination, although local reactions to the vaccine may be increased.

Treatment

A. Specific Measures

Human tetanus immune globulin, 500 units, should be administered intramuscularly within the first 24 hours of presentation. Whether intrathecal administration has any additional benefit is controversial. An unblinded, randomized trial comparing intramuscular tetanus immune globulin to intramuscular plus intrathecal tetanus immune globulin found clinical benefit in the intrathecal group. However, the exact immunoglobulin preparation was not specified and the total dose was 4000 units. Tetanus does not produce natural immunity, and a full course of immunization with tetanus toxoid should be administered once the patient has recovered.

B. General Measures

Debridement of wounds should be undertaken if implicated as the source. Metronidazole, 7.5 mg/kg administered intravenously or orally every 6 hours (maximum 4 g daily), is preferred and should be administered to all patients. Penicillin, 20 million units intravenously daily in divided doses, is an alternative. Minimal stimuli can provoke spasms, so the patient should be placed at bed rest and monitored under the quietest conditions possible. Sedation, paralysis with curare-like agents, and mechanical ventilation are often necessary. Enteral nutritional support should be given early.

Prognosis

High mortality rates are associated with a short incubation period, early onset of convulsions, and delay in treatment. Contaminated lesions about the head and face are more dangerous than wounds on other parts of the body.

Healy CM et al. Association between third-trimester Tdap immunization and neonatal pertussis antibody concentration. JAMA. 2018 Oct 9;320(14):1464–70. [PMID: 30304426]

3. Botulism

ESSENTIALS OF DIAGNOSIS

- Recent ingestion of home-canned or smoked foods; recovery of toxin in serum or food.
- Injection drug use.
- Diplopia, dry mouth, dysphagia, dysphonia, and muscle weakness progressing to respiratory paralysis.
- Pupils are fixed and dilated in most cases.

General Considerations

Botulism is a paralytic disease caused by botulinum toxin, which is produced by Clostridium botulinum, a ubiquitous, strictly anaerobic, spore-forming bacillus found in soil. Four toxin types—A, B, E, and F—cause human disease. Botulinum toxin is extremely potent and is classified by the CDC as a high-priority agent because of its potential for use as an agent of bioterrorism. Naturally occurring botulism exists in three forms: food-borne botulism, infant botulism, or wound botulism. Food-borne botulism is caused by ingestion of preformed toxin present in canned, smoked, or vacuum-packed foods such as home-canned vegetables, smoked meats, and vacuum-packed fish. Commercial foods have been associated with outbreaks of botulism. Infant botulism (associated with ingestion of honey) and wound botulism (often occurs in association with injection drug use) result from organisms present in the gut or wound that secrete toxin.

Clinical Findings

A. Symptoms and Signs

Twelve to 36 hours after ingestion of the toxin, visual disturbances appear, particularly diplopia and loss of accommodation. Ptosis, cranial nerve palsies with impairment of extraocular muscles, and fixed dilated pupils are characteristic signs. The sensory examination is normal. Other symptoms are dry mouth, dysphagia, and dysphonia. Nausea and vomiting may be present, particularly with type E toxin. The sensorium remains clear and the temperature normal. Paralysis progressing to respiratory failure and death may occur unless mechanical assistance is provided.

B. Laboratory Findings

Toxin in foods and patients’ serum can be demonstrated by mouse inoculation and identified with specific antiserum.

Differential Diagnosis

Because the clinical presentation of botulism is so distinctive and the differential diagnosis limited, botulism once considered is not easily confused with other diseases. Cranial nerve involvement may be seen with vertebrobasilar insufficiency, the C. Miller Fisher variant of Guillain-Barré syndrome, myasthenia gravis, or any basilar meningitis (infectious or carcinomatous). Intestinal obstruction or other types of food poisoning are considered when nausea and vomiting are present.

Treatment

If botulism is suspected, the practitioner should contact the state health authorities or the CDC for advice and help with procurement of equine serum heptavalent botulism antitoxin and for assistance in obtaining assays for toxin in serum, stool, or food. Skin testing is recommended to exclude hypersensitivity to the antitoxin preparation. Antitoxin should be administered as early as possible, ideally within 24 hours of the onset of symptoms or signs, to arrest progression of disease; its administration should not be delayed for laboratory confirmation of the diagnosis. Respiratory failure is managed with intubation and mechanical ventilation. Parenteral fluids or alimentation should be given while swallowing difficulty persists. The removal of unabsorbed toxin from the gut may be attempted. Any remnants of suspected foods should be assayed for toxin. Persons who might have eaten the suspected food must be located and observed.

ANTHRAX

ESSENTIALS OF DIAGNOSIS

- Epidemiologic setting: exposure to animals or animal hides or potential exposure from bioterrorism.
- A painless cutaneous black eschar on exposed skin, with marked surrounding edema and vesicles.

- Nonspecific flu-like symptoms that rapidly progress to extreme dyspnea and shock; mediastinal widening and pleural effusions on chest radiograph.

General Considerations

Naturally occurring anthrax is a disease of sheep, cattle, horses, goats, and swine. Bacillus anthracis is a gram-positive spore-forming aerobic rod. Spores—not vegetative bacteria—are the infectious form of the organism. These are transmitted to humans from contact with contaminated animals, animal products, or animal hides, or from soil by inoculation of broken skin or mucous membranes; by inhalation of aerosolized spores; or, rarely, by ingestion resulting in cutaneous, inhalational, or gastrointestinal forms of anthrax, respectively. Inhalation of aerosolized spores that were deliberately placed in the mail as an act of bioterrorism occurred in the United States in 2001. Spores germinate into vegetative bacteria that multiply locally in cutaneous and gastrointestinal anthrax but may also disseminate to cause systemic infection. Inhaled spores are ingested by pulmonary macrophages and carried via lymphatics to regional lymph nodes, where they germinate. The bacteria rapidly multiply within the lymphatics, causing a hemorrhagic lymphadenitis. Invasion of the bloodstream leads to overwhelming sepsis, killing the host.

Clinical Findings

A. Symptoms and Signs

1. Cutaneous anthrax—This occurs within 2 weeks after exposure to spores; there is no latency period for cutaneous disease as there is with inhalational anthrax. The initial lesion is an erythematous papule, often on an exposed area of skin that vesiculates and then ulcerates and undergoes necrosis, ultimately progressing to a purple to black eschar. The eschar typically is painless; pain indicates secondary bacterial infection. The surrounding area is edematous and vesicular but not purulent. Regional adenopathy, fever, malaise, headache, and nausea and vomiting may be present. The infection is self-limited in most cases, but hematogenous spread with sepsis or meningitis may occur.

2. Inhalational anthrax—Illness occurs in two stages, beginning on average 10 days after exposure, but may have a latent onset 6 weeks after exposure. Nonspecific viral-like symptoms such as fever, malaise, headache, dyspnea, cough, and congestion of the nose, throat, and larynx are characteristic of the initial stage. Anterior chest pain is an early symptom of mediastinitis. Within hours to a few days, progression to the fulminant stage of infection occurs in which symptoms or signs of overwhelming sepsis predominate. Delirium, obtundation, or findings of meningeal irritation suggest an accompanying hemorrhagic meningitis.

3. Gastrointestinal anthrax—Fever, diffuse abdominal pain, rebound abdominal tenderness, vomiting, constipation, and diarrhea occur 2–5 days after ingestion of food products contaminated with anthrax spores. The primary lesion is ulcerative, producing emesis that may be blood-tinged or coffee-grounds and stool that may be blood-tinged or melenic. Bowel perforation can occur. The oropharyngeal form of the disease is characterized by local lymphadenopathy, cervical edema, dysphagia, and upper respiratory tract obstruction.

B. Laboratory Findings

Laboratory findings are nonspecific. The white blood cell count initially may be normal or modestly elevated, with polymorphonuclear predominance and an increase in immature forms. Pleural fluid from patients with inhalational anthrax is typically hemorrhagic with few white cells. Cerebrospinal fluid from meningitis cases is also hemorrhagic. Gram stain of pleural fluid, cerebrospinal fluid, unspun blood, blood culture, or fluid from a cutaneous lesion may show the characteristic boxcar-shaped encapsulated rods in chains.

The diagnosis is established by isolation of the organism from culture of the skin lesion (or fluid expressed from it), blood, or pleural fluid—or cerebrospinal fluid in cases of meningitis. In the absence of prior antimicrobial therapy, cultures are invariably positive. Cultures obtained after initiation of antimicrobial therapy may be negative. If anthrax is suspected on clinical or epidemiologic grounds, immunohistochemical tests (eg, to detect capsular antigen), polymerase chain reaction assays, and serologic tests (useful for documenting past cutaneous infection) are available through the CDC and should be used to establish the diagnosis. Any suspected case of anthrax should be immediately reported to the CDC so that an investigation can be conducted.

C. Imaging

The chest radiograph is the most sensitive test for inhalational disease, being abnormal (though the findings can be subtle) initially in every case of bioterrorism-associated disease. Mediastinal widening due to hemorrhagic lymphadenitis, a hallmark feature of the disease, was present in 70% of the bioterrorism-related cases. Pleural effusions were present initially or occurred over the course of illness in all cases, and approximately three-fourths had pulmonary infiltrates or signs of consolidation.

Differential Diagnosis

Cutaneous anthrax, despite its characteristic appearance, can be confused with a variety of other also uncommon or rare conditions such as ecthyma gangrenosum, rat-bite fever, ulceroglandular tularemia, plague, glanders, rickettsialpox, orf (parapoxvirus infection), or cutaneous mycobacterial infection. Inhalational anthrax must be differentiated from mediastinitis due to other bacterial causes, fibrous mediastinitis due to histoplasmosis, coccidioidomycosis, atypical or viral pneumonia, silicosis, sarcoidosis, and other causes of mediastinal widening (eg, superior vena cava syndrome or aortic aneurysm or dissection). Gastrointestinal anthrax shares clinical features with a variety of common intra-abdominal disorders, including bowel obstruction, perforated viscus, peritonitis, gastroenteritis, and peptic ulcer disease.

Treatment

Strains of B anthracis (including the strain isolated in the bioterrorism cases) are susceptible in vitro to penicillin, amoxicillin, chloramphenicol, clindamycin, imipenem, doxycycline, ciprofloxacin (as well as other fluoroquinolones), macrolides, rifampin, and vancomycin. B anthracis may express beta-lactamases that confer resistance to cephalosporins and penicillins. For this reason, penicillin or amoxicillin is not recommended for use as a single agent in treatment of disseminated disease. Based on results of animal experiments and because of concern for engineered drug resistance in strains of B anthracis used in bioterrorism, ciprofloxacin is considered the drug of choice for treatment and for prophylaxis following exposure to anthrax spores. Other fluoroquinolones with activity against gram-positive bacteria (eg, levofloxacin, moxifloxacin) are likely to be just as effective as ciprofloxacin. Doxycycline is an alternative first-line agent. Combination therapy with at least one additional agent is recommended for inhalational or disseminated disease and in cutaneous infection involving the face, head, and neck or associated with extensive local edema or systemic signs of infection, eg, fever, tachycardia, and elevated white blood cell count. Single-drug therapy is recommended for prophylaxis following exposure to spores.

The required duration of therapy is poorly defined. In naturally occurring disease, treatment for 7–10 days for cutaneous disease and for at least 2 weeks following clinical response for disseminated, inhalational, or gastrointestinal infection have been standard recommendations. Because of concern about relapse from latent spores acquired by inhalation of aerosol in bioterrorism-associated cases, the initial recommendation was treatment for 60 days.

Several monoclonal antibodies are FDA approved as adjunctive treatments for inhalation anthrax. Raxibacumab is a human monoclonal antibody directed against the protective antigen component of lethal toxin and is used for treatment of inhalation anthrax in combination with recommended antibacterial treatments. Obiltoxaximab is another toxin-targeting monoclonal antibody and is given in combination with antibacterial drugs. A vaccine is also available for postexposure prophylaxis (and preexposure prophylaxis). This vaccine is administered at 0, 2, and 4 weeks postexposure combined with antimicrobial therapy.

Prevention

In 2001, the CDC offered one of two options for postal workers receiving prophylaxis for exposure to contaminated mail: (1) antibiotics for 100 days (fearing that even with 60 days of treatment late relapses might occur) or (2) vaccination with an investigative agent (three doses administered over a 1-month period) in conjunction with 40 days of antibiotic administration to cover the time required for a protective antibody response to develop. Insufficient information exists to favor one recommendation over the other.

An FDA-approved vaccine is available for persons at high risk for exposure to anthrax spores. The vaccine is cell-free antigen prepared from an attenuated strain of B anthracis. Multiple injections over 18 months and an annual booster dose are required to achieve and maintain protection. Existing supplies have been reserved for vaccination of military personnel. Raxibacumab and obiltoxaximab are approved for prevention of inhalation anthrax when other treatments are not available or appropriate.

Prognosis

The prognosis in cutaneous infection is excellent. Death is unlikely if the infection has remained localized, and lesions heal without complications in most cases. By contrast, the reported mortality rate for gastrointestinal and inhalational infections is up to 85%. Yet, the experience with bioterrorism-associated inhalational cases in which six of eleven victims survived suggests a somewhat better outcome with modern supportive care and antibiotics provided that treatment is initiated before the patient has progressed to the fulminant stage of disease. No cases of anthrax have occurred among the several thousand individuals receiving antimicrobial prophylaxis following exposure to spores.

DIPHTHERIA

ESSENTIALS OF DIAGNOSIS

- Tenacious gray membrane at portal of entry in pharynx.
- Sore throat, nasal discharge, hoarseness, fever.
- Myocarditis, neuropathy.
- Culture confirms the diagnosis.

General Considerations

Diphtheria is an acute infection caused by Corynebacterium diphtheriae that usually attacks the respiratory tract but may involve any mucous membrane or skin wound. The organism is spread chiefly by respiratory secretions. Exotoxin produced by the organism is responsible for myocarditis and neuropathy.

Clinical Findings

A. Symptoms and Signs

Nasal, laryngeal, pharyngeal, and cutaneous forms of diphtheria occur. Nasal infection produces few symptoms other than a nasal discharge. Laryngeal infection may lead to upper airway and bronchial obstruction. In pharyngeal diphtheria, the most common form, a tenacious gray membrane covers the tonsils and pharynx. Mild sore throat, fever, and malaise are followed by toxemia and prostration.

Myocarditis and neuropathy are the most common and most serious complications. Myocarditis causes cardiac arrhythmias, heart block, and heart failure. The neuropathy usually involves the cranial nerves first, producing diplopia, slurred speech, and difficulty in swallowing.

B. Laboratory Findings

The diagnosis is made clinically but can be confirmed by culture of the organism.

Differential Diagnosis

Diphtheria must be differentiated from streptococcal pharyngitis, infectious mononucleosis, adenovirus or herpes simplex infection, Vincent angina, pharyngitis due to Arcanobacterium haemolyticum, and candidiasis. A presumptive diagnosis of diphtheria should be made on clinical grounds without waiting for laboratory verification, since emergency treatment is needed.

Prevention

Active immunization with diphtheria toxoid is part of routine childhood immunization with appropriate booster injections. The immunization schedule for adults is the same as for tetanus (see Table 30–7). Women should receive Tdap with each pregnancy, preferably between 27 and 36 weeks.

Susceptible persons exposed to diphtheria should receive a booster dose of diphtheria toxoid (or a complete series if previously unimmunized), as well as a course of penicillin or erythromycin.

Treatment

Removal of membrane by direct laryngoscopy or bronchoscopy may be necessary to prevent or alleviate airway obstruction. Antitoxin, which is prepared from horse serum, must be given in all cases when diphtheria is suspected. For mild early pharyngeal or laryngeal disease, the dose is 20,000–40,000 units; for moderate nasopharyngeal disease, 40,000–60,000 units; for severe, extensive, or late (3 days or more) disease, 80,000–100,000 units. Diphtheria equine antitoxin can be obtained from the CDC.

Either penicillin, 250 mg orally four times daily, or erythromycin, 500 mg orally four times daily, for 14 days is effective therapy, although erythromycin is slightly more effective in eliminating the carrier state. Azithromycin or clarithromycin is probably as effective as erythromycin. The patient should be isolated until three consecutive cultures at the completion of therapy have documented elimination of the organism from the oropharynx. Contacts to a case should receive erythromycin, 500 mg orally four times daily for 7 days, to eradicate carriage.

LISTERIOSIS

ESSENTIALS OF DIAGNOSIS

- Ingestion of contaminated food product.
- Undifferentiated fever in a pregnant woman in her third trimester.
- Altered mental status and fever in an elderly or immunocompromised patient.
- Obtain blood and cerebrospinal fluid cultures to confirm the diagnosis.

General Considerations

Listeria monocytogenes is a facultative, motile, gram-positive rod that is capable of invading several cell types and causes intracellular infection. Most cases of infection caused by L monocytogenes are sporadic, but outbreaks have been traced to eating contaminated food, including unpasteurized dairy products, hot dogs, delicatessen meats, cantaloupes, and ricotta cheese. Outbreaks have been associated with significant morbidity and mortality in infected persons.

Clinical Findings

Five types of infection are recognized:

(1) **Infection during pregnancy**, usually in the last trimester, is a mild febrile illness without an apparent primary focus and may resolve without specific therapy. However, approximately one in five pregnancies complicated by listeriosis result in spontaneous abortion or stillbirth and surviving infants are at risk for clinical neonatal listeriosis.

(2) **Granulomatosis infantisepticum** is a neonatal infection acquired in utero, characterized by disseminated abscesses, granulomas, and a high mortality rate.

(3) **Bacteremia** with or without sepsis syndrome is an infection of neonates or immunocompromised adults. The presentation is of a febrile illness without a recognized source.

(4) **Meningitis** caused by L monocytogenes affects infants under 2 months of age as well as older adults, ranking third after pneumococcus and meningococcus as common causes of bacterial meningitis. Cerebrospinal fluid shows a neutrophilic pleocytosis. Adults with meningitis are often immunocompromised, and cases have been associated with HIV infection and therapy with tumor necrosis factor (TNF) inhibitors such as infliximab.

(5) **Focal infections**, including adenitis, brain abscess, endocarditis, osteomyelitis, and arthritis, occur rarely.

Prevention

At-risk patients (eg, pregnant women) should avoid unpasteurized milk products. Smoked seafoods, cold cuts, hot dogs, and meat spreads also carry risk. Thoroughly cook animal source food and wash raw vegetables.

Treatment

Ampicillin, 8–12 g/day intravenously in four to six divided doses (the higher dose for meningitis), is considered the treatment of choice. Gentamicin, 5 mg/kg/day intravenously once or in divided doses, is synergistic with ampicillin against Listeria in vitro and in animal models, and the use of combination therapy may be considered during the first few days of treatment to enhance eradication of organisms. In patients with penicillin allergies, trimethoprim-sulfamethoxazole has excellent intracellular and cerebrospinal fluid penetration and is considered an appropriate alternative. The dose is 10–20 mg/kg/day intravenously of the trimethoprim component. Mortality and morbidity rates still are high. Therapy should be administered for at least 2–3 weeks. Longer durations—between 3 and 6 weeks—have been recommended for treatment of meningitis, especially in immunocompromised persons.

INFECTIVE ENDOCARDITIS

ESSENTIALS OF DIAGNOSIS

- Fever.

- Preexisting organic heart lesion.
- Positive blood cultures.
- Evidence of vegetation on echocardiography.
- Evidence of systemic emboli.

General Considerations

Endocarditis is a bacterial or fungal infection of the valvular or endocardial surface of the heart. The clinical presentation depends on the infecting organism and the valve or valves that are infected. More virulent organisms—S aureus in particular—tend to produce a more rapidly progressive and destructive infection. Endocarditis caused by more virulent organisms often presents as an acute febrile illnesses and is complicated by early embolization, acute valvular regurgitation, and myocardial abscess formation. Viridans strains of streptococci, enterococci, other bacteria, yeasts, and fungi tend to cause a more subacute picture.

Predisposing valvular abnormalities include rheumatic involvement of any valve, bicuspid aortic valves, calcific or sclerotic aortic valves, hypertrophic subaortic stenosis, mitral valve prolapse, and a variety of congenital disorders such as ventricular septal defect, tetralogy of Fallot, coarctation of the aorta, or patent ductus arteriosus. Rheumatic disease is no longer the major predisposing factor in developed countries. Regurgitation lesions are more susceptible than stenotic ones.

The initiating event in native valve endocarditis is colonization of the valve by bacteria or yeast that gain access to the bloodstream. Transient bacteremia is common during dental, upper respiratory, urologic, and lower gastrointestinal diagnostic and surgical procedures. It is less common during upper gastrointestinal and gynecologic procedures. Intravascular devices are increasingly implicated as a portal of access of microorganisms into the bloodstream. A large proportion of cases of S aureus endocarditis are attributable to health care–associated bacteremia.

Native valve endocarditis is usually caused by S aureus, viridans streptococci, enterococci, or HACEK organisms (an acronym for Haemophilus aphrophilus [now Aggregatibacter aphrophilus], Actinobacillus actinomycetemcomitans [now Aggregatibacter actinomycetemcomitans], Cardiobacterium hominis, Eikenella corrodens, and Kingella species). Streptococcal species formerly accounted for the majority of native valve endocarditis cases; S aureus is now the leading cause. Gram-negative organisms and fungi account for a small percentage.

In injection drug users, S aureus accounts for over 60% of all endocarditis cases and for 80–90% of cases in which the tricuspid valve is infected. Enterococci and streptococci comprise the balance in about equal proportions. Gram-negative aerobic bacilli, fungi, and unusual organisms may cause endocarditis in injection drug users.

The microbiology of **prosthetic valve endocarditis** also is distinctive. Early infections (ie, those occurring within 2 months after valve implantation) are commonly caused by staphylococci—both coagulase-positive and coagulase-negative—gram-negative organisms, and fungi. In late prosthetic valve endocarditis, streptococci are commonly identified, although coagulase-negative and coagulase-positive staphylococci still cause many cases.

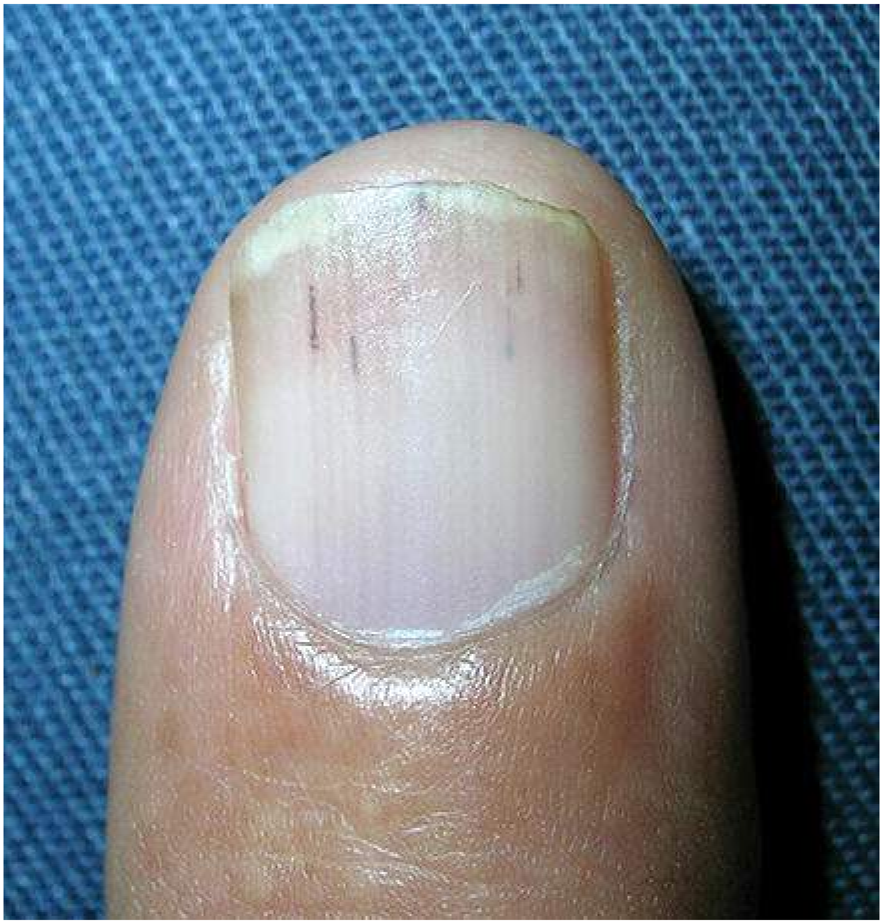
Clinical Findings

A. Symptoms and Signs

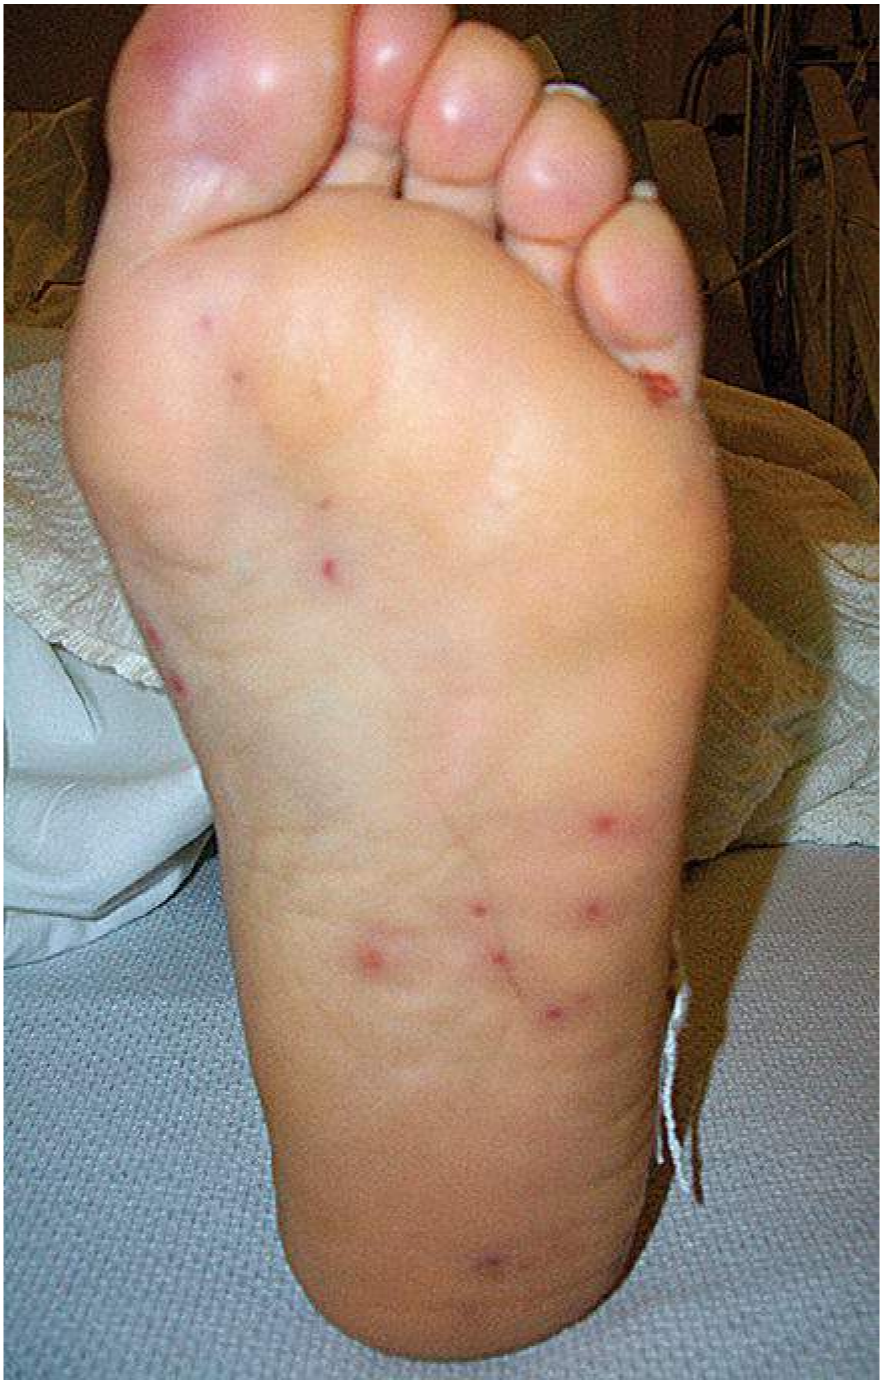
Virtually all patients have fever at some point in the illness, although it may be very low grade (less than 38°C) in elderly individuals and in patients with heart failure or kidney failure. Rarely, there may be no fever at all.

The duration of illness typically is a few days to a few weeks. Nonspecific symptoms are common. The initial symptoms and signs of endocarditis may be caused by direct arterial, valvular, or cardiac damage. Although a changing regurgitant murmur is significant diagnostically, it is the exception rather than the rule. Symptoms also may occur as a result of embolization, metastatic infection or immunologically mediated phenomena. These include cough; dyspnea; arthralgias or arthritis; diarrhea; and abdominal, back, or flank pain.

The characteristic peripheral lesions—petechiae (on the palate or conjunctiva or beneath the fingernails), subungual (“splinter”) hemorrhages (Figure 33–4), Osler nodes (painful, violaceous raised lesions of the fingers, toes, or feet) (Figure 33–5), Janeway lesions (painless erythematous lesions of the palms or soles), and Roth spots (exudative lesions in the retina)—occur in about 25% of patients. Strokes and major systemic embolic events are present in about 25% of patients and tend to occur before or within the first week of antimicrobial therapy. Hematuria and proteinuria may result from emboli or immunologically mediated glomerulonephritis, which can cause kidney dysfunction.



▲ **Figure 33–4. Splinter hemorrhages appearing as red lineal streaks under the nail plate and within the nail bed, in endocarditis, psoriasis, and trauma.** (Reproduced, with permission, from Richard P. Usatine, MD.)



▲ **Figure 33–5. Osler node causing pain within the pulp of the big toe and multiple painless flat Janeway lesions over the sole of the foot.** (Used, with permission, from David A. Kasper, DO, MBA, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. The Color Atlas of Family Medicine. McGraw-Hill, 2009.)

B. Imaging

Chest radiograph may show evidence for the underlying cardiac abnormality and, in right-sided endocarditis, pulmonary infiltrates. The electrocardiogram is nondiagnostic, but new conduction abnormalities suggest myocardial abscess formation.

Echocardiography is useful in identifying vegetations and other characteristic features suspicious for endocarditis and may provide adjunctive information about the specific valve or valves that are infected. The sensitivity of transthoracic echocardiography is between 55% and 65%; it cannot reliably rule out endocarditis but may confirm a clinical suspicion. Transesophageal echocardiography is 90% sensitive in detecting vegetations and is particularly useful for identifying valve ring abscesses as well as prosthetic valve endocarditis.

C. Diagnostic Studies

1. Blood cultures—Three sets of blood cultures are recommended before starting antibiotics to maximize microbiologic diagnosis. To maximize the yield of blood cultures, adequate volume is important. Each culture bottle should be filled with 10 mL of blood since half of adults have less than 1 colony forming unit of bacteria per mL blood. The yield of bacteria may be up to 5% higher for every additional milliliter collected. Optimal yield is with two or three sets of cultures from different sites. There is no difference in yield if blood is collected simultaneously or several hours apart.

Approximately 5% of cases will be culture-negative, usually attributable to administration of antimicrobials prior to cultures. If antimicrobial therapy has been administered prior to obtaining cultures and the patient is clinically stable, it is reasonable to withhold antimicrobial therapy for 2–3 days so that appropriate cultures can be obtained. Culture-negative endocarditis may also be due to organisms that require special media for growth (eg, Legionella, Bartonella, Abiotrophia species, formerly referred to as nutritionally deficient streptococci), organisms that do not grow on artificial media (Tropheryma whipplei, or pathogens of Q fever or psittacosis), or those that may require prolonged incubation (eg, Brucella, anaerobes, HACEK organisms). Bartonella quintana is an important cause of culture-negative endocarditis.

2. Modified Duke criteria—The Modified Duke criteria are useful for the diagnosis of endocarditis. Major criteria include (1) two positive blood cultures for a microorganism that typically causes infective endocarditis or persistent bacteremia, or a single positive blood culture for Coxiella burnetii or anti–phase 1 IgG antibody titer greater than or equal to 1:800; and (2) evidence of endocardial involvement documented by echocardiography showing definite vegetation, myocardial abscess, new partial dehiscence of a prosthetic valve, or new valvular regurgitation (increase or change in murmur is not sufficient). Minor criteria include the presence of a predisposing condition; fever of 38°C or higher; vascular phenomena, such as cutaneous hemorrhages, aneurysm, systemic emboli, or pulmonary infarction; immunologic phenomena, such as glomerulonephritis, Osler nodes, Roth spots, or rheumatoid factor; and positive blood cultures not meeting the major criteria or serologic evidence of an active infection. A definite diagnosis can be made with 80% accuracy if two major criteria, one major criterion and three minor criteria, or five minor criteria are fulfilled. A possible diagnosis of endocarditis is made if one major and one minor criterion or three minor criteria are met. If fewer criteria are found, or a sound alternative explanation for illness is identified, or the patient's febrile illness has resolved within 4 days, endocarditis is unlikely.

Complications

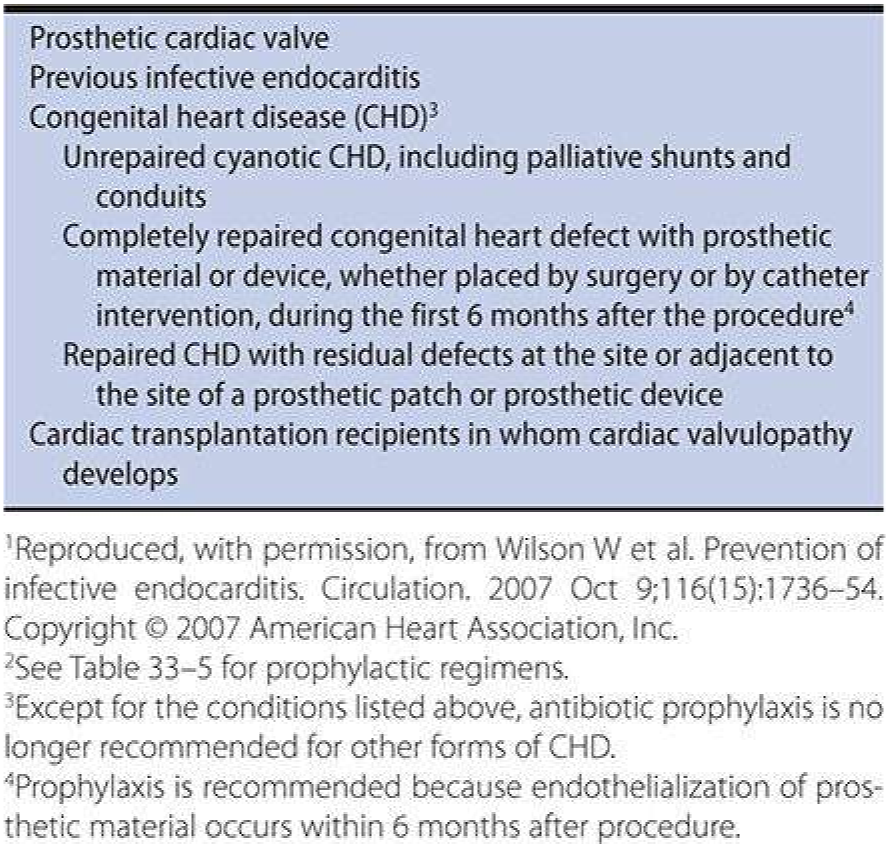
The course of infective endocarditis is determined by the degree of damage to the heart, by the site of infection (right-sided versus left-sided, aortic versus mitral valve), by the presence of metastatic foci of infection, by the occurrence of embolization, and by immunologically mediated processes. Destruction of infected heart valves is especially common and precipitous with S aureus, but can occur with any organism and can progress even after bacteriologic cure. The infection can also extend into the myocardium, resulting in abscesses leading to conduction disturbances, and involving the wall of the aorta, creating sinus of Valsalva aneurysms.

Peripheral embolization to the brain and myocardium may result in infarctions. Embolization to the spleen and kidneys is also common. Peripheral emboli may initiate metastatic infections or may become established in vessel walls, leading to mycotic aneurysms. Right-sided endocarditis, which usually involves the tricuspid valve, causes septic pulmonary emboli, occasionally with infarction and lung abscesses.

Prevention

The American Heart Association recommends antibiotic prophylaxis for infective endocarditis in a relatively small group of patients with predisposing congenital or valvular anomalies (Table 33–3) undergoing select dental procedures, operations involving the respiratory tract, or operations of infected skin, skin structure, or musculoskeletal tissue (Table 33–4). Current antimicrobial recommendations are given in Table 33–5.

Table 33–3. Cardiac conditions with high risk of adverse outcomes from endocarditis for which prophylaxis with dental procedures is recommended.[1,2]



Prosthetic cardiac valve

Previous infective endocarditis

Congenital heart disease (CHD)[3]

- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure[4]
- Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device

Cardiac transplantation recipients in whom cardiac valvulopathy develops

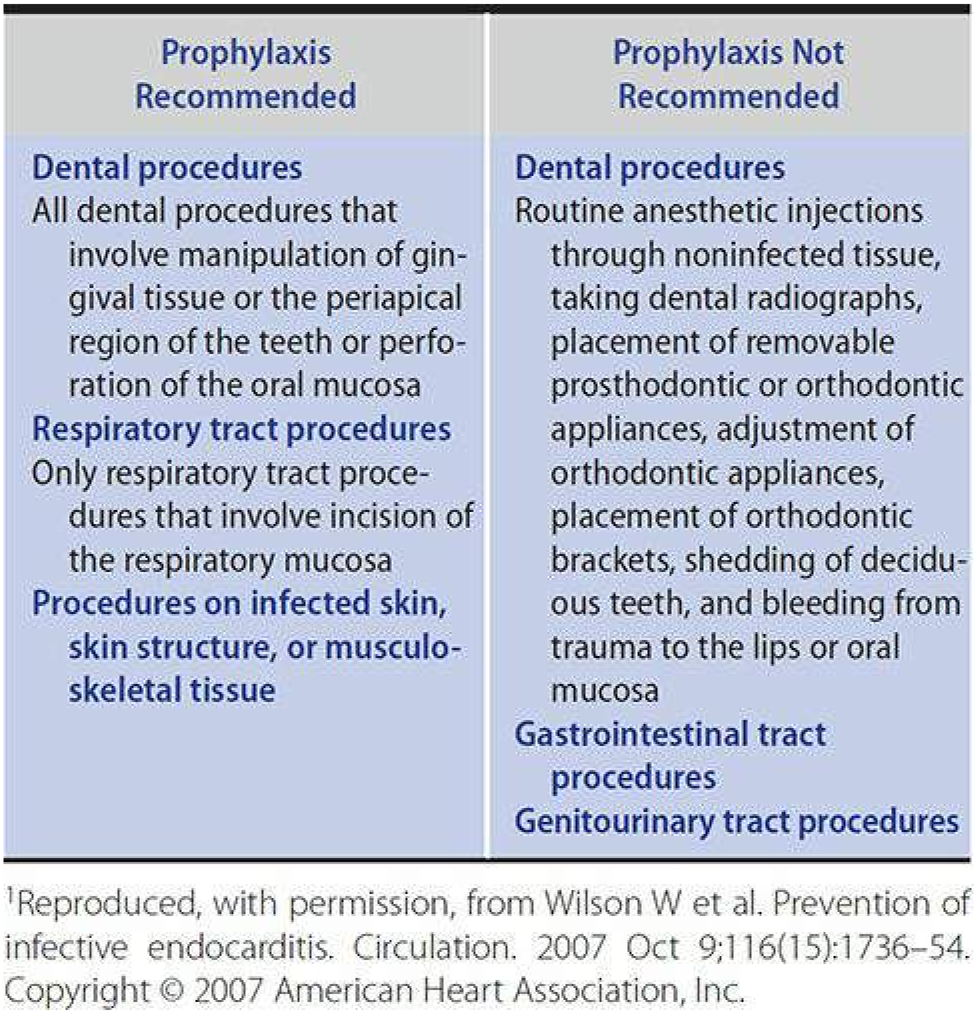
[1] Reproduced, with permission, from Wilson W et al. Prevention of infective endocarditis. Circulation. 2007 Oct 9;116(15):1736–54. Copyright © 2007 American Heart Association, Inc.

[2] See Table 33–5 for prophylactic regimens.

[3] Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for other forms of CHD.

[4] Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after procedure.

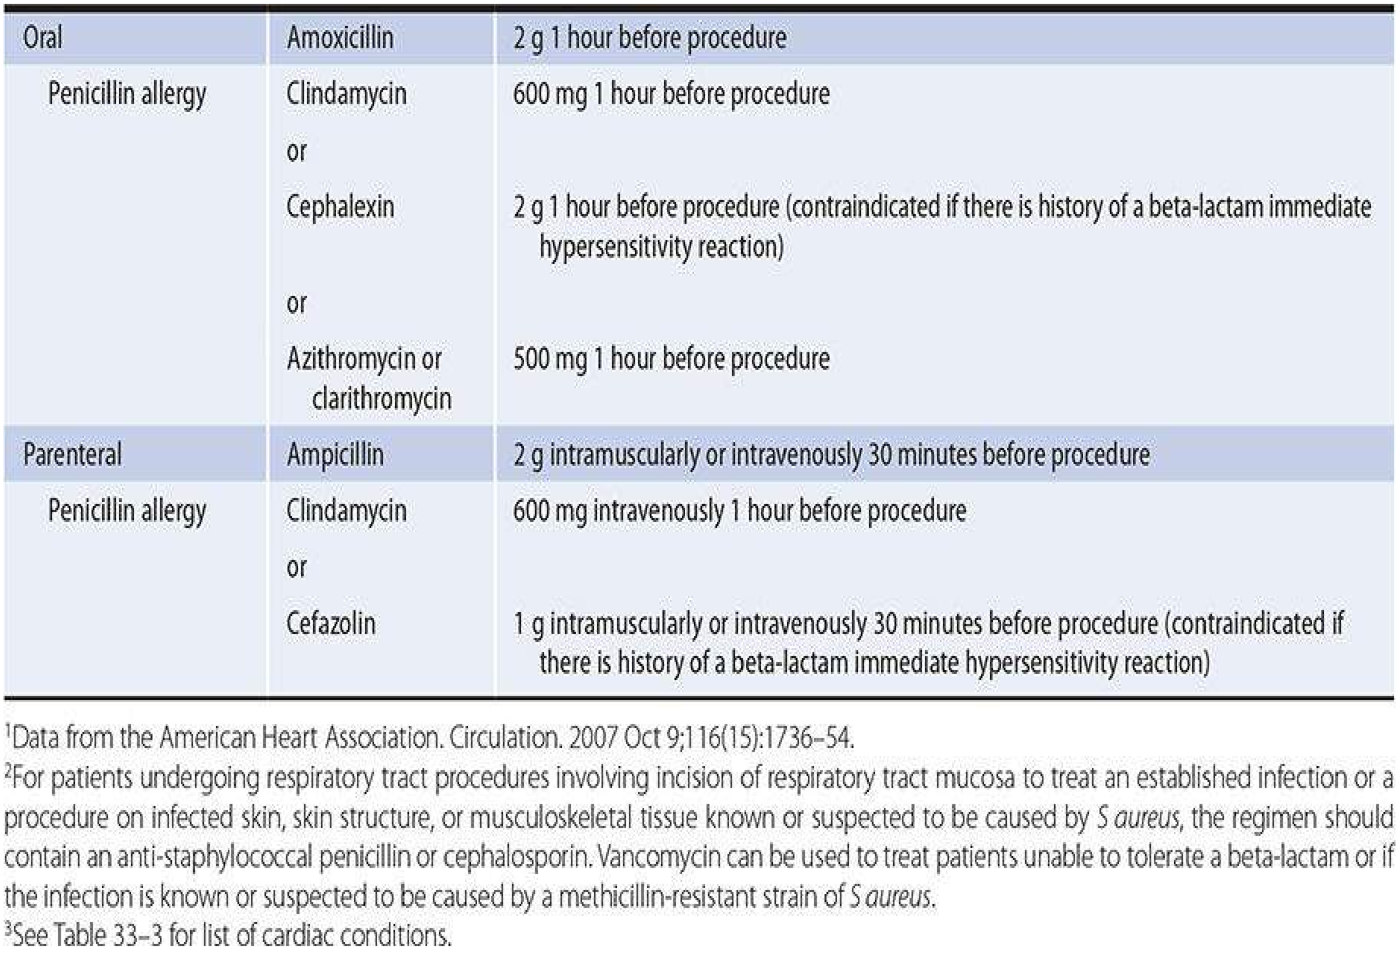
Table 33–4. Recommendations for administration of bacterial endocarditis prophylaxis for patients according to type of procedure.[1]



Prophylaxis Recommended	Prophylaxis Not Recommended
Dental procedures All dental procedures that involve manipulation of gingival tissue or the periapical region of the teeth or perforation of the oral mucosa **Respiratory tract procedures** Only respiratory tract procedures that involve incision of the respiratory mucosa **Procedures on infected skin, skin structure, or musculoskeletal tissue**	**Dental procedures** Routine anesthetic injections through noninfected tissue, taking dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips or oral mucosa **Gastrointestinal tract procedures** **Genitourinary tract procedures**

[1] Reproduced, with permission, from Wilson W et al. Prevention of infective endocarditis. Circulation. 2007 Oct 9;116(15):1736–54. Copyright © 2007 American Heart Association, Inc.

Table 33–5. American Heart Association recommendations for endocarditis prophylaxis for dental procedures for patients with cardiac conditions.[1–3]



Oral	Amoxicillin	2 g 1 hour before procedure
Penicillin allergy	Clindamycin	600 mg 1 hour before procedure
	or	
	Cephalexin	2 g 1 hour before procedure (contraindicated if there is history of a beta-lactam immediate hypersensitivity reaction)
	or	
	Azithromycin or clarithromycin	500 mg 1 hour before procedure
Parenteral	Ampicillin	2 g intramuscularly or intravenously 30 minutes before procedure
Penicillin allergy	Clindamycin	600 mg intravenously 1 hour before procedure
	or	
	Cefazolin	1 g intramuscularly or intravenously 30 minutes before procedure (contraindicated if there is history of a beta-lactam immediate hypersensitivity reaction)

[1] Data from the American Heart Association. Circulation. 2007 Oct 9;116(15):1736–54.

[2] For patients undergoing respiratory tract procedures involving incision of respiratory tract mucosa to treat an established infection or a procedure on infected skin, skin structure, or musculoskeletal tissue known or suspected to be caused by *S aureus*, the regimen should contain an anti-staphylococcal penicillin or cephalosporin. Vancomycin can be used to treat patients unable to tolerate a beta-lactam or if the infection is known or suspected to be caused by a methicillin-resistant strain of *S aureus*.

[3] See Table 33–3 for list of cardiac conditions.

Treatment

Empiric regimens for endocarditis while culture results are pending should include agents active against staphylococci, streptococci, and enterococci. Vancomycin 1 g every 12 hours intravenously plus ceftriaxone 2 g every 24 hours provides appropriate coverage pending definitive diagnosis; consultation with an infectious disease expert is strongly recommended when initiating treatment.

A. Viridans Streptococci

For penicillin-susceptible viridans streptococcal endocarditis (ie, MIC 0.1 mcg/mL or less), penicillin G, 18 million units intravenously either continuously or in four to six equally divided doses, or ceftriaxone, 2 g intravenously once daily for 4 weeks, is recommended. The duration of therapy can be shortened to 2 weeks if gentamicin, 3 mg/kg intravenously every 24 hours, is used with penicillin or ceftriaxone. The 2-week regimen is reasonable and can be considered in patients with uncomplicated endocarditis, rapid response to therapy, and no underlying kidney disease. For the patient unable to tolerate penicillin or ceftriaxone, vancomycin, 15 mg/kg intravenously every 12 hours for 4 weeks, is given with a desired trough level of 10–15 mcg/mL.

Prosthetic valve endocarditis is treated with a 6-week course of penicillin or ceftriaxone and the clinician can consider adding 2 weeks of gentamicin at the start of therapy.

Viridans streptococci relatively resistant to penicillin (ie, MIC greater than 0.12 mcg/mL but less than or equal to 0.5 mcg/mL) should be treated for 4 weeks. Penicillin G, 24 million units intravenously either continuously or in four to six equally divided doses, is combined with gentamicin, 3 mg/kg intravenously every 24 hours for the first 2 weeks. Ceftriaxone may be a reasonable alternative treatment option for isolates that are susceptible to ceftriaxone. In the patient with IgE-mediated allergy to penicillin, vancomycin alone, 15 mg/kg intravenously every 12 hours for 4 weeks, should be administered. Prosthetic valve endocarditis is treated with a 6-week course of penicillin or ceftriaxone plus gentamicin as above.

Endocarditis caused by viridans streptococci with an MIC greater than 0.5 mcg/mL or by nutritionally deficient streptococci should be treated the same as enterococcal endocarditis.

B. Other Streptococci

Endocarditis caused by S pneumoniae, S pyogenes (group A streptococcus), or groups B, C, and G streptococci is unusual. S pneumoniae sensitive to penicillin (MIC less than 0.1 mcg/mL) can be treated with penicillin 18 million units intravenously either continuously or in four to six equally divided doses or cefazolin 6 g intravenously either continuously or in three equally divided doses, or ceftriaxone 2 g daily intravenously for 4 weeks. High-dose penicillin (24 million units) or a third-generation cephalosporin may be required for the treatment of endocarditis (without meningitis) caused by strains resistant to penicillin (MIC greater than 0.1 mcg/mL). The addition of vancomycin and rifampin to ceftriaxone may be considered in patients with S pneumoniae strains with cefotaxime MIC greater than 2 mcg/mL. Group A streptococcal infection can be treated with penicillin or ceftriaxone for 4–6 weeks. Groups B, C, and G streptococci tend to be more resistant to penicillin than group A streptococci, and some experts have recommended adding gentamicin, 3 mg/kg intravenously every 24 hours, to penicillin for the first 2 weeks of a 4- to 6-week course. Endocarditis caused by S gallolyticus (bovis) is associated with liver disease, especially cirrhosis, and gastrointestinal abnormalities, especially colon cancer. Colonoscopy should be performed to exclude the latter.

C. Enterococci

For enterococcal endocarditis, penicillin or ampicillin alone is inadequate. One recommended regimen is ampicillin, 2 g intravenously every 4 hours, or penicillin G, 18–30 million units intravenously continuously or in six equally divided doses plus gentamicin, 1 mg/kg intravenously every 8 hours. The second recommended regimen is ampicillin (2 g intravenously every 4 hours) plus ceftriaxone 2 g intravenously every 12 hours. The recommended duration of therapy is 4–6 weeks (the longer duration for patients with symptoms for more than 3 months, relapse, or prosthetic valve endocarditis). The combination of ampicillin plus ceftriaxone is recommended for patients with creatinine clearance less than 50 mL/min or whose enterococcal isolates are resistant to gentamicin. In patients intolerant of penicillin and ampicillin or who have enterococcal isolate resistant to these agents, vancomycin plus gentamicin can be used.

Endocarditis caused by strains resistant to penicillin and vancomycin are difficult to treat and should always be managed in consultation with an infectious diseases specialist.

D. Staphylococci

For methicillin-susceptible S aureus isolates, nafcillin or oxacillin, 12 g intravenously daily given continuously or in four to six divided doses or cefazolin, 6 g intravenously daily given continuously or in three divided doses for 6 weeks, is the preferred therapy. In cases of brain abscess resulting from methicillin-susceptible S aureus endocarditis, nafcillin should be used instead of cefazolin. For patients with history of immediate type hypersensitivity to beta-lactams, a desensitization protocol should be undertaken. For patients with a history of nonanaphylactoid reactions to penicillins, cefazolin should be used. Patients who are infected with methicillin-resistant S aureus or who are unable to tolerate beta-lactam therapy should receive vancomycin, 30 mg/kg/day intravenously divided in two or three doses, to achieve a goal trough level of 15–20 mcg/kg, or daptomycin intravenously at greater than or equal to 8 mg/kg/day. Aminoglycoside combination regimens are not recommended. The effect of rifampin with antistaphylococcal drugs is variable, and its routine use is not recommended.

Because coagulase-negative staphylococci—a common cause of prosthetic valve endocarditis—are routinely resistant to methicillin, beta-lactam antibiotics should not be used for this infection unless the isolate is demonstrated to be susceptible. A combination of vancomycin, 30 mg/kg/day intravenously divided in two or three doses for 6 weeks; rifampin, 300 mg every 8 hours for 6 weeks; and gentamicin, 3 mg/kg intravenously every 8 hours for the first 2 weeks, is recommended for prosthetic valve infection. If the organism is sensitive to methicillin, either nafcillin or oxacillin or cefazolin can be used in combination with rifampin and gentamicin. Combination therapy with nafcillin or oxacillin (vancomycin or daptomycin for methicillin-resistant strains), rifampin, and gentamicin is also recommended for treatment of S aureus prosthetic valve infection.

E. HACEK Organisms

HACEK organisms are slow-growing, fastidious gram-negative coccobacilli or bacilli (H aphrophilus [now A aphrophilus], A actinomycetemcomitans, C hominis, E corrodens, and Kingella species) that are normal oral flora and cause less than 5% of all cases of endocarditis. They may produce beta-lactamase, and thus the treatment of choice is ceftriaxone (or another third-generation cephalosporin), 2 g intravenously once daily for 4 weeks. Prosthetic valve endocarditis should be treated for 6 weeks. In the penicillin-allergic patient, experience is limited, but fluoroquinolones have in vitro activity and should be considered.

F. Culture-Negative Endocarditis

Failure to culture microorganisms from patients with suspected infective endocarditis may be due to infection from organisms not recovered in routine microbiology testing or previous administration of antimicrobial agents before blood cultures were obtained. These cases must be managed with the assistance of an infectious disease specialist. Pathogens that are not able to be cultured by commonly used techniques include Bartonella species, Chlamydia species, Brucella species, and Tropheryma whipplei. Serologic testing should be performed in patients who have epidemiologic risk factors for these infections. Treatment should be directed at likely pathogens while awaiting serologic results; treatment of patients given prior antimicrobials before cultures were obtained must also consider likely pathogens.

G. Role of Surgery

While many cases can be successfully treated medically, operative management is frequently required. Acute heart failure unresponsive to medical therapy is an indication for valve replacement even if active infection is present. Infections unresponsive to appropriate antimicrobial therapy after 7–10 days (ie, persistent fevers, positive blood cultures despite therapy) are more likely to be eradicated if the valve is replaced. Surgery is nearly always required for cure of fungal endocarditis and is more often necessary with highly resistant bacteria. It is also indicated when the infection involves the sinus of Valsalva or produces septal abscesses. Recurrent infection with the same organism prompts an operative approach, especially with infected prosthetic valves. Continuing embolization presents a difficult problem when the infection is otherwise responding; surgery may be the proper approach. Particularly challenging is a large and fragile vegetation demonstrated by echocardiography in the absence of embolization. Most clinicians favor an operative approach with vegetectomy and valve repair if the patient is a good candidate. Operation without delay may be considered in patients with endocarditis and an ischemic stroke who have an indication for surgery. If not urgent or if intracranial hemorrhage is present, a delay of at least 4 weeks should be considered. Embolization after bacteriologic cure does not necessarily imply recurrence of endocarditis.

H. Role of Anticoagulation

Anticoagulation is contraindicated in native valve endocarditis because of an increased risk of intracerebral hemorrhage from mycotic aneurysms or embolic phenomena. The role of anticoagulant therapy during prosthetic valve endocarditis is more controversial. Reversal of anticoagulation may result in thrombosis of the mechanical prosthesis, particularly in the mitral position. Conversely, anticoagulation during active prosthetic valve endocarditis caused by S aureus has been associated with fatal intracerebral hemorrhage. One approach is to discontinue anticoagulation during the septic phase of S aureus prosthetic valve endocarditis. In patients with S aureus prosthetic valve endocarditis complicated by a CNS embolic event, anticoagulation should be discontinued for the first 2 weeks of therapy. Indications for anticoagulation following prosthetic valve implantation for endocarditis are the same as for patients with prosthetic valves without endocarditis (eg, nonporcine mechanical valves and valves in the mitral position).

Response to Therapy

If infection is caused by viridans streptococci, enterococci, or coagulase-negative staphylococci, defervescence occurs in 3–4 days on average; with S aureus or Pseudomonas aeruginosa, fever may persist for longer. Blood cultures should be obtained every 1–2 days to document sterilization. Other causes of persistent fever are myocardial or metastatic abscess, sterile embolization, superimposed hospital-acquired infection, and drug reaction. Most relapses occur within 1–2 months after completion of therapy. Obtaining one or two blood cultures during this period is prudent.

When to Refer

- Consider consulting an infectious diseases specialist in all cases of suspected infective endocarditis.
- Consult a cardiac surgeon in the situations mentioned in the Role of Surgery section above to prevent further embolic disease, heart failure, and other complications including death.

When to Admit

Patients with infective endocarditis should be hospitalized for expedited evaluation and treatment.

INFECTIONS CAUSED BY GRAM-NEGATIVE BACTERIA

BORDETELLA PERTUSSIS INFECTION (Whooping Cough)

ESSENTIALS OF DIAGNOSIS

- Predominantly in infants under age 2 years; adolescents and adults are reservoirs of infection.
- Two-week prodromal catarrhal stage of malaise, cough, coryza, and anorexia.
- Paroxysmal cough ending in a high-pitched inspiratory “whoop.”
- Absolute lymphocytosis, often striking; culture confirms diagnosis.

General Considerations

Pertussis is an acute infection of the respiratory tract caused by B pertussis that is transmitted by respiratory droplets. The incubation period is 7–17 days. Half of all cases occur before age 2 years. Neither immunization nor disease confers lasting immunity to pertussis. Consequently, adults are an important reservoir of the disease.

Clinical Findings

The symptoms of classic pertussis last about 6 weeks and are divided into three consecutive stages. The catarrhal stage is characterized by its insidious onset, with lacrimation, sneezing, and coryza, anorexia and malaise, and a hacking night cough that becomes diurnal. The paroxysmal stage is characterized by bursts of rapid, consecutive coughs followed by a deep, high-pitched inspiration (whoop). The convalescent stage begins 4 weeks after onset of the illness with a decrease in the frequency and severity of paroxysms of cough. The diagnosis often is not considered in adults, who may not have a typical presentation. Cough persisting more than 2 weeks is suggestive. Infection may also be asymptomatic.

The white blood cell count is usually 15,000–20,000/mcL (rarely, as high as 50,000/mcL or more), 60–80% of which are lymphocytes. The diagnosis is established by isolating the organism from nasopharyngeal culture. A special medium (eg, Bordet-Gengou agar) must be requested. Polymerase chain reaction assays for diagnosis of pertussis may be available in some clinical or health department laboratories.

Prevention

Acellular pertussis vaccine is recommended for all infants, combined with diphtheria and tetanus toxoids (DTaP). Infants and susceptible adults with significant exposure should receive prophylaxis with an oral macrolide. In recognition of their importance as a reservoir of disease, vaccination of adolescents and adults against pertussis is recommended (see Table 30–7 and www.cdc.gov/vaccines/schedules). Adolescents aged 11–18 years (preferably between 11 and 12 years of age) who have completed the DTP or DTaP vaccination series should receive a single dose of either Tdap product instead of Td (tetanus and diphtheria toxoids vaccine) for booster immunization against tetanus, diphtheria, and pertussis. Adults of all ages (including those older than age 64 years) should receive a single dose of Tdap. In addition, pregnant women should receive a dose of Tdap during each pregnancy regardless of prior vaccination history, ideally between 27 and 36 weeks of gestation, in order to maximize the antibody response of the woman and the passive antibody transfer to the infant. For any woman who was not previously vaccinated with Tdap and for whom the vaccine was not given during her pregnancy, Tdap should be administered immediately postpartum. The CDC has eliminated the recommendation that a 2-year period window is needed between receiving the Td and Tdap vaccines based on data showing that there is not an increased risk of adverse events.

Treatment

Antibiotic treatment should be initiated in all suspected cases. Treatment options include erythromycin, 500 mg four times a day orally for 7 days; azithromycin, 500 mg orally on day 1 and 250 mg for 4 more days; or clarithromycin, 500 mg orally twice daily for 7 days. Trimethoprim-sulfamethoxazole, 160 mg–800 mg orally twice a day for 7 days, also is effective. Treatment shortens the duration of carriage and may diminish the severity of coughing paroxysms. These same regimens are indicated for prophylaxis of contacts to an active case of pertussis that are exposed within 3 weeks of the onset of cough in the index case.

OTHER BORDETELLA INFECTIONS

Bordetella bronchiseptica is a pleomorphic gram-negative coccobacillus causing kennel cough in dogs. On occasion it causes upper and lower respiratory infection in humans, principally HIV-infected patients. Infection has been associated with contact with dogs and cats, suggesting animal-to-human transmission. Treatment of B bronchiseptica infection is guided by results of in vitro susceptibility tests.

MENINGOCOCCAL MENINGITIS

ESSENTIALS OF DIAGNOSIS

- Fever, headache, vomiting, delirium, convulsions.
- Petechial rash of skin and mucous membranes in many.

- Neck and back stiffness and positive Kernig and Brudzinski signs are characteristic.
- Purulent spinal fluid with gram-negative intracellular and extracellular diplococci.
- Culture of cerebrospinal fluid, blood, or petechial aspiration confirms the diagnosis.

General Considerations

Meningococcal meningitis is caused by Neisseria meningitidis of groups A, B, C, Y, and W-135, among others. Meningitis due to serogroup A is uncommon in the United States. Serogroup B generally causes sporadic cases. Serogroup C meningococcus is the most common cause of epidemic disease in the United States. Up to 40% of persons are nasopharyngeal carriers of meningococci, but disease develops in relatively few of these persons. Infection is transmitted by droplets. The clinical illness may take the form of meningococcemia (a fulminant form of septicemia without meningitis), meningococcemia with meningitis, or meningitis. Recurrent meningococcemia with fever, rash, and arthritis is seen rarely in patients with certain terminal complement deficiencies. Asplenic patients are also at risk.

Clinical Findings

A. Symptoms and Signs

High fever, chills, nausea, vomiting, and headache as well as back, abdominal, and extremity pains are typical. Rapidly developing confusion, delirium, seizures, and coma occur in some. On examination, nuchal and back rigidity are typical. Positive Kernig and Brudzinski signs (Kernig sign is pain in the hamstrings upon extension of the knee with the hip at 90-degree flexion; Brudzinski sign is flexion of the knee in response to flexion of the neck) are specific but not sensitive findings. A petechial rash appearing in the lower extremities and at pressure points is found in most cases. Petechiae may vary in size from pinpoint lesions to large ecchymoses or even skin gangrene that may later slough.

B. Laboratory Findings

Lumbar puncture typically reveals a cloudy or purulent cerebrospinal fluid, with elevated pressure, increased protein, and decreased glucose content. The fluid usually contains greater than 1000 cells/mcL, with polymorphonuclear cells predominating and containing gram-negative intracellular diplococci. The absence of organisms in a Gram-stained smear of the cerebrospinal fluid sediment does not rule out the diagnosis. The capsular polysaccharide can be demonstrated in cerebrospinal fluid or urine by latex agglutination; this is useful in partially treated patients, though sensitivity is 60–80%. The organism is usually demonstrated by smear and culture of the cerebrospinal fluid, oropharynx, blood, or aspirated petechiae.

Disseminated intravascular coagulation is an important complication of meningococcal infection and is typically present in toxic patients with ecchymotic skin lesions.

Differential Diagnosis

Meningococcal meningitis must be differentiated from other meningitides. In small infants and in older adults, fever or stiff neck is often missing, and altered mental status may dominate the picture.

Rickettsial, echovirus, and, rarely, other bacterial infections (eg, staphylococcal infections, scarlet fever) also cause petechial rash.

Prevention

Four meningococcal vaccines are available. There are two vaccines with coverage against meningococcal serogroups A, C, Y, and W-135 and two with coverage against meningococcal serogroup B. The two vaccines effective for meningococcal serogroups A, C, Y, and W-135 are the meningococcal polysaccharide vaccine (MPSV4) indicated for vaccination of persons over age 55 and the conjugate vaccine (MCV4) indicated for persons aged 2–55 years. The two vaccines against meningococcal serogroup B are MenB-FHbp and MenB-4C are approved for persons aged 10–25 years and are not interchangeable.

The Advisory Committee on Immunization Practices recommends immunization with a dose of MCV4 for preadolescents aged 11–12 with a booster at age 16 (see www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html). For ease of program implementation, persons aged 21 years or younger should have documentation of receipt of a dose of MCV4 not more than 5 years before enrollment to college. If the primary dose was administered before the sixteenth birthday, a booster dose should be administered before enrollment. Vaccine is also recommended as a two-dose primary series administered 2 months apart for persons aged 2 through 54 years with persistent complement deficiency, persons with functional or anatomic asplenia, and for adolescents with HIV infection. All other persons at increased risk for meningococcal disease (eg, military recruits, microbiologists, or travelers to an epidemic or highly endemic country) should receive a single dose. One of the meningococcal serogroup B vaccines may be administered to persons 10 years of age or older who are at increased risk for meningococcal disease. These persons include those with persistent complement component deficiencies; persons with anatomic or functional asplenia; microbiologists routinely exposed to isolates of Neisseria meningitidis; and persons identified to be at increased risk because of a serogroup B meningococcal disease outbreak. Vaccination of persons aged 16–23 years may provide short-term protection against most strains of serogroup B meningococcal disease.

Eliminating nasopharyngeal carriage of meningococci is an effective prevention strategy in closed populations and to prevent secondary cases in household or otherwise close contacts. Rifampin, 600 mg orally twice a day for 2 days, ciprofloxacin, 500 mg orally once, or one intramuscular 250-mg dose of ceftriaxone is effective. Cases of fluoroquinolone-resistant meningococcal infections have been identified in the United States. However, ciprofloxacin remains a recommended empiric agent for eradication of nasopharyngeal carriage. School and work contacts ordinarily need not be treated. Hospital contacts receive therapy only if intense exposure has occurred (eg, mouth-to-mouth resuscitation). Accidentally discovered carriers without known close contact with meningococcal disease do not require prophylactic antimicrobials.

Treatment

Blood cultures must be obtained and intravenous antimicrobial therapy started immediately. This may be done prior to lumbar puncture in patients in whom the diagnosis is not straightforward and for those in whom MR or CT imaging is indicated to exclude mass lesions. Aqueous penicillin G is the antibiotic of choice (24 million units/24 h intravenously in divided doses every 4 hours). The prevalence of strains of N meningitidis with intermediate resistance to penicillin in vitro (MICs 0.1 to 1 mcg/mL) is increasing, particularly in Europe. At what level of resistance penicillin treatment failure can occur is not known. Penicillin-intermediate strains thus far remain fully susceptible to ceftriaxone and other third-generation cephalosporins used to treat meningitis, and these should be effective alternatives to penicillin. In penicillin-allergic patients or those in whom Haemophilus influenzae or gram-negative meningitis is a consideration, ceftriaxone, 2 g intravenously every 12 hours, should be used. Treatment should be continued in full doses by the intravenous route until the patient is afebrile for 5 days. Shorter courses—as few as 4 days if ceftriaxone is used—are also effective.

When to Admit

All patients with suspected meningococcal infection including meningitis and meningococcemia should be admitted for evaluation and empiric intravenous antibiotic therapy.

MacNeil JR et al. Use of serogroup B meningococcal vaccines in adolescents and young adults: recommendations of the Advisory Committee on Immunization Practices, 2015. MMWR Morb Mortal Wkly Rep. 2015 Oct 23;64(41):1171–6. [PMID: 26492381]

INFECTIONS CAUSED BY HAEMOPHILUS SPECIES

H influenzae and other Haemophilus species may cause sinusitis, otitis, bronchitis, epiglottitis, pneumonia, cellulitis, arthritis, meningitis, and endocarditis. Nontypeable strains are responsible for most disease in adults. Alcoholism, smoking, chronic lung disease, advanced age, and HIV infection are risk factors. Haemophilus species colonize the upper respiratory tract in patients with chronic obstructive pulmonary disease and frequently cause purulent bronchitis.

Beta-lactamase–producing strains are less common in adults than in children. For adults with sinusitis, otitis, or respiratory tract infection, oral amoxicillin, 750 mg twice daily for 10–14 days, is adequate. For beta-lactamase–producing strains, use of the oral fixed-drug combination of amoxicillin, 875 mg, with clavulanate, 125 mg, is indicated. For the penicillin-allergic patient, oral cefuroxime axetil, 250 mg twice daily; or a fluoroquinolone (ciprofloxacin, 500 mg orally twice daily; levofloxacin, 500–750 mg orally once daily; or moxifloxacin, 400 mg orally once daily) for 7 days is effective. Azithromycin, 500 mg orally once followed by 250 mg daily for 4 days, is preferred over clarithromycin when a macrolide is the preferred agent. Trimethoprim-sulfamethoxazole (160/800 mg orally twice daily) can be considered, but resistance rates have been reported to be up to 25%.

In the more seriously ill patient (eg, the toxic patient with multilobar pneumonia), ceftriaxone, 1 g/day intravenously, is recommended pending determination of whether the infecting strain is a beta-lactamase producer. A fluoroquinolone (see above for dosages) can be used for the penicillin-allergic patients for a 10- to 14-day course of therapy.

Epiglottitis is characterized by an abrupt onset of high fever, drooling, and inability to handle secretions. An important clue to the diagnosis is complaint of a severe sore throat despite an unimpressive examination of the pharynx. Stridor and respiratory distress result from laryngeal obstruction. The diagnosis is best made by direct visualization of the cherry-red, swollen epiglottis at laryngoscopy. Because laryngoscopy may provoke laryngospasm and obstruction, especially in children, it should be performed in an intensive care unit or similar setting, and only at a time when intubation can be performed promptly. Ceftriaxone, 1 g intravenously every 24 hours for 7–10 days, is the drug of choice. Trimethoprim-sulfamethoxazole or a fluoroquinolone (see above for dosage) may be used in the patient with serious penicillin allergy.

Meningitis, rare in adults, is a consideration in the patient who has meningitis associated with sinusitis or otitis. Initial therapy for suspected H influenzae meningitis should be with ceftriaxone, 4 g/day in two divided doses, until the strain is proved not to produce beta-lactamase. Meningitis is treated for at least 7 days. Dexamethasone, 0.15 mg/kg intravenously every 6 hours, may reduce the incidence of long-term sequelae, principally hearing loss.

Sriram KB et al. Nontypeable Haemophilus influenzae and chronic obstructive pulmonary disease: a review for clinicians. Crit Rev Microbiol. 2018 Mar;44(2):125–42. [PMID: 28539074]

INFECTIONS CAUSED BY MORAXELLA CATARRHALIS

M catarrhalis is a gram-negative aerobic coccus morphologically and biochemically similar to Neisseria. It causes sinusitis, bronchitis, and pneumonia. Bacteremia and meningitis have also been reported in immunocompromised patients. The organism frequently colonizes the respiratory tract, making differentiation of colonization from infection difficult. If M catarrhalis is the predominant isolate, therapy is directed against it. M catarrhalis typically produces beta-lactamase and therefore is usually resistant to ampicillin and amoxicillin. It is susceptible to amoxicillin-clavulanate, ampicillin-sulbactam, trimethoprim-sulfamethoxazole, ciprofloxacin, and second- and third-generation cephalosporins.

LEGIONNAIRES DISEASE

ESSENTIALS OF DIAGNOSIS

- Patients are often immunocompromised, smokers, or have chronic lung disease.
- Scant sputum production, pleuritic chest pain, toxic appearance.

- Chest radiograph: focal patchy infiltrates or consolidation.
- Gram stain of sputum: polymorphonuclear leukocytes and no organisms.

General Considerations

Legionella infection ranks among the three or four most common causes of community-acquired pneumonia and is considered whenever the etiology of a pneumonia is in question. Legionnaires disease is more common in immunocompromised persons, in smokers, and in those with chronic lung disease. Outbreaks have been associated with contaminated water sources, such as showerheads and faucets in patient rooms and air conditioning cooling towers.

Clinical Findings

A. Symptoms and Signs

Legionnaires disease is one of the atypical pneumonias, so called because a Gram-stained smear of sputum does not show organisms. However, many features of Legionnaires disease are more like typical pneumonia, with high fevers, toxic appearance, pleurisy, and grossly purulent sputum. Nausea, vomiting, and diarrhea may be prominent. There may be relative bradycardia. Classically, this pneumonia is caused by Legionella pneumophila, though other species can cause identical disease.

B. Laboratory Findings

There may be hyponatremia, hypophosphatemia, elevated liver enzymes, and elevated creatine kinase. Culture of Legionella species has a 80–90% sensitivity. Dieterle silver staining of tissue, pleural fluid, or other infected material is also a reliable method for detecting Legionella species. Direct fluorescent antibody stains and serologic testing such as urinary antigen are less sensitive because these will detect only L pneumophila serotype 1. In addition, making a serologic diagnosis requires that the host respond with sufficient specific antibody production.

Treatment

Azithromycin (500 mg orally once daily), clarithromycin (500 mg orally twice daily), or a fluoroquinolone (eg, levofloxacin, 750 mg orally once daily), and not erythromycin, are the drugs of choice for treatment of legionellosis because of their excellent intracellular penetration and in vitro activity, as well as desirable pharmacokinetic properties that permit oral administration and once or twice daily dosing. Duration of therapy is 10–14 days, although a 21-day course of therapy is recommended for immunocompromised patients.

GRAM-NEGATIVE BACTEREMIA & SEPSIS

Gram-negative bacteremia can originate in a number of sites, the most common being the genitourinary system, hepatobiliary tract, gastrointestinal tract, and lungs. Less common sources include intravenous lines, infusion fluids, surgical wounds, drains, and pressure injuries.

Patients with potentially fatal underlying conditions in the short term such as neutropenia or immunoparesis have a mortality rate of 40–60%; those with serious underlying diseases likely to be fatal in 5 years, such as solid tumors, cirrhosis, and aplastic anemia, die in 15–20% of cases; and individuals with no underlying diseases have a mortality rate of 5% or less.

Clinical Findings

A. Symptoms and Signs

Most patients have fevers and chills, often with abrupt onset. However, 15% of patients are hypothermic (temperature 36.4°C or less) at presentation, and 5% never develop a temperature above 37.5°C. Hyperventilation with respiratory alkalosis and changes in mental status are important early manifestations. Hypotension and shock, which occur in 20–50% of patients, are unfavorable prognostic signs.

B. Laboratory Findings

Neutropenia or neutrophilia, often with increased numbers of immature forms of polymorphonuclear leukocytes, is the most common laboratory abnormality in septic patients. Thrombocytopenia occurs in 50% of patients, laboratory evidence of coagulation abnormalities in 10%, and overt disseminated intravascular coagulation in 2–3%. Both clinical manifestations and the laboratory abnormalities are nonspecific and insensitive, which accounts for the relatively low rate of blood culture positivity (approximately 20–40%). If possible, three blood cultures from separate sites should be obtained in rapid succession before starting antimicrobial therapy. The chance of recovering the organism in at least one of the three blood cultures is greater than 95%. The false-negative rate for a single culture of 5–10 mL of blood is 30%. This may be reduced to 5–10% (albeit with a slight false-positive rate due to isolation of contaminants) if a single volume of 30 mL is inoculated into several blood culture bottles. Because blood cultures may be falsely negative, when a patient with presumed septic shock, negative blood cultures, and inadequate explanation for the clinical course responds to antimicrobial agents, therapy should be continued for 10–14 days.

Treatment

Several factors are important in the management of patients with sepsis.

A. Removal of Predisposing Factors

This usually means decreasing or stopping immunosuppressive medications and, in certain circumstances, giving granulocyte colony-stimulating factor (filgrastim; G-CSF) to the neutropenic patient.

B. Identifying the Source of Bacteremia

By simply finding the source of bacteremia and removing it (central venous catheter) or draining it (abscess), a fatal disease becomes easily treatable.

C. Supportive Measures

The use of fluids, vasopressors, and corticosteroids in septic shock are discussed in Chapter 14; management of disseminated intravascular coagulation is discussed in Chapter 13.

D. Antibiotics

Antibiotics should be given as soon as the diagnosis is suspected, since delays in therapy have been associated with increased mortality rates, particularly once hypotension develops. In general, bactericidal antibiotics should be used and given intravenously to ensure therapeutic serum levels. Penetration of antibiotics into the site of primary infection is critical for successful therapy—ie, if the infection originates in the CNS, antibiotics that penetrate the blood-brain barrier should be used—eg, third- or fourth-generation cephalosporin—but not first-generation cephalosporins or aminoglycosides, which penetrate poorly. Sepsis caused by gram-positive organisms cannot be differentiated on clinical grounds from that due to gram-negative bacteria. Therefore, initial therapy should include antibiotics active against both types of organisms.

The number of antibiotics necessary remains controversial and depends on the cause. Table 30–4 provides a guide for empiric therapy. Although a combination of antibiotics is often recommended for "synergism," combination therapy has not been shown to be superior to a single-drug regimen with any of several broad-spectrum antibiotics (eg, a third-generation cephalosporin, piperacillin-tazobactam, carbapenem). If multiple drugs are used initially, the regimen should be modified and coverage narrowed based on the results of culture and sensitivity testing.

SALMONELLOSIS

Salmonellosis includes infection by any of approximately 2000 serotypes of salmonellae. All Salmonella serotypes are members of a single species, Salmonella enterica. Human infections are caused almost exclusively by S enterica subsp enterica, of which three serotypes—typhi, typhimurium, and choleraesuis—are predominantly isolated. Three clinical patterns of infection are recognized: (1) enteric fever, the best example of which is typhoid fever, due to serotype typhi; (2) acute enterocolitis, caused by serotype typhimurium, among others; and (3) the "septicemic" type, characterized by bacteremia and focal lesions, exemplified by infection with serotype choleraesuis. All types are transmitted by ingestion of the organism, usually from tainted food or drink.

1. Enteric Fever (Typhoid Fever)

ESSENTIALS OF DIAGNOSIS

- Gradual onset of malaise, headache, nausea, vomiting, abdominal pain.
- Rose spots, relative bradycardia, splenomegaly, and abdominal distention and tenderness.

- Slow (stepladder) rise of fever to maximum and then slow return to normal.
- Leukopenia; blood, stool, and urine cultures positive for Salmonella.

General Considerations

Enteric fever is a clinical syndrome characterized by gastrointestinal symptoms as well as constitutional symptoms such as fever, malaise, and headache. It may have a long incubation period (6–30 days), and the gastrointestinal symptoms may resolve but then recur. Progressive infection often evolves with delirium. Enteric fever can be caused by any Salmonella species, including S typhi (typhoid fever) and non-typhoidal strains, especially S paratyphi subtype A in the United States. Infection begins when organisms breach the mucosal epithelium of the intestines. Having crossed the epithelial barrier, organisms invade and replicate in macrophages in Peyer patches, mesenteric lymph nodes, and the spleen. Serotypes other than typhi usually do not cause invasive disease, presumably because they lack the necessary human-specific virulence factors. Bacteremia occurs, and the infection then localizes principally in the lymphoid tissue of the small intestine. Peyer patches become inflamed and may ulcerate, with involvement greatest during the third week of disease. The organism may disseminate to the lungs, gallbladder, kidneys, or CNS.

Clinical Findings

A. Symptoms and Signs

During the prodromal stage, there is increasing malaise, headache, cough, and sore throat, often with abdominal pain and constipation, while the fever ascends in a stepwise fashion. After about 7–10 days, it reaches a plateau and the patient is much more ill. There may be marked constipation, especially early, or “pea soup” diarrhea; marked abdominal distention occurs as well. If there are no complications, the patient’s condition will gradually improve over 7–10 days. However, relapse may occur for up to 2 weeks after defervescence.

During the early prodrome, physical findings are few. Later, splenomegaly, abdominal distention and tenderness, relative bradycardia, and occasionally meningismus appear. The rash (rose spots) commonly appears during the second week of disease. The individual spot, found principally on the trunk, is a pink papule 2–3 mm in diameter that fades on pressure. It disappears in 3–4 days.

B. Laboratory Findings

Leukopenia is typical. Typhoid fever is best diagnosed by blood culture, which is positive in the first week of illness in 80% of patients who have not taken antimicrobials. The rate of positivity declines thereafter, but one-fourth or more of patients still have positive blood cultures in the third week. Cultures of bone marrow occasionally are positive when blood cultures are not. Stool culture is unreliable because it may be positive in gastroenteritis without typhoid fever.

Differential Diagnosis

Enteric fever must be distinguished from other gastrointestinal illnesses and from other infections that have few localizing findings. Examples include tuberculosis, infective endocarditis, brucellosis, lymphoma, and Q fever. Often there is a history of recent travel to endemic areas, and viral hepatitis, malaria, or amebiasis may be in the differential.

Complications

Complications occur in about 30% of untreated cases and account for 75% of deaths. Intestinal hemorrhage, manifested by a sudden drop in temperature and signs of shock followed by dark or fresh blood in the stool, or intestinal perforation, accompanied by abdominal pain and tenderness, is most likely to occur during the third week. Appearance of leukocytosis and tachycardia should suggest these complications. Urinary retention, pneumonia, thrombophlebitis, myocarditis, psychosis, cholecystitis, nephritis, osteomyelitis, and meningitis are less often observed.

Prevention

Immunization is not always effective, but should be considered for household contacts of a typhoid carrier, for travelers to endemic areas, and during epidemic outbreaks. A multiple-dose oral vaccine and a single-dose parenteral vaccine are available. Their efficacies are similar, but oral vaccine causes fewer side effects. Boosters, when indicated, should be given every 5 years and 2 years for oral and parenteral preparations, respectively.

Adequate waste disposal and protection of food and water supplies from contamination are important public health measures to prevent salmonellosis. Carriers cannot work as food handlers.

Treatment

A. Specific Measures

Because of increasing antimicrobial resistance, fluoroquinolones—such as ciprofloxacin 750 mg orally twice daily or levofloxacin 500 mg orally once daily, 5–7 days for uncomplicated enteric fever and 10–14 days for severe infection—are the agents of choice for treatment of salmonella infections. Ceftriaxone, 2 g intravenously for 7 days, is also effective. Although resistance to fluoroquinolones or cephalosporins occurs uncommonly, the prevalence is increasing. When an infection is caused by a multidrug-resistant strain, select an antibiotic to which the isolate is susceptible in vitro. Alternatively, increasing the dose of ceftriaxone to 4 g/day and treating for 10–14 days or using azithromycin 500 mg orally for 7 days in uncomplicated cases may be effective. In years past, ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole had been effective treatments but resistance has spread globally.

B. Treatment of Carriers

Ciprofloxacin, 750 mg orally twice a day for 4 weeks, has proved to be highly effective in eradicating the carrier state. Cholecystectomy may also achieve this goal. When the isolate is susceptible, treatment of carriage with ampicillin, trimethoprim-sulfamethoxazole, or chloramphenicol may be successful.

Prognosis

The mortality rate of typhoid fever is about 2% in treated cases. Elderly or debilitated persons are likely to do worse. With complications, the prognosis is poor. Relapses occur in up to 15% of cases. A residual carrier state frequently persists in spite of therapy.

2. Salmonella Gastroenteritis

By far the most common form of salmonellosis is acute enterocolitis, which can be caused by both typhoidal and non-typhoidal Salmonella. The incubation period is 8–48 hours after ingestion of contaminated food or liquid.

Symptoms and signs consist of fever (often with chills), nausea and vomiting, cramping abdominal pain, and diarrhea, which may be grossly bloody, lasting 3–5 days.

Differentiation must be made from viral gastroenteritis, food poisoning, shigellosis, amebic dysentery, and acute ulcerative colitis. The diagnosis is made by culturing the organism from the stool. The disease is usually self-limited, but bacteremia with localization in joints or bones may occur, especially in patients with sickle cell disease.

In most cases, treatment of uncomplicated enterocolitis is symptomatic only. However, patients who are malnourished or severely ill, patients with sickle cell disease, and patients who are immunocompromised (including those who are HIV-positive) should be treated with ciprofloxacin, 500 mg orally twice a day; ceftriaxone, 1 g intravenously once daily; trimethoprim-sulfamethoxazole, 160 mg/80 mg orally twice a day; or azithromycin, 500 mg orally once daily for 7–14 days (14 days for immunocompromised patients).
